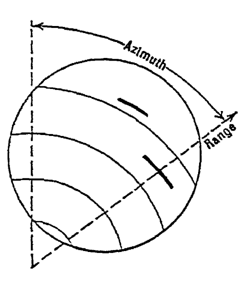
The most widely used intensity-modulated radar display, called plan position indication (PPI), in which the range of the echo is given by its distance from the center of the display, and its bearing by the angular position. The display may be either stabilized, so that north is at 0°, or unstabilized, in which case 0° represents the ship's or plane's heading. To produce this display, a radial sweep starting from the center at the instant of the transmitted pulse moves outward in the direction in which the antenna is pointing at the moment. The rotating sweep may be produced by a linear sawtooth current in a single-axis deflection coil mounted around the neck of a magnetic deflection CRT, the coil being rotated in synchronism with the antenna. Alternatively, a stationary two-axis coil may be used, with x- and y-axis sawtooth currents whose amplitudes are at any given time proportional to cos θ and to sin θ respectively, θ being the direction in which the antenna is pointing. Electrostatic deflection CRT may also be used, sawtooth voltages similarly modulated being applied to the two pairs of deflection plates.

Two modifications of the centered PPI are: (*a*) the "open-center PPI," in which increased accuracy in determining azimuth at close ranges can be obtained by starting the radial sweeps from a circle of arbitrary radius, and (*b*) the "delayed PPI," in which increased accuracy in determining the range of distant objects results from delaying the beginning of each sweep from the center by an arbitrary known time.

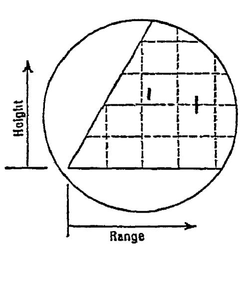


Off-center PPI or Sector Display

The off-center PPI is a variation of the centered PPI described above, in which the center of the pattern may be arbitrarily displaced in any direction, and the sweep expanded, so that any desired portion of the entire area within the range of the radar set can be made to fill the entire screen of the CRT. Such a display affords the possibility of greatly increased resolution while still preserving the undistorted map feature of the PPI. This is accomplished in the case of a rotating coil PPI by the superposition of a steady deflecting field upon the rotating sweep field. In the fixed x- and y-axis coil system, the same result may be attained by proper control of the delay and sweep speeds of the two components. The resulting display is often called a "sector display," although it may not be a complete sector if the origin of the pattern is not on the CRT screen.

Type R

The designation R (for range) applies to a type A display in which a fast linear sweep is employed, the start of the sweep being delayed by a precision calibrated delay circuit. Precision electronic time markers may also be used. The R display is generally used in conjunction with a standard type A display in which the time interval covered by the R sweep is indicated on the A sweep by intensifying the corresponding time interval. Both sweeps may be displayed on a single CRT at the same time by using electronic switching of the two sweeps and vertical displacement of the two traces.



Type RHI

This display is used to indicate the range and height of aircraft, hence the symbol RHI. Since the vertical distance (height) to be measured is in this case usually much less than the horizontal distance (range), the useful area of the CRT face can be greatly increased by expanding the vertical dimension. The display is usually obtained by applying simultaneous sawtooth currents to the x- and y-deflection coils of the CRT, such that $i_x = A \cos \theta \cdot t$ and $i_y = nA \sin \theta \cdot t$, where θ is the angle of elevation of the antenna, and n is the vertical expansion factor, usually between 5 and 10. In practice, the range sweep is usually simplified to $i_x = A \cdot t$, the resulting distortion being unimportant. Lines of constant height are straight and horizontal. The range sweep may be delayed for increased range resolution at large distances.

SECTION 16

SOUND-REPRODUCTION SYSTEMS

SOUND-REPRODUCTION SYSTEMS

Sound energy is transformed into some other form and retransformed back into sound for one of three general purposes: it may be desired to reproduce the sound instantly but at some other location, as in telephony or broadcasting; it may be desired to reproduce the sound at some subsequent time, as in phonographs and sound pictures; or it may be desired to reproduce the sound instantly and at the same location, but with increased energy content, as in public-address systems. The discussion herein is limited to reproduction by electric means, or at least partially by electric means, although other means are sometimes used (e.g., acoustic phonographs).

An electrical sound-reproduction system consists always of a microphone, or device to translate sound energy into electric energy; an amplifier and associated control equipment, to control the loudness of the sound; and a loudspeaker, or device to translate electric energy into sound energy. Similar considerations govern the choice and installation of these devices in all systems.

In addition, in phonographs and sound pictures there are devices to record the sound permanently and to effect the subsequent reproduction of the sound, as well as means to synchronize the recording and reproducing machines accurately. In telephone and radio broadcast systems a transmission link is inserted in the circuit; also in telephony a complicated switching system is included to permit any subscriber to talk privately to any other subscriber. (See Section 17).

AUDIO FACILITIES FOR SOUND SYSTEMS

By Howard A. Chinn

1. SOUND STUDIOS

Sound-reproduction systems in common use employ a single channel for transmission and for reproduction. Regardless of how many microphones are utilized for a given pick-up, their outputs are ultimately blended into one audio channel. This results in a single-channel system which imposes problems of a special nature upon the design of studios and sets used for sound broadcasting or for sound recording.

When a person listens to sound directly, the listening is done with both ears, or binaurally. *Binaural* hearing is indispensable for the localization of sound and for sound perspective. When listening to music in a concert hall, for example, one can largely ignore disturbing noises, provided they originate in a direction that is different from that of the desired sound and are not of unreasonable intensity. Furthermore, it is even possible to concentrate upon a particular section of the orchestra (for example, the strings in preference to the brass, or vice versa) and to ignore sounds that may be of no interest, or perhaps even unpleasant.

In listening to a single-channel system, on the other hand, nearly all sense of location of the sound is lost, as well as its extension in space. (A simple but effective demonstration of this is to block one ear, while conversing in a noisy room. The ability to continue to understand the speaker will be greatly impaired, if not entirely destroyed, because of the inability to exclude unwanted sound.) This same limitation exists when sound is transmitted over a single channel and reproduced by a loudspeaker system. Even though both ears are used for listening to the loudspeaker, the sound comes from a single source (multiple-unit loudspeakers, such as are sometimes required on wide-range, high-fidelity systems, do not change the effect) and the ability to discriminate against undesirable sounds is almost completely lacking. Hence, the sound that is heard from radio or television broadcasting, and in the cinema theater, is lacking in sound perspective. The design of studios for sound-reproduction purposes must be undertaken with these considerations in mind.

By combining acoustically correct architecture with suitable microphone pick-up and blending techniques, a single-channel sound system will produce pleasing results. However, the acoustical design problems are considerably more severe than those encountered in ordinary architectural work. Since the ability to localize sound is lacking, it is necessary to remove all sources of confusion or interference incident to monaural listening. This may be done by (a) proper control of reverberation, (b) the elimination of echoes, and (c) the elimination of disturbing noise. The first two items involve problems in acoustical treatment; the last one, problems of sound isolation—the two are not necessarily related.

OPTIMUM REVERBERATION TIME. Experience has shown that the most satisfactory reverberation time for broadcasting or sound-recording studios is less than that which is considered optimum for binaural listening. (See Section 12.) However, the reduction should be no more than is required to obtain the desired result. An excessive reduction in reverberation time will result in the elimination of the reverberant characteristics normally associated with the type of sound being reproduced. For example, the timbre or quality of a church organ being played in an acoustically dead room would sound as if it were out-of-doors. The reverberant quality associated with church music would be completely missing. The proper amount of reverberation must, therefore, be retained to create the desired psychological effect.

The use of studios that are acoustically too dead results in another undesirable effect. Musical organizations performing in an environment of this type are handicapped in several ways. The performer, discovering that his instrument does not produce the sound intensity to which he is accustomed, generally tries to produce the normal amount of sound, with the result that he concludes the studio is a "difficult" one in which to work. In addition, the performer may find that it requires special attention to hear the other members of his group in order to keep in time and in tune. Finally, the listener gains the impression that the orchestra is a much smaller aggregation than it actually is.

The type of the production dictates the optimum reverberation time for any given studio. In general, studios intended for speech or dramatic productions are less reverberant than those used for musical presentations. It is evident, therefore, that no one optimum will cover all situations. Furthermore, since maximum studio usage requires that a given unit be capable of accommodating all types of productions, some means of adjusting the acoustics is not only desirable but actually essential for full flexibility. In Fig. 1 there are shown recommended minimum and maximum reverberation times, at

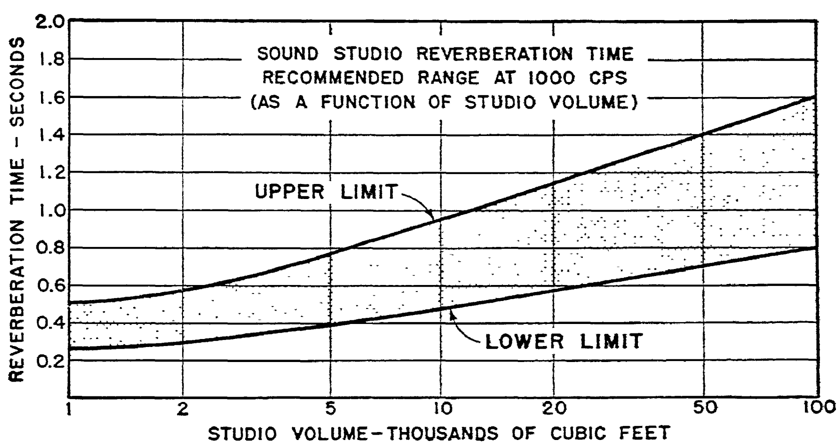


FIG. 1. Recommended Range of Sound Studio Reverberation Time (at 1000 Cycles)

1000 cycles, as a function of studio volume. The most reverberant condition shown is suitable for symphonic orchestras, church organ music, and other musical productions normally associated with large halls; the least reverberant condition is suitable for dramatic productions and musical programs where no "room tone" is desired.

It is desirable that studios be designed to provide a variation of reverberation time between the two limits shown in Fig. 1. This amount of flexibility makes it possible to adapt a studio for practically any kind of production. The advantages of being able to do this are obvious. The maximum load factor for every unit is assured without placing groups in studios having unsuitable acoustical characteristics. This feature alone will justify many times over the additional design problems that variable acoustics entails. Since a studio with variable acoustics can be used for all types of productions, fewer studio units are needed in any given group. The results are not only greater performer satisfaction but also a smaller initial investment and a smaller operating cost for the studio group as a whole.

VARIATION OF REVERBERATION TIME WITH FREQUENCY. In addition to the reverberation time at a specific mid-range frequency, the manner in which the reverberation time varies with frequency is important. Various investigators have discussed the shape of the reverberation characteristic from theoretical, subjective, experience, and environment viewpoints. Their findings are not conclusive, however. Furthermore, practically all were based upon binaural listening conditions.

Experience gained from broadcasting and recording studio applications seems to indicate that, except in the larger studios (i.e., those of about 50,000 cu ft or more) the reverberation time should be essentially independent of frequency (in practice, however, the humidity often limits the reverberation time at high frequencies). In the very large studios some increase in the reverberation time at the low frequencies is often beneficial for the type of productions for which such studios are used.

In a studio having variable acoustics, provisions may also be made to obtain variations in the shape of the reverberation-frequency characteristic. By properly locating various types of acoustical material on the absorbing side of adjustable panels (or on the wall back of movable panels), it is possible to change the shape of the characteristic, within limits. Variation, at the low frequencies, from a flat characteristic to a rising or falling one may often prove useful. A change of 20–30 per cent above a flat characteristic at 100 cycles to a like amount below should prove entirely adequate.

SOUND DECAY RATE. The manner in which sound decays in a studio is as important as the reverberation time, or even of greater importance. In some studios, sound does not decay logarithmically as geometrical acoustics assumes. Experience indicates, however, that a smooth logarithmic decay of sound results in the most acceptable type of studio. A decay curve of this nature insures the absence of discrete echoes and eliminates one of the sources of confusion to monaural listening already mentioned. For good acoustics it is generally considered desirable to have a constant decay rate for at least the first 30 or 40 db.

The desired type of sound decay can be obtained by creating a diffuse distribution of the sound. This can be done in a number of ways, such as employing a random distribution of the sound-absorbing materials, by the use of serrated walls and ceilings, or by substituting curvilinear surfaces for flat ones. It can be shown, theoretically, that curved panels, as contrasted to flat serrated panels, increase the area over which sound wave is dispersed. Likewise, it follows, that multicurved surfaces are an improvement over cylindrical ones. However, it is not yet generally realized that from a sound pickup viewpoint the diffusion of sound in an enclosure can be carried too far. Experience indicates that an entirely adequate amount of sound diffusion can be readily obtained with serrated flat surfaces. Consequently, there is little need to resort to the more complicated (from a construction viewpoint) curvilinear surfaces, except as may be deemed desirable from an esthetic point of view.

ACOUSTICAL NOISE LEVELS. The residual noise in studios, from all sources, should be as low as possible. However, there is a lower limit below which it is not justifiable to reduce the noise from either a theoretical or economical viewpoint. The maximum sound intensities normally encountered in studios at the normal microphone pick-up position (relatively close to the speaker for speech but relatively distant for music) range from about 75 db (above the acoustical reference level of 10^{-16} watt per cm^2) for speech to 95 db for music. The listener, on the other hand, indicates that noises that are 50 to 60 db below the signal are either unobjectionable or not detectable. Taking these considerations into account, together with the economic ones, it is evident that a residual-noise level 25 db above the reference level is quite satisfactory. Sound isolation methods are discussed in detail in Section 12.

2. MICROPHONES

The types of microphones most commonly employed for program pick-up purposes are: condenser, moving-coil (or dynamic), velocity-actuated ribbon, crystal (piezoelectric), and combination units. These last microphones usually combine a velocity- and a pressure-actuated ribbon or velocity-actuated ribbon and a moving coil into a single unit. The phasing between the two units of the assembly is arranged so as to obtain a directional effect, such as a unidirectional or a cardioid pattern. The characteristics of various microphones are discussed in detail in Section 13.

The output level of wide-range, high-quality microphones is extremely low—so low, in fact, that the signal-to-thermal-noise ratio existing at the output terminals of the microphone often determines the overall performance of the system. The sound intensities existing at the microphone position for the usual type of program productions is such that a net insertion gain of 50 to 60 db is usually required to raise the output level to 0 vu, the standard reference level (see below). Still greater gain is required, of course, to raise the level sufficiently for transmission over program circuits, for operating loudspeakers and recorders, or for modulating a transmitter.

The output impedance of condenser and crystal microphones is very high, and, as a rule, these units are operated directly into the grid of a tube. On the other hand, the output impedance of the moving-coil, ribbon, and combination microphones has ranged from a few ohms to several thousand ohms, depending upon the type. Such a variation greatly restricted the universal use of various kinds of microphones with different equipment. The situation has now been recognized, and microphones intended for broadcasting purposes have been standardized at 150 ohms. In most cases, a transformer must be supplied as an integral part of the microphone in order to provide the standard output impedance.

MICROPHONE PLACEMENT. In determining the proper placement of a microphone for a given type of program it is necessary to take into consideration the directional properties of the particular microphone being used as regards both its amplitude and its frequency response characteristics. Each type of microphone has a directional characteristic peculiar to that type, and both the horizontal and the vertical plane directional pattern of the microphone must be considered in connection with its application and placement. Some microphones are unidirectional, others bidirectional, and still others nondirectional in the horizontal plane. These properties are extremely important and useful for discriminating against undesired sources of sound and for obtaining a desired relation between sounds from different sources.

Figure 2 illustrates the placement of two bidirectional microphones which, for the purposes of illustration, are assumed to have a figure 8 directional pattern in the horizontal plane. The performance being picked up is assumed to consist of a chorus, a soloist, and an accompanying orchestra. Microphone A is used for the chorus and soloist pick-up, the artists being grouped on both sides of the instrument. The orientation of this microphone is such that the null point or direction of minimum pick-up is towards the orchestra. Microphone A, therefore, is actuated primarily by the chorus and soloist and picks up very little of the orchestra music. Microphone B, on the other hand, is so located as to derive its major source of energy from the orchestra, and its null point is towards the singers. The electrical outputs of these microphones, one of which consists primarily of the voices and the other of the musical accompaniment, are then properly combined or "mixed" so as to obtain the desired balance. The technician responsible for this operation has control over the relative magnitudes of the singers' voices and the music. He can adjust the relation between the two and also the overall amplitude to obtain any desired result. Still other microphones may be used for picking up sound effects, announcements, audience or crowd noise, etc. By the proper placement each microphone can more or less be confined to the pick-up of its assigned source of sound.

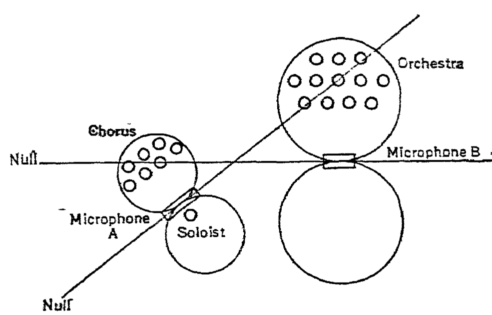

FIG. 2. An Illustration of the Placement of Bidirectional Microphones to Achieve Control of Sound Pickup

Microphones having relatively sharp directional characteristics are sometimes used for outdoor or long-distance sound pick-ups. These devices are particularly good for confining the source of pick-up of sounds at a large outdoor gathering to a particularly interesting part of the crowd such as a cheering section or a band of musicians. In television pick-ups they provide a means for keeping the microphone out of the camera angle.

The use of more than one microphone for the pick-up of a given performer or group of performers working as a unit (orchestra, chorus, etc.) is generally to be avoided. Serious frequency and delay distortion is likely to result if more than one instrument is employed for the pick-up because under these circumstances each microphone will be a different distance away from a given source of sound. As a result the sound waves do not reach each microphone at the same instant, and the combined outputs of the microphones will result in complete or partial reinforcement or cancelation, depending upon the resultant phase relationships. Furthermore, the phase relation is dependent upon the frequency of the sound source and does not, therefore, remain a constant quantity for all sounds.

In practice it is sometimes advisable, however, to countenance these potential sources of distortion and use more than one microphone for the pick-up of a given group of performers. For example, an orchestra may have a string choir too small for good balance. Under such circumstances, supplementing the main microphone by a strategically placed and judiciously used secondary microphone may enhance the overall balance. It is important to note, in an operation of this type, that the contribution of the additional microphones must always be maintained at a low level.

The frequency-response characteristic of some microphones varies with the angle of incidence of the sound wave upon the instrument. Microphones that exhibit this characteristic usually have a decreasing response to the higher frequencies as the source of sound moves around from the front to the side of the instrument. In placing such microphones this characteristic must be taken into consideration. The unidirectional dynamic and the condenser microphones are of this type. The velocity, non-directional dynamic, and crystal microphones, on the other hand, maintain the same relation between the high and low frequencies at all angles of incidence.

3. AUDIO AMPLIFIERS AND CONTROL EQUIPMENT

A complete sound system entails, in addition to microphones for converting sound energy into electrical energy, facilities for: (*a*) amplifying the exceedingly low microphone output to a usable level; (*b*) blending, into a balanced whole, program elements from several channels (known as "mixing"); (*c*) adjusting the balanced program to the desired transmission level *without* altering the balance; (*d*) aurally and visually monitoring the transmission.

These elements are found in audio systems used for broadcasting, sound recording, and public-address applications. Figure 3 illustrates, in block diagram form, a typical audio system incorporating the elements listed above. The components of the complete system are described below in the order in which they appear in the block diagram.

FIG. 3. Simplified Block Diagram of Typical Sound System Studio Audio Facilities

PRELIMINARY AMPLIFIERS. It is common practice in reproduction systems to have a mixer volume control associated with each microphone or other source of pick-up. As already noted, however, the output level of microphones is so low that any attenuation, prior to amplification of the signal, would degrade the signal-to-noise ratio of the system (the cause of the noise at this point being largely thermal). Therefore, before any volume controlling can be done, it is necessary to raise the level of the signal well above the thermal-noise level. In fact, one of the cardinal principles of good audio system design is never to permit the signal level to fall below the value existing at the output terminals of the microphone. It is therefore common practice to insert a preliminary amplifier between the microphone and the mixer volume control (or any other circuit element such as a sound-effects filter, dialogue equalizer, etc.). By using this arrangement the mixer control is introduced into a circuit at a point where the level of the microphone output has been raised considerably above the thermal-noise level of the circuit. As a result, when attenuation is introduced for mixing purposes, the signal-to-noise ratio is not degraded.

Preliminary amplifiers usually consist of one or two stages of amplification having an overall gain in the neighborhood of 30 to 40 db. The amplifier must be carefully designed because any noise originating in it will be amplified by the following amplifier stages. It is therefore imperative that amplifier noises such as microphonics and hum background be practically non-existent in the preliminary amplifier. The input transformer of the preamplifier, if one is used, is a particularly susceptible point for the pick-up of stray, unwanted, interfering fields. This unit must be very carefully shielded both electrostatically and electromagnetically.

Low-impedance microphones, such as the dynamic and velocity types, are connected to the input of the first amplifier tube by means of a suitable transformer. However, microphones of this type are basically voltage-generating devices; consequently their output impedance (150 ohms in broadcasting practice) is *not* matched to the input impedance of the preliminary amplifier. Rather, the preliminary amplifier is designed to have a high input impedance, thereby realizing as much of the open-circuit voltage of the microphone as possible. The input transformer is normally designed with as high a step-up ratio as commensurable with the required response-frequency characteristic. The leads connecting the microphone to the preamplifier input transformer may be several hundred feet long without seriously impairing the performance of the device.

The condenser and crystal types of microphones are connected directly to the input of the amplifier tube through a suitable network of resistors and condensers. In this case it is desirable that the leads connecting the pick-up device to the amplifier tube be of very low electrostatic capacitance. (Connecting cable capacitance attenuates the microphone's output voltage but does *not* impair its response as a function of frequency.) It is common practice to make these leads very short by building the preamplifier into the mounting which houses the microphone head. In the floor-stand type of mounting this amplifier is sometimes built into the base of the stand.

In the design of preliminary amplifiers care must be exercised that the output stage has adequate power-handling capacity. Since no gain control is ever inserted between the microphone and the preliminary amplifier, the input to the amplifier will vary over wide limits. The output level of the usual microphone under the average conditions met in practice has already been noted. However, if a microphone is placed close to a musical instrument that is being played very loudly (or near another source of loud sound) its output level may be as much as 20 db higher than that "normally" obtained. The output stage of preliminary amplifiers must be capable of handling without overloading the output level resulting from this input level. The output of the preamplifier is usually matched to the mixer circuit impedance by means of a suitable output transformer. For broadcasting applications the standard output impedances are 600 and 150 ohms.

MIXER VOLUME CONTROLS. A mixer circuit is an arrangement of volume controls for combining into one program channel, in any desired proportions, program elements of several channels. The multiple microphone, transition, and fading effects, which contribute so much to program continuity, are obtained with mixer controls. For instance, separate microphones may be used for a soloist and for the accompanying orchestra (Fig. 2) and the outputs combined to form a balanced whole. Since the gain of each microphone channel may be regulated independently of the others, a method of controlling the balance between various pick-ups is provided which does not impair the quality of the individual sources of sound.

A mixer is also used to "fade down" a musical transmission so that announcements or talks may be superimposed. All these effects contribute a degree of smoothness to a program which would otherwise be impossible. Because of their use these controls are sometimes known as "faders."

The mixer control is, in effect, a variable-resistance attenuation pad, usually of a T structure, having a constant or nearly constant input and output impedance. The device is capable of providing attenuation over a range from 0 to about 120 db. The attenuation generally varies uniformly with the angle of rotation of the control knob throughout the range from 0 to approximately 50 db. From this point to maximum attenuation the increase is very rapid, occurring in perhaps one-tenth of the full arc of rotation. For broadcasting applications the standard mixer control impedances are 600 or 150 ohms.

MIXER MATCHING NETWORK. A mixer matching network combines the output of a number of mixer controls into a single channel while maintaining correct impedance relations. The matching network provides the proper load impedance for the individual mixer controls and also the desired source impedance for the following circuit element.

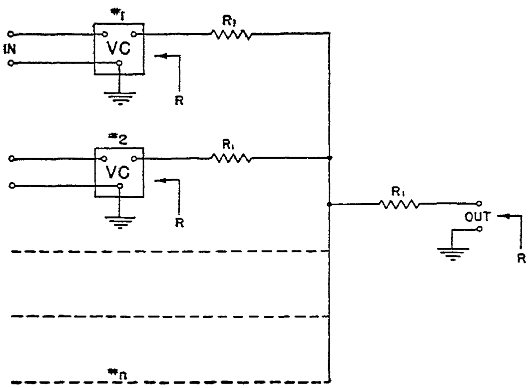

FIG. 4*a*. Differential Matching Network Having Like Input and Output Impedance

One of the simplest forms of matching networks is shown in Fig. 4*a*. In the general case of n mixer positions, the value of the building-out resistors, R_1, is

$$R_1 = \frac{R(n-1)}{n+1}$$

Where the input and output impedance of the network are assumed to be alike and equal to R.

The loss between the output of any given mixer control and the matching network load is

$$\text{db loss} = 20 \log_{10} n$$

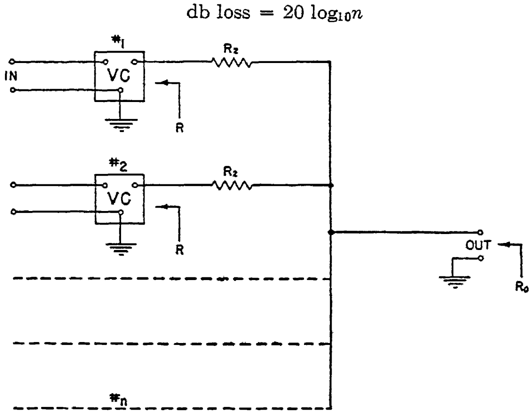

FIG. 4*b*. Minimum-loss Differential Matching Network. Input and output impedances are *not* alike.

If the requirements of like input and output impedance are waived, a lower loss network can be used, Fig. 4*b*. Here, the building resistor value R_2 is

$$R_2 = \frac{R(n-1)}{n}$$

The output impedance R_0 is

$$R_0 = \frac{R(2n-1)}{n^2}$$

The loss of the network is

$$\text{db loss} = 10 \log_{10} (2n-1)$$

In this case the output impedance can be restored to the same value as the input impedance (or to any other value) by means of a matching transformer.

BOOSTER AMPLIFIER. The amount of attenuation introduced in an audio system by the mixer controls and the associated matching network is often so great that amplification must be supplied before further volume controlling (see Master Volume Control, next paragraph) can be effected. The amplifier used for this purpose is termed a booster amplifier. It usually employs one or two stages of amplification, has a gain of 30 to 40 db, and is designed to operate from a source impedance and into a load impedance of finite value (e.g., 600 and 150 ohms in broadcast service).

Whether a booster amplifier is required between the mixer circuit and the master gain control is determined by the signal levels existing for normal input levels and normal settings of the controls. Its use is indicated if, by its omission, the signal would fall below the level existing at the output terminals of the microphone.

MASTER VOLUME CONTROL. The master volume control or "gain" control is "master" over the output of the individual mixer controls. After these mixer controls are adjusted to obtain the proper relation between the various parts of the performance the resultant overall volume of the program material may be adjusted to the desired level by means of the master gain control without affecting the balance that exists. This device also permits the properly balanced performance to be faded in or out while the same relation is maintained between the individual parts of the program. The master gain control is similar in construction and operation to the mixer volume controls.

PROGRAM AMPLIFIER. The purpose of the program amplifier is to bring the level of the studio output up to the point necessary to permit its being fed directly into the audio amplifier stage of a transmitter, into the program line connecting the studio with a transmitter, into a loudspeaker amplifier or a recording system. At a network key station, the output of the program amplifier is fed into a bus for distribution to the proper network or networks.

This amplifier follows the preamplifiers, mixers, and master gain control to amplify the output of the microphones or other program source further. Although one preamplifier is needed for each microphone in use, only one program amplifier is necessary for a given studio channel. The amplification obtainable in these units is generally in the vicinity of 50–60 db. The amplifiers are usually capable of an output level of approximately 250 milliwatts without serious overloading. The input impedance of this amplifier is matched to the output impedance of the preceding master gain control by means of a suitable transformer. The output impedance is similarly matched to the load which follows this unit.

4. MONITORING FACILITIES

AURAL MONITORING FACILITIES. A monitoring system consisting of a suitable amplifier and loudspeaker is a part of every complete sound system. These facilities provide a means for those responsible for the production of hearing the program exactly as it is being sent to the transmitter, the network, or the recorder. It is essential that the fidelity of the aural monitoring equipment be in keeping with the remainder of the broadcasting or recording system.

An output of 10 to 25 watts and an amplification of approximately 50 db are generally obtainable from the monitoring amplifier. The input impedance of the monitoring amplifier is usually very high in order that it may be bridged across the program circuit at a convenient point without affecting the level or impedance balance of the circuit to any appreciable extent. The output circuit is provided with a suitable transformer to effect an impedance match with the particular type of loudspeaker or speakers being employed.

Broadcasting and sound-recording control rooms often afford a limited amount of space for the installation of a monitoring loudspeaker, placing several special requirements upon the design of the unit. For instance, the directional properties of the loudspeaker must be such as to provide uniform coverage for all occupants of the control room who are concerned with the production in hand. This requirement usually entails some special arrangement to insure uniform distribution of the high frequencies. Furthermore, since the loudspeaker may be relatively close to the listener, multichannel loudspeakers (if used) must be especially arranged so that the separate sources of sound cannot be distinguished as such.

VOLUME INDICATOR FOR VISUAL MONITORING. A volume indicator is used in order to provide a precise, visual means of determining the volume level of the program material being transmitted by an audio system. The standard volume indicator consists of a copper oxide rectifier and a d-c indicating instrument. The characteristics of the rectifier, together with the dynamic, electrical, and other performance characteristics of the indicating instrument, are all carefully standardized. When calibrated and used in the prescribed way, the standard volume indicator gives an accurate indication of volume level. This is expressed as so many "vu" above (or below) reference volume—the number of vu being numerically equal to the number of decibels that the volume level is above (or below) reference volume.

REFERENCE VOLUME—VU. Reference volume is that level of program which causes the standard volume indicator, when calibrated and used in the prescribed way, to read 0 vu. By definition, the reading of the standard volume indicator shall be 0 vu when it is connected to a 600-ohm resistance in which there is flowing 1 milliwatt of sine-wave power or n vu when the calibrating power is n decibels above one milliwatt.

Reference volume, as applied to program material, should not be confused with the single-frequency power used to calibrate the volume indicator. Speech or program waves that result in a volume reading of 0 vu have instantaneous peaks of power many times 1 milliwatt and an average power which is a fraction of 1 milliwatt. In other words, reference volume is not 1 milliwatt, except in the special case of sine-wave measurements.

DBM VS. VU. For steady-state measurements a reading in "vu" denotes a specific single-frequency audio power; for dynamic program indications vu denotes only a "volume" level. This dual meaning of vu is avoided by use of the term "dbm" for all steady-state measurements. Using this terminology, a reading expressed in dbm indicates the *power level* of a steady *single-frequency* signal where the number of dbm is equal to the number of decibels above (or below) a reference power of 1 milliwatt. On the other hand, a reading in vu denotes a volume-level indication of a program signal. A vu reading can be made only on a standard volume indicator (since the dynamic characteristics are involved) whereas sine-wave power level measured with the standard volume indicator or with any other suitable a-c instrument can be expressed in dbm.

The practice of expressing measurement-signal levels in dbm, and of limiting vu to expression of dynamic volume levels, has certain advantages. Thus, dbm is a unit of finite audio power, whereas vu may be considered only a unit of volume level and, as mentioned above, has no connotation of finite power level.

However, it is necessary to establish a relation between the vu level to be used for program peaking and the dbm level to be used for performance measurements. It has been found that on typical program peaks reaching a given crest amplitude the standard volume indicator reaches an indication 8 to 14 db below that reached on a steady tone of the same crest amplitude. To take into account this 8- to 14-db difference in response, it is standard practice to require that performance requirements be met at a single-frequency test-tone level 10 db higher than the normal program level. This will reasonably insure that system performance is within standards under most operating conditions.

TALK-BACK EQUIPMENT. A "talk-back" system is generally employed in order to provide a means for communication between the control room and the studio during the course of rehearsals. This equipment consists of a microphone in the control room, a suitable amplifier, and a loudspeaker in the studio. By means of this equipment the technician or the production man in the control room may talk to and direct the performers in the studio during rehearsals.

The talk-back equipment is interlocked with the regular studio equipment so that the studio microphones and the control-room monitor speaker are turned off whenever the talk-back equipment is energized for use. This prevents the generation of an acoustic feedback because of coupling between the input and the output circuits of the amplifier systems. The regular preamplifiers, studio channel amplifier, and monitor amplifier associated with the studio are sometimes employed, by suitable switching means, for the talk-back service. Inasmuch as both services do not function simultaneously, this arrangement results in an economical use of the equipment already available. The switching complications, however, often do not justify this practice. Under these circumstances separate or partly separate talk-back equipment is used.

ELECTROACOUSTIC EQUIPMENT

By R. J. Kowalski

5. AUDITORIUM ACOUSTICS

When an auditorium is designed for use with a sound-reproducing system one of the most important design considerations is the acoustic characteristics. (See also Section 12). The sound emanating from the stage loudspeakers reaches the listener only after being influenced by the acoustic conditions of the auditorium. In view of the technical perfection of modern sound-reproducing equipment, it is frequently these acoustic conditions that determine whether the sound reaches the ear of the listener with all its original naturalness and realism or whether it is distorted, unnatural, and wholly unsatisfactory to the listener.

The most common acoustic defects encountered in auditoriums are reverberation, echo, resonance, poor distribution (loud and dead spots), and noise.

Optimum reverberation times for auditoriums of various sizes are shown in Fig. 1. It will be noted that as the volume increases the allowable reverberation time also increases.

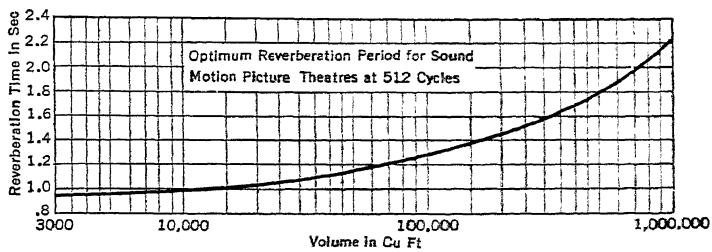

FIG. 1. Optimum Reverberation Times for Auditoriums

It will also be noted that the optimum reverberation time recommended is from 10 to 20 per cent below the usual values for an auditorium that uses live talent without a sound-reinforcing system. This is because there is an abundance of sound energy and hence reverberation is not necessary to augment loudness. In fact some recent thinking favors overtreating an auditorium with sound-absorptive material to eliminate most acoustic defects and then artificially introducing the proper amount of reverberation in the sound-reinforcing system by means of reverberation or echo chambers. These can be designed to give any desired amount of reverberation and can be quickly and cheaply changed to meet different conditions.

It will be noted in Fig. 2 that at the lower frequencies longer reverberation periods can be tolerated while at the higher frequencies the allowable period is somewhat reduced.

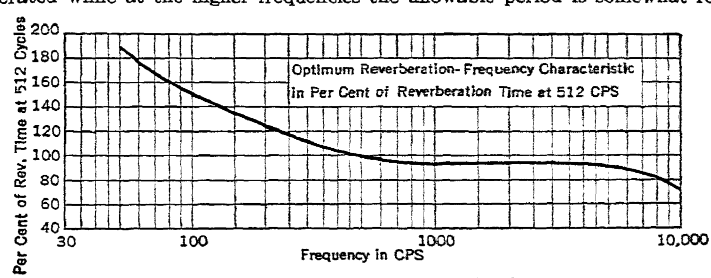

FIG. 2. Optimum Reverberation Time with Frequency

By referring to the table of absorption coefficients of building materials in Section 12 it will be noted that most materials have a different coefficient for different frequencies. Because of this, it is possible by proper selection of materials to arrive at a design which will give optimum reverberation time throughout the frequency range. Owing to the extension of the low-frequency and the high-frequency ranges of modern reproducing equipment great care should be observed in the choice of sound-absorbing materials and treatment.

Echo consists of a delayed repetition, sometimes several rapid repetitions, of the original sound. It is most often encountered in large auditoriums, particularly those with curved ceilings and walls and other surfaces sufficiently remote from the source of original sound to cause a definite time interval between the arrival of the original and reflected sounds at the listener's position. A multiple or flutter echo (several distinct repetitions) is often caused by parallel walls with smooth hard surfaces. With the extension of the high-frequency range of modern equipment the problem of echo and sound concentration was somewhat intensified because the high frequencies, or high-pitched notes, on account of their short wavelengths, are more easily reflected by small, smooth surfaces.

Echoes have much the same effect as reverberation in that they tend to blur speech and music. Echoes are eliminated by first localizing them and then applying light drapes or other sound-absorbing materials, or by breaking up the regularity of the offending surfaces by stepping, angling, etc., thereby dispersing or scattering the sound striking them. When it is necessary to add sound-absorbing material to correct for reverberation time, it is best to apply it first to the rear wall of the auditorium. Since the speakers are directed toward this wall it is usually the worst offender for echoes. If the side walls are parallel, the next best place to apply treatment material is on alternate panels of the side walls with the treated panels staggered so that no two untreated surfaces are opposite each other. This helps to eliminate flutter echo between walls. Flutter echo between ceiling and floor can best be avoided by specifying heavy carpeting with padding in the aisles and heavily upholstered seats.

The phenomenon of resonance, or the ability to vibrate best at certain frequencies, may occur either in structures or in the air in rooms. The effect is a build-up or overemphasis of certain frequencies. Structural resonance usually is not harmful unless the resonant body is mechanically coupled close to the source of sound. An offending object can usually be located quickly by connecting an audio-frequency oscillator to the input of the sound-reproducing system and varying the frequency until resonance is reached. By surveying the room while this frequency is maintained, the vibrating object can usually be located. The vibration can then be eliminated by changing the mounting or adding damping material. Resonance in air chambers is usually encountered in small, highly reverberant rooms; it rarely is a problem in the main body of a large auditorium, though it may give trouble in smaller sections such as the stage, which usually has hard, bare, parallel walls, or under a balcony, in alcoves, or in foyers. To eliminate such resonance conditions on the stage, as well as to help reduce reverberation on the stage, absorbing material should be draped in the region around the loudspeakers.

Poor distribution of sound (i.e., loud and dead spots due to the shape of the auditorium) can usually be overcome by the proper type and proper orientation of the loudspeakers. This problem is discussed further in article 6.

Noise may be defined as any unwanted sound. Noise is undesirable particularly because it has a masking and a frequency discriminating effect on the desirable sounds which, therefore, require added loudness or power to override the noise An auditorium in a noisy city location should have its outside walls insulated against the transmission of outside noises into the auditorium. See Section 12 for a full discussion of noise reduction.

The following recommendations will serve as a guide in designing an auditorium to get the best results from a modern sound-reproducing system:

1. All seats should be of the heavily upholstered type.
2. Heavily padded carpeting should be used in all aisles and corridors.
3. The rear wall, being potentially the greatest source of echo, should be lined with an efficient type of sound-absorbing material and/or sloped or otherwise shaped to direct the reflected sound to nearby audience or treated areas to prevent echo.
4. Surfaces with concave curvature should be avoided as much as possible. If such surfaces are necessary they should be broken up with smaller convex flutes to disperse the sound or heavily treated to absorb most of the incident sound.
5. Large unbroken surface areas, except when used for beneficial reflections, such as reflection from the splayed ceiling and walls at the proscenium, should be avoided.
6. Long narrow auditoriums, high ceilings, and excessively long and low balcony overhangs should be avoided.
7. The cubical content of the auditorium should be made as small as possible, compatible with the seating capacity and architectural design.
8. A rising slope in the orchestra floor should be used to give unobstructed "sound" lines as well as "sight" lines.
9. All auditorium walls should provide sufficient sound insulation to prevent extraneous noises from entering.
10. All machinery and ventilating noises should be isolated from the auditorium.

POWER REQUIREMENTS. In calculating the power requirements for a sound-reproducing system there are several factors to be taken into consideration. In an outdoor installation the listener gets only the direct sound from the speakers, while in a small room or auditorium the total energy reaching the listener is the sum of the direct energy and the reflected reverberant energy. Hence the total absorption of the auditorium must be known to determine the acoustic power required. It is also necessary to know what sound pressures it is desired to attain before calculating acoustic power. For high-fidelity reproduction of both sound and music it is generally assumed that sound pressures on peaks and loud passages will reach 20 dynes per sq cm, or 100 db above the threshold of audibility. Finally, since we are chiefly interested in the electrical power needed in the reproducing amplifiers, it is necessary to consider the conversion efficiency of the loudspeakers and the coverage efficiency, that is, the percentage of the total radiated sound energy actually distributed to the required area.

In making calculations for any given installation, the following formula is recommended:

$$P = 0.0009 \frac{S_F}{E_L} \left[\frac{A_0 S_T}{A_0 S_T + 4R_F S_F} \right] \text{ watts}$$

where S_F = floor or seating area in square feet.
E_L = loudspeaker efficiency expressed in fractions thus, 50 per cent = 0.50.
A_0 = average absorption coefficient of room.
S_T = total area of room surfaces in square feet.
R_F = reflection coefficient of seating area. This equals 1 minus the absorption coefficient $R_F = (1 - A_F)$.

The constant in this formula is calculated to give a sound pressure of 100 db. If less acoustic power is required, as in small rooms, the power as calculated by the formula may be decreased an equivalent number of decibels. For outdoor reproduction, the absorption is considered infinite, hence the factor in brackets goes to unity, simplifying the equation to $P = 0.0009 S_F/E_L$. Assuming an efficiency of 45 per cent, which is average for a modern directional loudspeaker of the type used in outdoor installations, the formula becomes $P = 0.002 S_F$. This indicates that, in order to develop sound pressures of 100 db without the benefit of reverberation, using a loudspeaker with an overall efficiency of 45 per cent, it is necessary to supply 2 watts of electrical energy for each 1000 sq ft of audience area.

6. LOUDSPEAKERS

Through the years, a good many different types of loudspeakers have been developed to convert electrical energy into acoustic energy (see Section 13). Among them were the head-phone-type magnetic-diaphragm units, the condenser speakers, the magnetic-armature speakers, and the moving-coil-type speakers. In recent years the moving coil or so-called dynamic speakers have proved the most efficient, and hence this is the only type now in common use. The magnetic field that the voice coil moves in is supplied by a field coil energized with direct current or by a permanent magnet. With the new magnetic alloys like Alnico it is possible to get flux densities in the permanent-magnet type that are as great as those obtained when using an electrically energized field. Hence the efficiencies of the two types are comparable. The permanent-magnet type is rapidly becoming the most popular, because, though it is a little more expensive to build, it saves the cost of an electrical field supply as well as considerable additional wiring, which is quite a factor when a good many speaker units are located at remote points. Aside from the type of field, dynamic speakers are classified in two general types: (1) the direct radiator type and (2) the horn type. The direct radiator type uses a large cone with a relatively small-diameter voice coil for a radiator. This unit is generally mounted on a flat baffle or in a cabinet. The horn-type unit has a relatively small diaphragm driven by a large-diameter coil. This unit is specifically designed to be used with a directional type of horn.

The direct radiator or cone type of speaker on a flat baffle is generally used in small spaces such as hotel guest rooms, school classrooms, or hospital ward rooms. Although this type of loudspeaker is frequently considered non-directional, it has a definite distribution angle, particularly at the higher audio frequencies. For a rough approximation at the most important frequency range, this angle may be considered to be 90°, that is, 45° off from either side of the central axis. Since the shape of the cone is symmetrical, this distribution angle is the same for both the horizontal and vertical planes. In determining the number of speaker units to place in a given room, not only the power-handling capacity but also the coverage must be considered. A floor plan of the room may be sketched to scale, and speakers may be located, and the coverage of each plotted.

If the distribution angle of one speaker does not cover at least 75 per cent of the total area, two or more speakers should be placed along the wall until this much of the area is covered. All speakers must be connected to operate in phase. When speakers of this type are used for incidental music such as in a hospital or restaurant it is preferable to increase the number of speakers and hence cut down the power per speaker to get the most uniform sound intensity throughout the room.

For larger installations in auditoriums or in unconventionally shaped rooms much more efficient distribution of sound energy can be obtained through the use of horn-type loudspeakers with directional horns. The more concentrated beam distributes the sound in the desired area and at the same time keeps it off walls and ceilings, hence helping to avoid serious echo effects. In de luxe installations where high-fidelity reproduction of music is desired best performance can be obtained by using a two-way speaker system with multicellular exponential high-frequency horns and a folded baffle for the low-frequency speakers.

In auditoriums or theaters, the location of the speakers for best illusion is usually above and to the front of the proscenium arch. If this location will not allow for the projection of sound into the rear of the orchestra floor under the balcony, it will be necessary to place additional speakers to the sides of the proscenium directed to cover this area. These speakers should be kept as high as possible and should be angled to get as little sound as possible into the front rows of seats. When locating speakers, caution should be used to see that the projected sound beam does not pass through the microphone pick-up area where it would cause acoustic feedback and hence limit the gain of the reinforcing system.

When more than a single speaker unit is used, it is essential that all units operate in phase. On better speakers, the phasing is carefully controlled in production and the terminals of the speaker are marked so it is only necessary to connect all similar terminals together to get proper phasing. If the speakers are not marked it is possible to energize the speaker fields and then apply a small d-c voltage to each voice coil. By reversing the polarity of the battery it is possible to determine to which terminal of the speaker the positive terminal of the battery should be connected to give a forward deflection of the speaker diaphragm. If these positive terminals are connected all the speakers will be properly phased.

7. AMPLIFIERS AND CONTROL EQUIPMENT

Before selecting the proper amplifier for a given installation it is necessary to determine the power requirements as described in article 5. Strict adherence to this formula in small auditoriums might indicate relatively low power requirements; however, the Research Council of the Academy of Motion Picture Arts and Sciences recommends a minimum of 10 watts of audio power for the smallest of theaters. Though the average power used in normal reproduction will be considerably below this figure, the reserve power will make it possible to reproduce peaks and loud passages without distortion. This minimum of 10 watts is recommended for auditoriums up to 500 seats. The recommended power rises approximately 10 watts for each additional 500 seats. In multiroomed installations like hotels, the total power requirements are found by adding up the power requirements of the individual rooms. Systems of this type frequently have a varying use factor for each room so that all rooms might not have to be supplied simultaneously. Although this use factor varies widely with different types of installations, the suggested values for hotels are: 100 per cent for a single channel installation, 90 per cent for two channels, 75 per cent for three channels, and 60 per cent for four channels.

For theatrical use the amplifiers should be capable of reproducing all frequencies within the range of 50 cycles to 10,000 cycles.

PUBLIC-ADDRESS SYSTEMS

By R. J. Kowalski

Public-address systems fall in two general classifications according to application. A system for amplifying speech or music presented directly to a large audience, whether in an auditorium or out in the open, is appropriately named a sound-reinforcing system. A system by which a speaker at a central location addresses people simultaneously at various locations is known as a paging system. In general, the equipment specifications for sound reinforcing, particularly indoors, are more exacting than those for paging applications.

8. INDOOR SOUND-REINFORCING SYSTEMS

The essential requirements of a sound-reinforcing system are that it must pick up all desired sounds and project them, unaltered, with sufficient intensity and distribution to all listeners within a given area. For maximum effectiveness, the system should function so as not to detract the attention of the listeners from the performers.

When installing a reinforcing system in an auditorium, particular attention should be given to the acoustic conditions. A certain amount of the sound energy emanating from the loudspeakers finds its way back to the microphone. Unless the difference between the level of the sound energy leaving the speakers and that arriving at the microphone is greater than the gain of the system amplifier, the system will oscillate because of acoustic feedback. Directional microphones aid in avoiding feedback, because, with them, it is possible to position the axis of maximum response toward the desired sound and the null axis toward the reflected sound. Mounting the microphones in acoustically treated compartments in the footlight trough also shields them from considerable reflected sound. Unless feedback can be corrected by repositioning the microphones or redirecting the loudspeakers it will be necessary to limit the gain of the amplifier and hence the amount of reinforcing obtained. However, if the auditorium is well designed acoustically, there should be no difficulty in getting sufficient amplification before feedback occurs.

The sound-reinforcing equipment in large auditoriums and theaters is usually custom built and permanently installed. The microphones and preamplifiers are broadcast quality, and the main amplifiers and loudspeakers are generally of the type used in sound-motion-picture reproduction. The amplifiers should have uniform frequency response over the complete range of audio frequencies from 50 to 10,000 cycles. The amplifier output capacity should be such that at least 1 acoustic watt per 1000 ft of floor space can be delivered. The amplifier should be able to deliver this amount of power with less than 2 per cent total harmonic distortion over the range from 50 cycles to 5000 cycles. The loudspeaker system should have directional horns to distribute the sound energy efficiently in the proper area. Many theaters employ two-way speaker systems for their reinforcing systems as well as for the movie-sound system. The two-way system assures uniform, highly efficient operation over the complete audio spectrum. The input equipment should be highly flexible to accommodate a wide variety of microphone combinations because different types of programs require different pick-up arrangements. See article 2. Where the pick-up area is great, such as an entire stage area for vaudeville and stage productions, microphones are usually located in the footlight troughs, suspended from the scenery drops, and sometimes concealed in stage props. The optimum spacing of footlight microphones has been found to be 8 to 10 feet. In order to control the input from all these microphones to get the proper balance in sound levels, a mixer is required with controls for each input. The most satisfactory location of the mixer console is somewhere in the audience area, preferably at the head of the balcony where the operator can hear the direct sound from the system speakers and adjust the various inputs for best balance.

An excellent example of a high-quality sound-reinforcing system is the one at Radio City Music Hall, New York City. Because of the width of the stage, a three-channel reinforcing system is used to obtain the best possible illusion. The stage microphones are split into three groups: right stage, center stage, and left stage. Each group is fed through its separate section of the mixer console, then to its separate amplifier, and thence to the speakers over the proscenium arch. The speakers, too, are split into three groups which are fed by the three amplifier channels. Therefore, a sound originating on the right side of the stage is picked up by the right-side microphones, amplified by the right channel amplifier, and reproduced by the right group of loudspeakers. As an actor moves across the stage the sound moves with him, creating an excellent illusion. Sound reproduction in this system is so well balanced that, despite the tremendous size of the auditorium, the people in the remotest corners can hear as well as those seated up front.

Besides these large, expensive systems, many small portable systems are available commercially that can be used for meetings, banquets, etc., in small rooms. These systems generally contain microphones, folding microphone stands, amplifier, and loudspeakers all in one compact carrying case. The sides of the case serve as baffles for the speakers when they are put in use.

9. OUTDOOR SOUND-REINFORCING SYSTEMS

Sound-reinforcing systems for outdoor use are generally higher powered than indoor systems, because the average area to be covered is greater, and the power per unit area is also greater since there is no beneficial reverberation to augment the direct sound. In order to utilize the available sound energy most efficiently, highly directional loudspeaker horns are used almost exclusively for outdoor work. Since the low-frequency cutoff on practical sized horns of this type is well up in the audio-frequency range, the system fidelity is not generally as good as that found in indoor systems. The fidelity could be improved with a more expensive speaker set-up; but, in most cases, intelligibility is more important in outdoor systems than fidelity. Since the low-frequency tones do not contribute materially to intelligibility, they may be sacrificed in the interest of holding down the practical size of the equipment. As in indoor systems, the loudspeakers should be located to give the best illusion; but they should be carefully directed to prevent any direct energy from reaching the microphone and causing feedback. This problem is obviously much less serious in outdoor than in indoor installations.

For indoor work, the ribbon-type velocity microphone is the most popular because of its uniform frequency response, its useful directional pattern, and its ability to pick up sounds at a considerable distance. In outdoor work this microphone is not too satisfactory because it is somewhat fragile and is subject to extraneous noises generated by the wind disturbing the ribbon. A much better microphone for this application is the dynamic pressure type.

10. PAGING SYSTEMS

Although the sound-reinforcing application of public-address equipment is probably more familiar to the layman, paging systems have become even more important. During the war years, large permanently installed plant broadcast systems became vital parts of most big factories, making it possible to locate key men quickly in the acres of floor area, and to coordinate production activities throughout the plant. Announce systems of many types, installed on practically all fighting ships of the fleet, proved to be the most important means of internal communication. New-type announcing systems for schools make it possible to communicate quickly with all rooms and to distribute educational programs as desired. Besides these, there are hundreds of more commonplace applications like train announcers at railroad stations and call systems in hospitals, hotels, restaurants, and other business establishments.

PLANT BROADCAST SYSTEMS. Though the leading manufacturers are building equipment components specifically designed for industrial use, there is no such thing as a universal industrial sound system. The desired services, plant layout, and conditions of operation vary so greatly that each installation becomes a custom-engineered job. Some of the many services furnished by a properly designed and managed industrial system are:

1. Paging. The telephone operator or a special paging operator, through announcements to selected areas of the plant, can quickly locate personnel.
2. Emergency and alarm. By using combinations of special signal generators and verbal announcements the system is highly effective in fire, damage, and accident control.
3. Time signals. The system may be connected to the main time clock to broadcast time signals at preselected intervals.
4. General announcements. The paging operator or one of the plant executives may use the system to supplant the bulletin boards for messages pertaining to plant operations.
5. Work music. To increase the efficiency of personnel, planned music programs may be given at periodic intervals during the work period. The source of the music may be recordings, a wired-in service, or radio programs.
6. Entertainment. During rest or lunch periods, programs may be presented by live talent, such as employee groups or visiting celebrities.
7. Morale building. The system may be used to bring about more personal contact in personnel relationship through inspirational messages, drives, safety campaigns, and announcements of general interest.

In recent years many scientific tests have been made on the value of music in industry. These have proved that periodic musical intervals have a beneficial effect on most types of workers, but especially on those engaged in repetitive manual operations associated with modern assembly-line manufacture. The chief effects are the relief of fatigue and boredom and the dispelling of nervous tension. Tangible results have been accomplished in the reduction of labor turnover, reduction of accidents, increased production, and improved quality of product.

The central control equipment of the average plant broadcasting system is located in a sound-treated room that serves as a studio. The central control console, or mixer, is located here to control the various inputs. These inputs may include a paging microphone, one or more studio microphones, one or more executive microphones in the executive offices, one or more radio inputs, one or two phonograph turntables, time clock signal generator, and possibly a fire or other emergency alarm signal generator. The mixer console should include an attenuator to control each input and a master attenuator to control the overall level of any combination of inputs. It should also include a volume-indicator meter to permit the operator to maintain the proper signal level on the system. The output of the mixer is fed into a program amplifier which in turn feeds a group of zone selector switches on the operator's console. In almost any setup it is best to divide the plant into convenient zones or areas for programming and paging. In a simple system the division might merely be "offices" and "factory," but in a larger plant an individual zone might be established for each building or each department. This makes possible selective announcements or paging calls to any one part of the plant. The output of the zone switches is fed to the individual zone power amplifiers that drive the loudspeakers in each zone. If the plant is small and all zones are in a single building, it is best to install all the zone power amplifiers in the studio or equipment room so that they will be in a central location to facilitate service work. However, if the plant is spread over considerable area, or in many buildings, it is best to mount the zone power amplifiers in the buildings they serve. The input signal can be fed from the studio at the zone power amplifier at zero level over standard telephone lines which normally link most buildings of a large plant. This is more economical on amplifier power than trying to feed high-level energy over long lines.

In a larger system it might be desirable to have provisions for sending two different programs to different areas simultaneously. This is especially helpful when an urgent paging announcement has to be sent to one zone during a regular musical program. The particular zone can be paged on a separate channel without disturbing the music going out to the other zones. To do this, it is necessary to add a second program amplifier and another volume indicator meter to monitor the level on this second channel. Each input switch should be a three-position switch so that, besides an "off" position, any of the inputs may be connected to either of the two program amplifiers. The zone selector switches should also be three-position switches so any zone may be connected to either of the two program channels or may be completely disconnected. In plants subject to serious emergencies, the switching arrangement may be so arranged that, whenever the alarm signal generator is sounded, it takes priority over all other inputs and is automatically fed to all loudspeakers regardless of the position of the zone switches. Alarm contactors to energize the signal generators may be located throughout the plant at critical points.

Associated with the studio equipment should be a monitor speaker with a switch which enables the system operator to monitor audibly any program going out to the plant or to check on proper tuning of the radio receiver before connecting it to the program bus. Adjacent to the studio should be a suitable storage room for storing the record library for musical programs as well as spare microphones, etc., for the system. Records for in-industrial use should be selected with some care. In general popular records are suitable for factory working periods with possibly light classical music for the plant restaurant during the lunch hour. Considerable research has been done on the psychological effects of different types of music. By reference to the bibliography following this article, additional information on this subject may be obtained. From a practical standpoint, since most factories are rather noisy the recorded music selected should have fairly constant level. If a recording having very loud and very soft passages is reproduced in a noisy area, the low passages will be lost completely unless the overall level is made so high that the loud passages are annoying.

The primary design consideration for equipment for industrial use is ruggedness. In many cases the equipment will have to operate continuously through a 24-hour working day. All components should be conservatively rated so they are used well within their capacity and hence will give long life. Precautions should be taken in the design of the switching system so that the equipment cannot be damaged by improper operation of the controls. Occasionally inexperienced personnel will attempt to operate the equipment, and so these safeguards are necessary.

The necessary overall fidelity of the equipment varies with the application and the noise levels encountered. If the system is to be used solely for verbal announcements, an overall frequency response of 300 to 3000 cycles is adequate; however, if music is to be reproduced, the response should extend from 50 to 10,000 cycles. This wide frequency range is not merely to give high-fidelity reproduction but also to add needed definition to music being reproduced under adverse conditions. Noise generally occurs at specific frequencies. If the music is reproduced with a limited band of frequencies, some of the frequencies will coincide with those of the noise and hence will be masked. The loss of certain notes reduces the definition of the music and makes it hard to follow. Of course, the difficulty can be overcome by making the volume louder to override the noise, but this might make the music annoying. By extending the frequency range, the definition may be improved without increasing the overall volume.

Plant noise levels and the shape of the building determine the size, type, number, and locations of loudspeakers. In high-noise areas, best results are obtained from horn-type loudspeakers which can direct the sound energy to the important areas. However, if the noise level is below 90 db, well-baffled cone-type loudspeakers should be used. It is possible to get more uniform distribution over wide areas with this type of speaker. The power required for any given zone may be computed fairly accurately by means of the formula given in article 5. Where the existing noise level is above 100 db, the power as computed by the formula should be increased accordingly. Most standard types of microphones are suitable for reproduction from a studio; but if the microphone is located in a high-noise-level area out in the plant, a specially designed close-talking microphone should be used to reduce the response to unwanted room noise. A phonograph turntable for industrial use should be weighted and dynamically balanced, and it should be driven by a heavy-duty motor to insure constant speed. Home-type record changers should never be used in an application such as this.

Before actually selecting the equipment for a particular plant, a thorough plant survey should be made. This survey should supply the following information:

1. Noise. All sources of noise should be located on a copy of the plant's floor plans as well as the average level of the noise in all areas. This information can be quickly obtained with a portable sound-level meter.

2. Coverage. On the basis of the above measurements, the types of speakers should be selected and their locations marked on the print.

3. Plant zoning. All areas should be zoned with reference to industrial operations for determining switching requirements.

4. Locations. The location of the studio, input sources, amplifier equipment, and controls should be determined and marked on the prints.

5. Special considerations. Any special information such as desired priority of signals and temporary microphone locations should be noted.

On the basis of the above information it will be possible to engineer a system that will exactly fill the needs of the plant. To fill the needs of a wide variety of different plants, some manufacturers have designed a series of very flexible sectionalized units which may be put together like building blocks to make up any desired type of system out of standard equipment.

NAVY ANNOUNCE EQUIPMENT. A modern fighting ship is a complex organization with a huge staff of personnel engaged in a wide variety of activities necessary to operate it. To coordinate all these activities it is necessary to use a shipwide, selective, announce system. When the ship is under way, the orders originate on the bridge; when the ship is in port, the ship's control center is the quarter deck, hence orders originate from this station. The ship is divided into sections so that orders may be issued to selected sections. In addition, each section is subdivided into smaller subgroups which can be separately disconnected in the event of battle damage; then if one speaker line is shorted, it may be cut loose so that it does not affect the rest of the system. Besides the shipwide general announce system, a large ship has many more specialized systems such as: (1) the engineer's announce system between the engineering log room and the various fire rooms, boiler rooms, and other engineering spaces; (2) the damage control system between the damage control office and several damage control stations; (3) turret control systems for communication between the turret captain in each of the primary battery turrets and the gun pointer, the gun layer, and the various shell-handling and power-handling decks below the turret; and (4) the secondary battery announce system communicating between the gun directors and the gun mounts of the secondary batteries. Moreover, there are high-powered systems using a single loudspeaker that can be directed for ship-to-ship, ship-to-dock, and ship-to-plane sound communication, and a variety of low-powered intercommunication systems between specialized points.

The requirements for ruggedness in ship equipment are even more exacting than in equipment for industrial uses. All ship equipment must be shockproof, and loudspeakers on the weather decks should be weatherproof, watertight, and blastproof to stand the pounding seas and the terrific concussion of gunfire. Microphones are generally of the close-talking dynamic type to reduce the response to undesired noises.

SCHOOL SYSTEMS. Small specialized versions of industrial systems have been designed for school use. The control console is located in the principal's office, where announcements and programs originate. The control console has a selector switch for each room so that announcements may go to any room or any group of rooms. A special connection with a talk-back amplifier makes it possible to use each classroom speaker as a microphone. In this way, it is possible to establish two-way communication between the principal and any of the teachers. Available inputs besides microphones include a radio tuner and a record player.

The main features of school equipment should be simplicity of controls and relatively low cost, which is achieved by a slight sacrifice in overall quality of reproduction, while maintaining a safety factor in the choice of component parts to insure dependability of operation.

SOUND RECORDING AND PROJECTION

11. RECORDING PRACTICES

By O. B. Gunby

Sound motion pictures are released extensively, either 16 mm or 35 mm, depending upon the application. The use of 16-mm film is on the increase in advertising and educational fields. The majority of the studios make all their pictures on 35-mm film, even though some of them will be reduced to 16 mm before release, because of the greater flexibility obtainable from the 35-mm equipment commercially available.

Recent trends in the design and operation of sound-motion-picture equipment include the general use of electronic mixers (volume compressors) or limiters to vary the volume range of the recordings or to prevent overloads on loud signals. Also, particularly in the recording of music, synchronously driven acetate recordings are often made so that an immediate playback of the recorded material is possible, thus permitting a quick and accurate check on quality.

A block diagram of a typical production-type dialogue channel is shown in Fig. 1. The same type of a channel may be used for recording sound effects or for the recording of

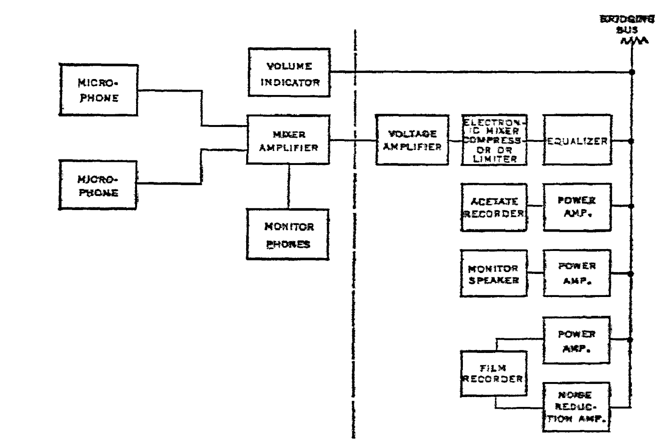

Fig. 1. Simplified Scoring or Dialogue Recording Channel

music, which is usually referred to as scoring. For scoring, however, it is customary to use more microphone inputs than are indicated for a dialogue channel. Since the picture is usually made before the music is recorded, a motion-picture screen is generally provided on a scoring stage so that the orchestra leader can watch the picture while he is directing the orchestra.

In a dialogue channel the microphones are usually located 4 ft or less away from the actors, but out of range of the camera. The microphones are usually mounted on long adjustable booms so that they can be moved to follow the action closely and yet avoid the camera. Microphones of the unidirectional type are used frequently because of their ability to discriminate between the wanted sound from the set and the extraneous noises from other directions.

The sound stage in which the recording channel is used must be constructed to exclude external noises. This frequently involves double wall construction with intervening air spaces and accoustic treatment on the interior to provide the desired reverberation time.

The mixer is located near the set in a position where the operator has an unobstructed view of the action being recorded. This helps him to anticipate changes in mixer adjustment to suit the sound source. Monitoring is accomplished with high-fidelity headphones. The remainder of the recording channel may be located in a small room on the sound stage, in a recording truck parked adjacent to the stage, or in a centrally located building on the studio grounds and connected to the sound stage by suitable transmission lines.

Figure 2 is a block diagram of a typical rerecording channel. It is essential that the console be installed in a room having acoustic properties comparable to those of an average

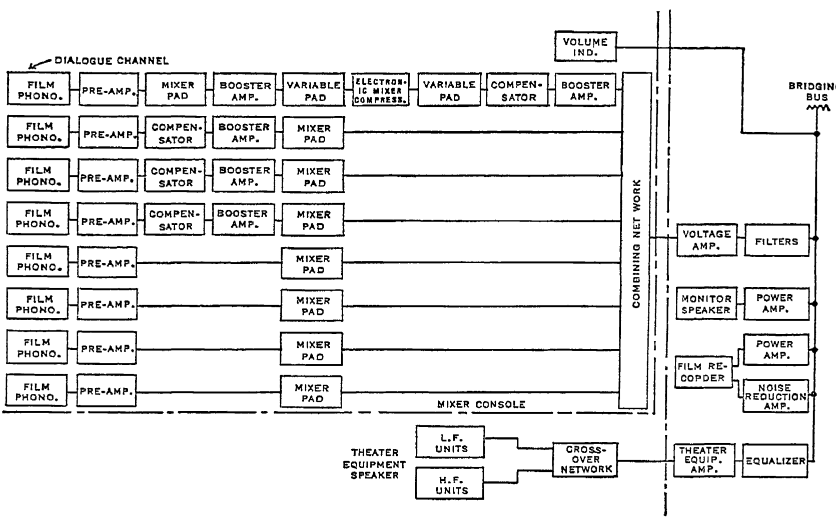

FIG. 2. Simplified Rerecording Channel

theater so that the desired sound quality may be determined through the monitor speaker system as the numerous sources are blended together to make a final sound track.

The various sound sources are usually recorded on separate films in order to provide the desired degree of flexibility. In general, the sound tracks will include dialogue, music, and any number of sound-effect tracks that may be required. These films are threaded in separate film phonographs whose audio outputs are individually controlled by the operator at the mixer console. The threading of the films is indicated by suitable marks so that sound and picture are synchronized. The various film-handling machines are driven by Selsyn motors which provide an electrical interlock during the operating cycle.

During a rehearsal the film phonographs and the projector are run by the Selsyn driving system, and the operator varies the audio signals from the film phonographs to fit the mood of the picture. Several rehearsals are usually required in obtaining the desired effect. Once this has been achieved, the films are rethreaded and another run is made, including the film recording machine. During this run the operator endeavors to repeat the changes in level, etc., that were made during the successful rehearsal. The procedure is repeated, if necessary, until a satisfactory rerecording is made.

During the rerecording process, in addition to changes in level that are made in the incoming signals, changes may also be made in the frequency response to adjust for day-to-day differences in the original recording or to obtain certain special effects such as telephone quality, old phonograph quality, and so forth.

The more progressive studios usually have facilities for the control of reverberation. A reverberation chamber is one means of control. A portion of the sound requiring reverberation is fed into a loudspeaker in the chamber; the sound is picked up by a microphone located in the same room and mixed with the original sound to obtain the desired effect.

A third type of recording channel, the single-film system, is shown in Fig. 3. This channel is generally used in the field for the original recording of newsreels and to a lesser extent for recordings on locations impractical for recording with the more cumbersome production-type channels. As the name implies, this system uses one film on which both the picture is photographed and the sound is recorded.

The more modern equipments use a specially designed camera having in it a mechanically filtered drum on which the light beam from a compact recording optical system can be focused. With some equipments, a conventional camera is used and the sound is recorded directly on the camera sprocket.

The amplifier is designed to have small size, light weight, and low power drain, and the facilities provided are kept to a minimum. Power for the amplifier, exposure lamp, and camera motor are often provided by a single small low-voltage storage battery.

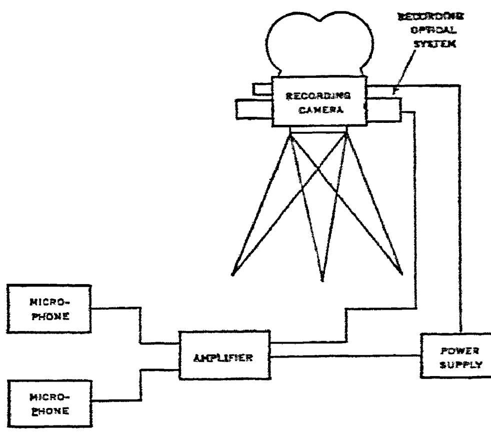

FIG. 3. Single Film Recording Channel

Some newsreel channels use class B pushpull recording since this type of track provides excellent noise reduction by optical means and does not add to the size, weight, or power drain of the equipment. This track requires rerecording to standard track before it can be released to theaters, but since it is always rerecorded to provide sound effects, music, etc., this requirement presents no problem in the production of the newsreels.

Modern recording equipments are capable of producing films having a flat frequency response over a range greater than 30 to 10,000 cycles and a volume range in excess of 50 db. However, in practice it is usually found desirable to restrict the frequency range from about 70 to 7000 cycles and the volume range to approximately 20 to 25 db. This limitation in frequency and volume range is a compromise resulting from the necessity of evolving a technique that provides commercially acceptable sound quality while recognizing the following variable factors: (*a*) reasonable quality tolerances for each of the steps in sound motion picture production, (*b*) the wide variety of conditions under which sound films are reproduced in the many theaters.

12. PROJECTION PRACTICES

By J. D. Phyfe

The sound-reproducing system of a modern motion-picture theater is the combined product of many highly specialized arts and sciences, embracing the fields of optics, acoustics, electronics, and mechanics.

The following description of the major component items of a typical sound-reproducing system will illustrate how these components are combined into a complete system.

The equipment housed in the projection room usually consists of two picture projectors and associated lamp houses, two soundheads which are mounted below the projector mechanisms, and an amplifier system. The projectors and soundheads for all theaters are quite similar, the power output rating of the amplifier and loudspeaker systems being modified to compensate for changes in the seating capacities of various theaters.

The sound-reproducing industry has set progressively higher standards of performance, as exemplified in constant development work fostered by all manufacturers of theater equipment. Tentative standards of reproduction have been established by the Research Council of the Academy of Motion Picture Arts and Sciences.

The film, upon which are photographed both the picture and sound records, must be moved through the mechanism of the soundhead at a constant rate of speed to insure a high quality of sound reproduction free from "wows" or "flutter." These terms denote minute variations in the speed of the film.

Advances have been made in the design of the film-moving mechanism to reduce to a minimum irregularities in speed of the film. Two types of film motion filter are in current use, both employing a film-driven rotating drum coupled to a flywheel. One type,

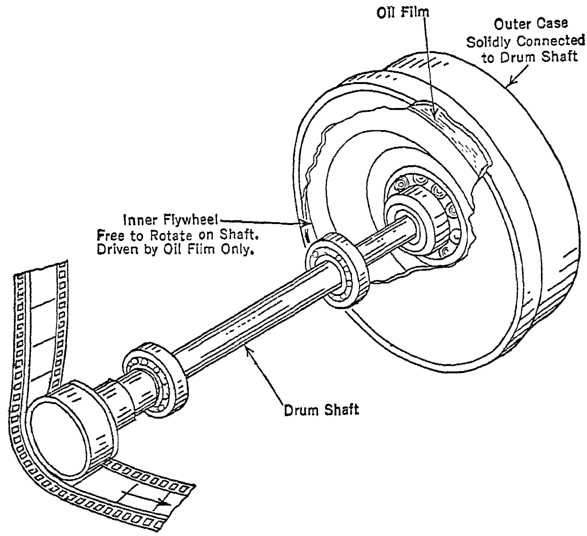

FIG. 4. Soundhead Film Motion Filter (Rotary Stabilizer)

known as the Rotary Stabilizer (see Fig. 4), consists of two flywheels connected by a viscous medium. The other type utilizes a solid flywheel in conjunction with a dampened idler roller for its filtering action.

A picture of a modern soundhead is shown in Fig. 5. The view is of the "operating side" of the unit through which the film passes.

Light from a source termed an "exciter lamp" passes through an optical system where the dimensions of the beam are rigidly defined into a narrow slit 0.00125 in. wide and 0.084 in. long. This slit image is focused upon the sound track of the film, which is moving

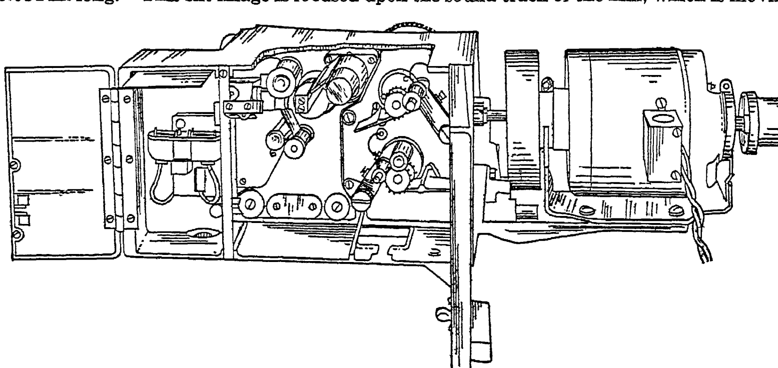

FIG. 5. Operating Side of Modern Soundhead

and presenting a continuously variable ratio of clear film to the dark or exposed area of the film that is being scanned by the light (Fig. 6). The film effectively serves to control the transmission of the light in conformity with the light and dark areas that comprise the sound record. The variation in the transmission of light is translated into a corresponding variation in current by means of a photoelectric cell. (See Section 15, article 7.)

Because the photocell currents are weak, it is necessary to provide a means of amplification; this may consist of a one- or two-stage voltage amplifier. Amplifiers are usually separate units, either incorporated into the soundhead or mounted on the front wall of the projection booth near the soundhead. They may also be placed in the main amplifier rack and coupled to the soundhead by means of transformers or suitable low-capacity coaxial cables.

Further amplification of the photocell voltage is furnished by the main or power amplifier, raising the low-level currents to a satisfactory value where they can be made to operate the theater loudspeaker system.

In order that the projectionist be informed constantly of both the volume level and quality of the sound, a small monitor loudspeaker is installed in the projection room.

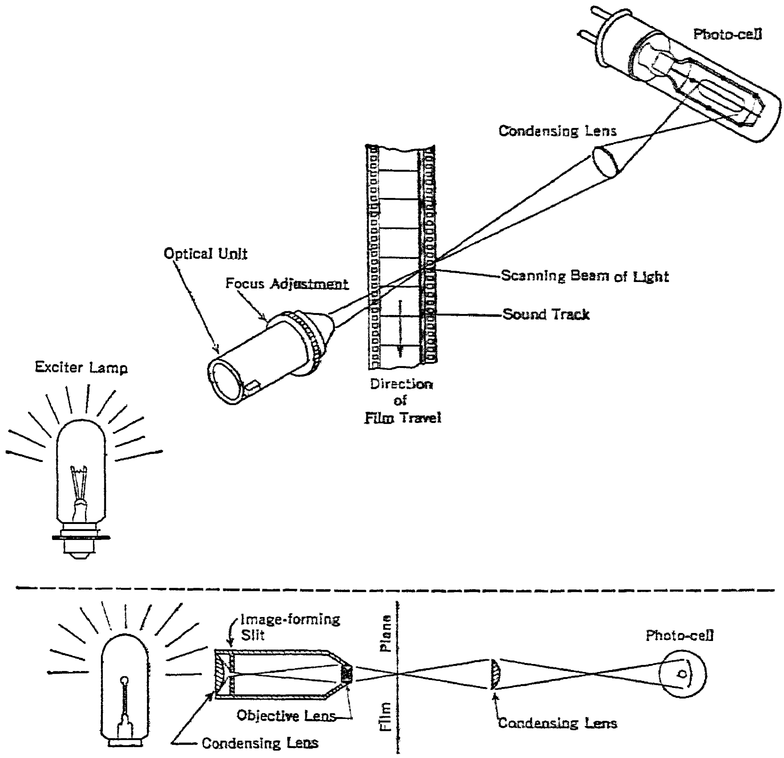

FIG. 6. Optical System of Modern Soundhead

Equalizers are frequently employed to adjust the electrical response characteristics of the amplifier system so as to provide optimum acoustical results in a given theater.

It is common practice to select the output of the desired soundhead by alternate switching of the exciter lamp currents or by selecting the audio output of either soundhead by means of a "change-over switch" or "fader."

The projectionist is notified of the proper time for making the change-over between projection equipments by two small cue marks. These marks will appear in the picture area of the film and are visible on the screen. The cues are placed several seconds apart on the film as it passes through the outgoing projector. The first mark signals the operator to start the motor of the incoming machine. The second cue mark, appearing shortly after the machine has attained full operating speed, marks the point of actual change-over. The picture is switched by an electric dowser actuated by a foot switch operating in synchronization with the sound change-over.

TWO-WAY LOUDSPEAKER SYSTEM. The loudspeakers employed in theater sound reproduction are located behind the picture screen. Small perforations in the screen, not noticeable from the seating area of the theater, permit the sound to pass readily through the screen. A typical two-way loudspeaker system is shown in Fig. 7.

The wide frequency range and the large power-handling requirement of modern theater loudspeaker systems cannot be met by a single speaker mechanism. The result has been the development of the two-way loudspeaker in almost universal use today. For the higher frequencies, a unit having a small light-weight diaphragm coupled to a multicellular

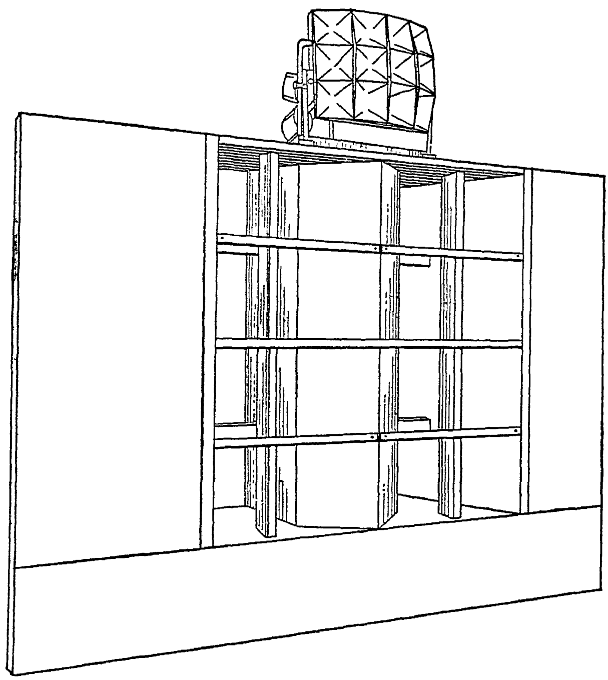

FIG. 7. Two-way Theater Loudspeaker System

directional horn is employed. The low-frequency portion of the signal is assigned to a unit having a larger diaphragm coupled to a very large horn or baffle. The division of the high- and low-frequency components is accomplished electrically through a "cross-over network." The schematic diagram of such a network appears in Fig. 8. The cross-over frequency is in the region of 400 cycles.

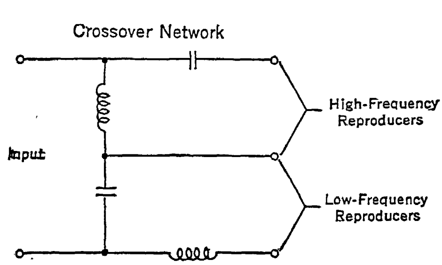

FIG. 8. Schematic Diagram of Crossover Network for Two-way Loudspeaker System

A block schematic of a complete theater sound-reproducing system is shown in Fig. 9. The relative circuit positions of the components covered above may be readily observed.

RECENT DEVELOPMENTS. Recent achievements in motion-picture-sound engineering are the development of the control-track system of reproduction and the drive-in type of theater. The first-named system employs a control track consisting of variations in the area of exposure of the small portion of film lying between adjacent sprocket holes.

The system has been utilized to produce a 96-cycle tone, the frequency being governed by the number of sprocket holes per second passing a small scanning light. The variations in light actuate a separate photoelectric cell as described earlier in this chapter. The photocell current, after amplification, is rectified and used as a control voltage to regulate the output level of the main theater amplifier and to cut into operation an auxiliary loudspeaker system placed at each side of the picture screen. This complete system permits a tremendous volume range not otherwise obtainable and provides a wider source of sound

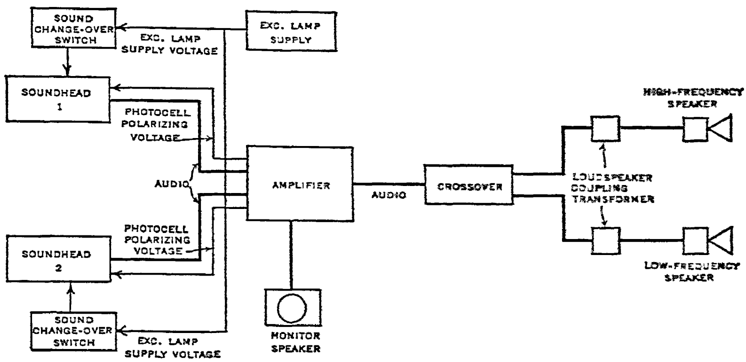

FIG. 9. Overall Block Diagram of Theater Sound-reproducing System

during loud passages than speakers alone placed behind the screen; it heightens the dramatic effect of certain loud passages.

DRIVE-IN THEATERS. The popularity of the drive-in type of theater has increased considerably during the last few years. The picture is shown on a large outdoor screen. The patrons remain seated in their automobiles, which are located in an arc to permit viewing the picture through the windows. The trend is toward the use of individual loudspeakers which may be placed inside the cars.

RADIO TELEPHONE BROADCASTING

By Howard A. Chinn

Radio broadcasting is a means for delivering intelligence for general reception at distant points. A complete system consists of: (*a*) a radio broadcasting transmitting system; (*b*) the medium through which transmission takes place; (*c*) a number of receiving installations.

A radio broadcasting transmitting system consists, essentially, of:

1. A studio, stage, theater, auditorium, or other suitable place for the performance that is to be broadcast. (See article 1, above.)
2. An acoustoelectric device (microphone) actuated by sound energy and delivering electrical energy. (See article 2, above.)
3. Amplifiers for increasing the amplitude of this electrical energy. (See article 3 above.)
4. Control equipment for the regulation and adjustment of this electrical energy. (See articles 3 and 4 above.)
5. Wire lines to carry the electrical replica of the original sound waves from the studio to the radio transmitter.
6. Radio transmitter for converting this electrical energy into radio-frequency energy.
7. Antenna system for radiating the radio-frequency energy into space.

A schematic diagram of a typical broadcast transmitting system, showing the general type of circuit layout employed, is given in Fig. 1. A single studio and a single remote pick-up point are represented, each such point requiring a duplicate of the equipment

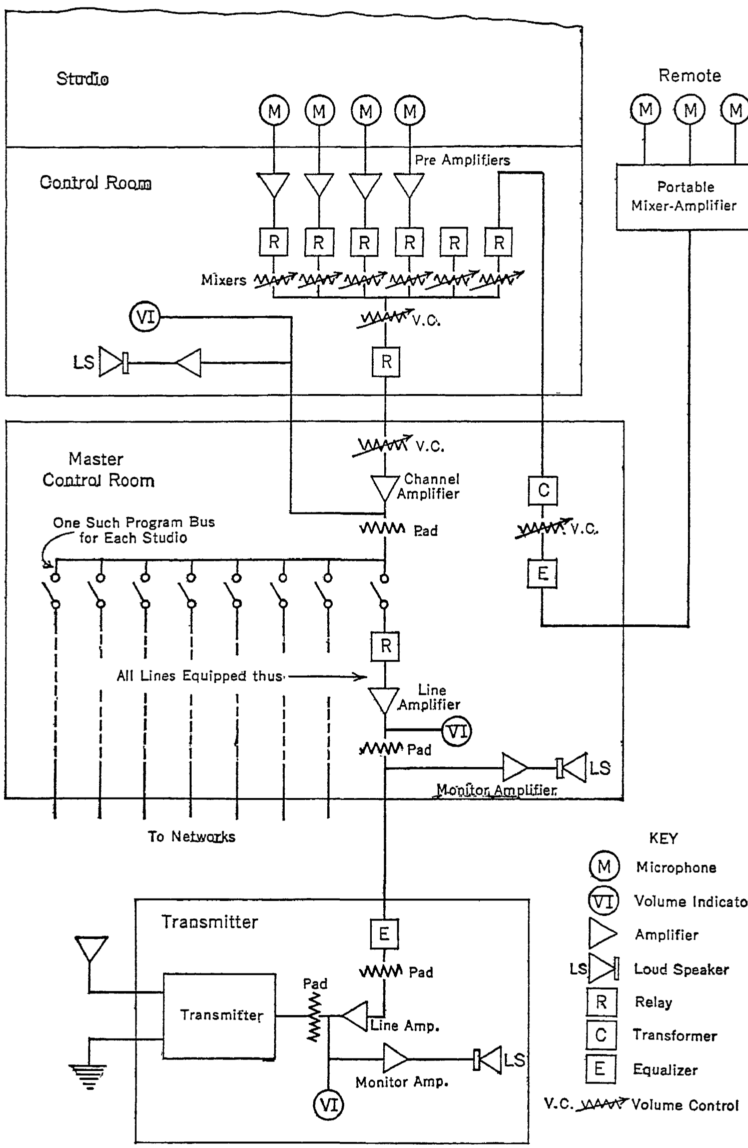

FIG. 1. Broadcasting System Layout

shown, up to and including the relays associated with the outgoing lines to the various networks.

The first four items listed above as parts of a complete broadcasting system have been described in detail in the opening articles of this section, "Audio Facilities for Sound Systems." The remaining items listed are more or less peculiar to broadcasting systems and are covered below.

13. PROGRAM DISTRIBUTION SYSTEMS

NETWORK SWITCHING EQUIPMENT. The key stations of a network of broadcasting stations must provide means whereby the output of any studio may be distributed to any of the networks or combination of networks radiating out from the city in which the key station is located. Frequently different programs, coming from different origination points, are simultaneously sent to the various legs of the network radiating from the key station. In order to accomplish these operations switching means are used which permit the connection of a line amplifier across the program bus of the desired program source.

The facilities for switching are usually such that the proper studio and network line-up may be arranged previous to "air time" but without actually connecting the studios involved to their respective networks until a master switch is operated. Upon the proper cue, or at the proper time, operation of the master switch connects the various studios involved to the right networks. The actual switching is seldom accomplished by manually operating the switches but rather through the medium of conveniently located relays which are remotely controlled from the operating desk.

BRIDGING AMPLIFIER. The purpose of the bridging amplifier is to isolate the outgoing "radio" lines from one another and to provide a means of connecting any number of outgoing lines to any program source, at will, without causing any unbalancing or impedance mismatch of the equipment line-up. If two or more outgoing radio lines feeding different networks, but carrying the same program, were to be connected in parallel and thence to the output of the program amplifier, then, should any noise, ground, or other fault develop on one line, it would affect the operation of the others. By placing a bridging amplifier (which is, of course, a one-way device) in each line, complete isolation is effected and there is no possibility that one line will affect others being fed from the same studio.

The bridging amplifier also permits the connection of any reasonable number of lines to the output of a given studio amplifier without causing an impedance mismatch which would adversely affect the operation of the system. To accomplish this connection, the output of the program amplifier is terminated in a resistance of the proper size, thereby presenting a practically constant load for the amplifier. The input impedance of the bridging amplifier is then made very high and is "bridged" across the desired program bus without appreciably affecting the load impedance being presented to the output of the program amplifier.

A bridging amplifier is associated with each of the outgoing lines leading to a local transmitter or to a network of stations.

14. PROGRAM LINES

Telephone lines are employed for the purpose of transmitting a program from one studio or station to another station. The facilities involved may be divided into two classes: (1) local lines for connecting the studio remote pick-up points, such as athletic fields, theaters, and hotels, and also those lines used for connecting the studios to the local transmitter; (2) long lines interconnecting a network of transmitting stations throughout the country.

LOCAL LINES. When the stations involved are in the same city the line connecting facilities are known as loops. These relatively short lines may, by the employment of proper terminal equipment, be made to have an essentially flat transmission vs. frequency characteristic over the entire range of audio frequencies necessary for high-fidelity broadcast service (see Section 16, article 18). In order to obtain this desirable feature the natural attenuation characteristics of the lines, which for the most part are cable circuits, are modified at the receiving terminals by means of an attenuation equalizer.

LONG LINES. If the stations to be interconnected are in different cities the connecting facilities consist of special telephone lines which are either non-loaded open wire or loaded cable circuits (see Section 17, article 18). Present cable facilities are loaded at intervals slightly in excess of $^1/_2$ mile. Amplifiers, equalizers, and phase correctors are installed at approximately 50-mile intervals on cable circuits and about 125 miles apart on open wire facilities. The cable circuits have automatic regulators installed about every 150 miles in order to keep the loss of the circuit independent of the temperature along the circuit.

Attenuation equalizers are employed on these circuits just as in local lines. Velocity correctors (see Section 5, article 10, and Section 17, article 18) are also necessary to compensate for the natural characteristic of the lines which results in an unequal time delay in the transmission of the various component waves of different frequencies. In circuits less than 500 miles long these devices would not be necessary, but with present circuit requirements of 2000 to 3000 miles they are indispensable.

Long-line facilities are available with overall transmission vs. frequency characteristics that are essentially uniform over the entire audio-frequency range necessary for high-quality broadcasting.

ATTENUATION EQUALIZER. (See also Section 17, Article 18.) An attenuation equalizer is bridged across the receiving terminals of a line in order to modify the natural characteristics of the line so as to provide a circuit having an essentially uniform transmission vs. frequency characteristic over the range of frequencies desired. The device is connected at the receiving end of the line in order to obtain the best ratio of signal-to-noise and interference on the circuit.

An attenuation equalizer is an electrical network which introduces a loss at each frequency such that the sum of the line and equalizer losses is the same for all frequencies over the useful range.

In its most elementary form the equalizer consists of a simple resonant circuit in series with a variable resistance. The frequency of the resonant circuit is selected so that, with the proper value of series resistance, the overall transmission characteristic of the circuit is as uniform as practical.

15. BROADCASTING TRANSMITTER PLANT

A broadcasting transmitting plant consists of audio input equipment, modulator, radio-frequency generator and amplifier, radio-frequency transmission line, antenna tuning equipment, and antenna system.

The audio equipment associated with a transmitter plant provides facilities for such switching operations as are required, microphone and turntable equipment for local program origination in an emergency, and amplifiers for increasing the volume level of the program material received from the line connecting the studios to the transmitter. After being sufficiently amplified the incoming program material passes to the modulator tube which modulates the radio-frequency energy generated and amplified by the equipment supplied for that purpose (see Section 7, article 17; also Section 8, article 4). The resultant modulated radio-frequency energy may either be further amplified or sent directly to the antenna tuning equipment. The antenna is usually located a relatively short distance from the building housing the transmitter, and a radio-frequency transmission line is used to convey the energy from the transmitter to the antenna. The antenna tuning equipment is usually located at the base of the antenna in an appropriate protective shelter.

STANDARD A-M BROADCASTING TRANSMITTING ANTENNAS. (See Section 6, article 31.) For standard broadcasting (amplitude modulation in the 540-1600 kc band), the vertical-radiator antenna is generally used. The use of an antenna having an electrical height slightly in excess of 0.5 wavelength, and operated below the fundamental, results in the largest field intensities on the horizon for a given radiated power. At the optimum point of operation the electric field at the receiver resulting from the ground wave radiated by the antenna may be as much as 40 per cent greater than that obtained from a 0.25-wave antenna radiating the same power. This improvement results from the fact that more energy is radiated along the ground, where it is desired, and less up in the air. It does not follow from this, however, that the maximum coverage is secured by an antenna having this optimum height.

For the low-powered transmitter where the primary range is limited by the field intensity falling below the prevailing interference level, an antenna of the optimum height would probably result in an increased service area. The cost of such a radiator in comparison with the cost of increasing the power of the transmitter sometimes precludes its use, however.

For the high-powered transmitter the primary range is generally limited to that distance where "mushing" results from the admixture of the ground and the sky wave, at this point the strength of the waves being of about the same magnitude. In this case variations in the sky wave brought about by varying the height of the antenna are far more important in determining the primary range of the station than attendant variations in the ground wave. The height that is the best operating point for the greatest ground-wave intensity is not always the best height from the viewpoint of pushing out the incipient fading distance by the reduction of the sky wave. Hence, the best operating condition for maximum primary coverage is not necessarily that height which results in the maximum ground wave. The best height for a given antenna depends upon the attenuation of the ground wave, which in turn depends upon the effective conductivity of the soil, its dielectric constant, and the frequency of operation. In any event the optimum electrical height is likely to be between 0.5 and 0.6 wavelength.

The economical advantage of an antenna of this height depends upon the transmitted power. The initial investment and the cost of operation of the transmitting plant increase with the power, whereas the cost of the radiating structure remains practically constant. At the higher powers this type of radiator represents a good balance between the two investments.

DIRECTIONAL ANTENNAS FOR STANDARD (A-M) BROADCASTING. The application of antenna systems having definite directional properties to broadcasting purposes has been undertaken in a number of instances. Among the circumstances which have led to the installation of a directional system are: the need for suppressing radiation in a particular direction or directions in order to prevent interference with a distant station or stations operating on the same channel; the desire to suppress radiation in a given direction where no audience exists and to reinforce transmission towards the populated area, as for instance in a station located on a seacoast or to one side of a town which constituted its principal audience.

A suitable number of vertical antenna elements properly phased and spaced are usually employed in order to obtain the desired directional characteristic. By the proper combination of these antenna elements and their proper phasing almost any desired directional pattern may be obtained (see Section 6, article 29). Either vertical-wire antennas or towers insulated at their base are used for the antenna elements.

F-M BROADCASTING TRANSMITTER ANTENNAS. For f-m broadcasting (frequency modulation in the 88- to 108-Mc band), a horizontally polarized antenna system is employed. In general the antenna is non-directional in a horizontal plane. However, since most receiving sites are located within a few degrees of the horizon, it is advantageous to utilize an antenna system which directs the radiation towards the horizon. The gain realized by this practice permits the use of lower actual transmitter power for a given "effective" radiated power (effective radiated power is the actual power multiplied by the power gain of the antenna in the direction of the horizon). In practice, the cost of transmitters of various power levels must be balanced against the cost of directional antennas of various gains in determining the optimum combination.

The f-m broadcasting antenna must be located at a point of high elevation in order to reduce to a minimum the shadow effect on propagation of hills and buildings. To provide the best service to an area, a high antenna is usually preferable to a lower one with increased transmitter power.

STANDARD (A-M) BROADCAST STATION TRANSMITTER SITES. The selection of a good site for a standard (a-m) broadcast transmitter is a very complex problem which involves many considerations. The site should be selected with the view to providing:

1. Satisfactory coverage of the area comprising the population it is desired to serve. Usually this consideration will fix the maximum distance from the center of the city that the transmitter can be located.

2. Maximum coverage of adjacent populated areas consistent with fulfilling the above requirement.

3. Minimum population in the area immediately adjacent to the transmitter where the signal is likely to be so strong that special precautions may have to be taken to insure good reception from other stations.

4. Good soil conditions at the transmitter site. The conductivity of the soil within several wavelengths of the antenna has considerable bearing upon the efficiency of the antenna and the nature of its radiation characteristics.

5. Good power and program circuit facilities. If possible, two sources of power coming from different directions should be obtained. In order to obtain better regulation, it is often advisable to obtain power from a high-voltage line and have a local substation installed. Because of their relative immunity from storms, telephone lines in cable should be obtained.

6. Low cost of land. The size of the plot necessary will depend upon the size of the ground system, the spacing of the towers, and the distance between the anchors for the guys.

7. Good publicity value and accessibility. These are good assets for a station but may be overemphasized. Of course, roads leading to the transmitter should be usable in any kind of weather.

8. Immunity from floods, storms, sleet, etc., whenever possible, and ground suitable for good tower foundations. In some instances severe storms are localized in certain areas that can be avoided. Severe storms may cripple power and telephone facilities.

9. Proper location with respect to airports and airways.

10. Proper location with respect to large metal obstructions, buildings, etc.

F-M BROADCAST STATION TRANSMITTER SITES. The selection of a site for a f-m broadcasting station entails considerations somewhat different than those for standard broadcast stations. Many of the differences stem from the quasi-optical nature of the very-high-frequency-wave propagation. The transmitter site should be chosen with these factors in mind:

1. The location should be as near the center of the proposed service area as possible consistent with the availability of a site with sufficient elevation to provide service throughout the area.

2. The location should provide line-of-sight over the principal city or cities to be served. No major obstructions should be in the path.

3. The site should be so situated that the field intensity in the urban area is sufficiently great to provide satisfactory service in spite of the generally higher electrical interference in such areas.

4. Good power and program circuit facilities are required.

5. If the cite is a high building, consideration must be given to the problems of installing the antenna and the transmitter.

6. Cognizance must be taken of the possible hazard of the antenna to aviation.

16. BROADCAST FREQUENCY ALLOCATION

The frequency spectrum now known to the radio art extends over a wide range and includes frequencies having widely different characteristics. This spectrum is occupied not only by broadcasting services but also by other kinds of radio services such as communication with ships and aircraft, police services, and amateur, experimental, transoceanic, and transcontinental point-to-point communication, both telegraph and telephone. Exploratory work is still going on in the higher frequencies at the upper end of the spectrum and is directed in part to determining their usefulness for broadcasting purposes.

The nations of the world have agreed to devote certain portions of the radio-frequency spectrum to broadcasting purposes. The standard a-m (amplitude modulation) broadcast band extends from 540 to 1600 kc per sec and is used generally throughout the world. A band extending from 160 to 265 kc is used in Europe but not in this country for a-m broadcasting. Several narrow bands in the high-frequency spectrum (above 6000 kc) are also in use for long-distance a-m broadcasting services. Finally, a band extending from 88 to 108 Mc is used in this country for f-m (frequency modulation) broadcasting. The wave propagation characteristics of transmissions made in these various bands differ radically (see Section 10, article 24).

STANDARD BROADCASTING. The term "standard broadcasting" is applied to a-m stations operating in the band of frequencies from 540 to 1600 kc. Each station is assigned a particular carrier frequency. On the North American continent the assignable frequencies extend throughout the range in 10-kc intervals. Thus the assignments are 540, 550, 560, etc., up to 1600 kc, making a total of 107 distinct channels.

There are three classes of standard broadcast channels: clear, regional, and local.

A clear channel is one on which the dominant station or stations render service over wide areas and which are cleared of objectional interference within their ground-wave service areas and over all or a substantial portion of their sky-wave service areas.

A regional channel is one on which several stations may operate with powers not in excess of 5 kw. The ground-wave service area of a station operating on any such channel may be limited, as a consequence of interference, to a given field-intensity contour.

A local channel is one on which several stations may operate with powers not in excess of 250 watts. The ground-wave service area of a station operating on any such channel may be limited, as a consequence of interference, to a given field-intensity contour.

By assigning adjacent channels in widely separated areas of the country potential interference is minimized. In any one area it is common practice to separate the channels by approximately 30 kc. This leaves sufficient frequency separation to enable receiving sets to select one channel to the exclusion of all others in that area.

HIGH-FREQUENCY BROADCASTING. By international agreement high-frequency bands have been allocated for broadcasting services in the vicinity of 6, 9, 11, 15, 17, and 21 Mc. Transmissions in these bands are utilized for a purpose and in a manner entirely different from those in the a-m or f-m broadcast bands. High-frequency transmissions are primarily intended for long-distance broadcasts to distant colonial possessions, isolated territories, and overseas broadcasting. This type of service depends entirely upon the sky wave for reception as contrasted to regular broadcast transmissions which utilize the ground wave for primary coverage (see below). High-frequency transmission to distant points is not very satisfactory when reception is obtained with the relatively simple equipment available for the broadcast listener. Magnetic disturbances and atmospheric conditions seriously affect high-frequency transmissions and cause amplitude and selective fading and associated deterioration of tonal quality.

F-M (FREQUENCY MODULATION) BROADCASTING. Frequencies above 30,000 kc are referred to as very high frequencies. These waves are sometimes known as quasi-optical waves because their transmission characteristics resemble, in many respects, those of visible light waves (see Section 10, article 20). As a consequence the service range of a very-high-frequency broadcasting station, even if located on a high point so that the waves travel to the receiving station with a minimum of obstacles in their path, is limited to several tens of miles.

As compared with standard a-m broadcasting frequencies, very high frequencies present several advantages. Interference caused by natural atmospheric disturbances (static) is essentially non-existent, and therefore reception is markedly less dependent on seasonal influences. The service range of the station is more clearly defined and independent of any normal Heaviside layer conditions. The area over which a very-high-frequency station creates interference with other stations on the same or adjacent frequencies is not so great, compared to the useful service area, as in standard broadcasting frequencies. A substantial advantage exists in this respect that is of real assistance in very-high-frequency allocation. The dimensions of the receiving antenna can be small, and directional transmission and reception are relatively easy.

The disadvantages of very-high-frequency waves are inherent in their very nature. The high absorption during propagation limits the service range so that the covering of a large geographical area by this means on an economical basis presents a problem. Because of the quasi-optical character of the very-high-frequency waves there may be propagation shadows and areas of relatively poor reception, particularly near hilly terrain or high buildings.

In this country the band of frequencies from 88 to 108 Mc has been assigned for very-high-frequency broadcasting. The assignable frequencies extend throughout the range in 200-kc intervals. Thus the assignments are 88.1, 88.3, 88.5, etc., up to 107.9 Mc, making a total of 100 distinct channels. Frequency modulation, with a carrier swing of ± 75 kc, is used. The term f-m broadcasting is applied to this class of service.

Currently in this country there are two classes of f-m stations. Those designated as Class A are designed to render service primarily to a community or to a city or town other than the principal city of the area and the surrounding rural area. Class B stations are designed to render service primarily to metropolitan districts or principal cities and surrounding rural area, or to rural areas removed from large centers of population.

17. BROADCASTING STATION SERVICE

STANDARD BROADCAST COVERAGE. In considering the probable service area of a standard broadcast station it is necessary to take into account the effects of both the ground and sky waves which are radiated by the transmitting antenna.

The ground wave (or direct ray) which travels directly over the surface of the earth from the transmitter to the receiver is unaffected in its propagation by meteorological or seasonal conditions and is of the same intensity during both the day and the night. The sky wave (or indirect ray) which traverses the Heaviside layer is subject to a great deal of variation in strength and character before reaching the receiving point (see Section 10, article 24).

The radiated energy which follows close to the earth, called the ground wave, is characterized by: (*a*) high field intensities near the transmitter; (*b*) attenuation to low values within a few tens of miles, depending upon the character of the ground, the power and frequency of the transmitter signal, and the type of transmitting antenna; (*c*) relatively steady values.

The energy which is reflected back from the ionosphere (chiefly evident after sunset), called the sky wave, is characterized by: (*a*) considerable field intensity at distances of hundreds of miles from the transmitter; (*b*) wide variation in field intensity from moment to moment, from night to night, and from year to year; (*c*) considerable variation with latitude of the transmission path and the earth characteristics in the vicinity of the transmitter, and some variation with frequency.

Because of its steady nature and the strong signals obtainable in areas near the transmitter, the preferable service of any station is that obtained from ground waves. The extent of the areas of ground-wave service is determined not only by the transmitter power, by the frequency and type of antenna, and by the ground conductivity in the area, but also by the interference to the desired signal caused by atmospheric noise, man-made noise, other stations on the same or adjacent channels, or, under certain conditions at night, by the fading and distortion caused by a mixture of ground wave and sky wave. Since the intensity of these limiting factors varies widely from moment to moment and from night to night, the area of satisfactory service also varies.

Since the strong steady ground-wave service is in general available only within a relatively short distance of the transmitter, a considerable part of the country lies outside such areas. This is particularly true at night, when strong sky-wave signals from distant stations on the same channel cause considerable interference in many instances and thus reduce the effective service area from its daytime value. At night in these areas use can be made of any interference-free sky-wave signals for service, but, because of its wide variation in intensity and occasional periods of signal distortion, such service is considered in general less desirable than ground-wave service. The extent of the area of satisfactory sky-wave service depends upon the interference to the desired signal caused by atmospheric and man-made noise, other stations on the same and adjacent channels, and under certain conditions by the fading and distortion caused by a mixture of the station's own ground- and sky-wave signals. In view of the wide variation in sky-wave-signal level from night to night, the area in which satisfactory listening can be had on any one night will vary greatly.

The zone in which fading is first encountered is at that distance where the sky wave becomes of such intensity as to interfere with the ground wave. The primary range of the station may be extended either by increasing the strength of the ground wave or by decreasing the strength of the sky wave (see Section 10, article 23). If the receiver is located within the incipient fading distance an increase in transmitting power above the noise level improves reception and increases the primary range. In the fading zone, however, an increase in power beyond that required to produce an average field intensity sufficient to override noise produces no further increase in service area. This is because the strength of the ground wave and that of the sky wave are being increased simultaneously and thus the relationship between them is maintained constant. It is therefore evident that with the low-powered transmitter the primary range is limited by the field intensity falling below the prevailing noise level at the receiving point. With the high-power transmitter the primary range is more likely to be limited by fading and attendant objectionable phenomena since the ground wave will usually be strong enough to override noise out to and beyond the point where fading begins. For detailed calculations of broadcast station range see Section 10, article 24.

F-M BROADCASTING COVERAGE. Although some service may be provided by tropospheric waves, the service area of a f-m broadcasting station is considered to be only that served by the ground wave. The extent of the service area is determined by the point at which the ground wave is no longer of sufficient intensity to provide satisfactory reception. The field intensity necessary for service in city, business, or factory areas is generally considered to be 1000 microvolts per meter. In rural areas, on the other hand, 50 microvolts per meter is generally believed to be sufficient for good reception. These figures are based upon the usual noise levels encountered and upon the absence of interference from other stations.

The ground-wave-signal range of a f-m broadcasting station is a function of the heights of the transmitting and receiving antennas, the gain of the antennas, the transmitter power, the frequency, the ground conductivity, and the dielectric constant. The service area of a f-m station, just like that of standard a-m broadcasting stations, may be accurately calculated by known methods (see Section 10, article 20). A detailed study of the service areas possible with f-m broadcasting stations develops these facts:

1. The service area of approximately half of all United States low-power (100- and 250-watt) standard a-m broadcast stations could be increased by going to frequency modulation.
2. Standard broadcast stations in areas of poor soil conductivity would benefit by a change to frequency modulation.
3. Standard broadcast stations having frequency assignments in the high-frequency end of the band would gain by a change to frequency modulation.

INTERFERENCE TO BROADCAST SERVICE. The strength of the electric field produced at the receiving location depends on many factors such as the power of the transmitting station, the nature and efficiency of the antenna system, the distance involved, the nature of the intervening terrain, and in some cases the time of the day and the season of the year. At a particular receiving location, in addition to the electric field strength produced by the desired broadcast station, other electric fields will exist which may hamper or prevent reception. It is not the absolute electric field strength produced by the desired broadcast station which determines whether reception will be satisfactory; it is the ratio of the desired field strength to the predominating interfering fields, coupled with the ability of the receiving set to discriminate against those interfering fields, which determines the success of the reception.

Interfering fields may arise from atmospheric disturbances (static), from industrial electrical interference, and from stations operating on the same or different channels.

The intensity of the atmospheric noise is not constant throughout the radio-frequency spectrum. At night it varies inversely with the frequency; daytime atmospheric noise varies approximately inversely as the square of the frequency. The magnitude of the noise depends upon the geographical location of the receiving point, the season of the year, and the conditions existing at the receiver.

Industrial electrical interference produced by the operation of non-radio electrical devices is, on the average, inversely proportional to the radio frequency. There are also present within the receiving apparatus, itself, sources of noise that require consideration: resistor noise, tube noise, contact noise, and noise associated with the tube power supply. In general, this receiving-set noise is independent of the radio frequency to which the receiver is tuned.

CONTINUITY OF SERVICE. One of the prime prerequisites for the successful operation of a broadcasting station is the absolute continuity of service throughout the broadcast day. The necessity for such operation arises from the keen competition among the many stations in this country and the psychological reaction of the average listener to an interruption in the program service.

This requirement imposes a severe responsibility upon the equipment and on the maintenance crew of a broadcasting station, inasmuch as the stations at the broadcasting centers and those associated with the major chains operate from 16 to 18 hours continuously every day of the year. In planning a broadcasting station many precautionary measures must be taken and suitable devices must be provided to permit the instant isolation and replacement of any equipment that becomes defective during the course of operation.

18. FIDELITY REQUIREMENTS OF BROADCAST SYSTEM

A high-quality broadcasting system is one which acoustically transports the listener in fancy from his loudspeaker to the studio or auditorium. It must be free from frequency, non-linear, and velocity distortion. It must not introduce extraneous sounds of annoying nature or distracting magnitudes.

TONAL RANGE. Complete freedom from frequency distortion implies that the system should be uniformly responsive over the entire range of audible frequencies. The audible range of the ear depends upon a great many factors (see Section 12, article 2), the extreme limits being in the neighborhood of 16 to 16,000 cycles per second—some 10 octaves. In practice, few persons can hear this extreme range at the listening levels normally used in the home (65–75 db above the acoustical reference level of 10^{-16} watt per cm^2). Furthermore, studies seem to indicate that few care to hear this extreme range when listening to broadcast music.

Several kinds of investigations have been undertaken to obtain data that would be of assistance in determining the optimum tonal range of a practical system. One series of tests was based on the acuity of hearing of the listeners. These experiments were concerned only with the physical ability to hear differences in band width; they disregarded the question of the enjoyment or esthetic appreciation of wider bands. The types of program material included a dance orchestra, two symphony orchestras, male speech, and a dramatic sketch. The observers were engineers who had had extensive experience in tests of program quality and were considerably more critical than the average radio listener. It was found that a change of band width from 15 to 8 kc had to be made to be as readily detected as a change from 8 to 5 kc. These changes, for speech, are just sufficient to have an equal chance of being detected by listeners having experience in such tests.

Changes in band width were found to be about twice as readily detected with music as with speech. Thus, for music, the changes that were just discernible half of the time were found to be 15 to 11 kc, 11 to 8 kc, 8 to 6.5 kc, and 6.5 to 5 kc.

In another kind of test the tonal range preferences of a cross-section of radio broadcast listeners were studied. As contrasted to the studies that have been made to determine the ability to distinguish between different band widths, this undertaking ascertained the tonal range that the average listener considered most pleasant, that is, the method of reproduction the listener would select in his home when listening for enjoyment. Classic and popular music, male and female speech, piano, and mixed voices with sound effects were employed. Every possible precaution was taken during the tests to remove any possibility of factors other than tonal range from influencing the listeners. A noise-free, essentially distortionless system was used, and the reproduction level was adjusted in accordance with the listener's desires.

In these tests the cut-off of both the low and the high frequencies was gradual, in keeping with the type found in actual radio receivers. It was found that listeners preferred a tonal range whose upper frequency limit was down about 3 db at 5000 cycles, about 20 db at 8000 cycles, and about 30 db at 10,000 cycles with respect to the mid-range frequencies. (The experiments did not test the preference for different rates of cut-off but, rather, for different tonal ranges all having cut-offs of about the same rate as the one mentioned.) Most listeners preferred a limited tonal range to a wider one even when told that one condition was representive of "low fidelity" and the other of "high fidelity."

In practice, broadcast transmitting systems are designed to provide uniform transmission over a wide range of frequencies. A-m broadcast transmitters, for example, are capable of covering the audio spectrum from 50 to at least 10,000 cycles, with negligible variations. F-m broadcast transmitters cover a still wider band, extending to at least 15,000 cps. On the other hand, except for a few isolated instances, commercially available receiving sets are not capable of faithfully reproducing anywhere near this range of frequencies.

Intercity network wire facilities having a very uniform frequency characteristic, particularly at the higher frequencies, can be secured, but their general use is a matter of economic consideration. For all practical purposes, the overall frequency-response characteristics of a complete broadcasting system is limited by the wire line characteristics.

The rate at which high-fidelity receiving equipment is put into service will, to a great extent, influence the employment of better wire line facilities between studios and radio stations.

DYNAMIC VOLUME RANGE. The dynamic volume range of a sound source of varying intensity is the ratio of the loudest sound produced to the minimum sound that is distinguishable. In broadcasting and sound recording, the loudest sound intensities are usually experienced with symphonic orchestras or special sounds such as explosions, gunfire, and factory noises (see Section 12). The minimum audible sound intensity is a function of the residual noise level.

As noted above (article 1), the maximum sound intensities encountered in studios is about 95 db for music. Furthermore, it was stated that room noise levels of 25 db are generally considered satisfactory. Thus it is evident that the maximum dynamic range likely to be encountered in original performances is about 70 db (excluding special sounds which may reach any intensity). This is a somewhat wider range (about 10 db) than can be accommodated by most complete sound-reproducing systems. It is considerably wider than the range that listeners prefer.

Very few listening environments are capable of making full use of even a 60-db dynamic range. In the home, for example, the average listening level is between 65 and 70 db above the acoustical reference. The residual noise level, on the other hand, is 43 db in the average residence, and in only 1 per cent of the homes is it as low as 30 db. Thus, even in the quietest suburban homes the noise level is about 40 db below the average listening level and in the average home about 30 db down. However, the source of the noise is not likely to be in the same direction from the listener as the radio receiver. Consequently, the benefits of binaural hearing (article 1, above) will assist the listener in partially disregarding room noise. Nevertheless, at the average listening level, a 60-db dynamic range cannot be fully exploited by the listener even in the quietest homes.

As a corollary to the question of dynamic range, it has been found, by studies in which a cross-section of broadcast listeners participated, that listeners prefer to hear music and speech at about the same *peak* levels (as read by a standard volume indicator, see article 4, above). It was also found that the limit of the range of *peak* volume levels tolerated by the largest number of listeners is approximately 8 db (4 db above and below the average volume level of the program). Even within this 8-db range it appears that changes in volume level are less annoying when made gradually. The 8-db limit refers to the range of *peak* or maximum volume levels, *not* to the range of minimum and maximum sound intensities or "dynamic range." (It is important that this preferred range in *peak* levels not to be confused with dynamic range, which was discussed in the opening paragraphs of this section.)

It was also found that, regardless of the absolute sound intensity at which the listener operates his radio, he still prefers an even peak intensity level. This is true whether he is listening to variety, drama, narrative, or musical programs. The peak intensities of the main program material (but not necessarily background effects) must not fall more than 8 db below the maximum peak level; otherwise the conditions for easy listening are violated.

POLICE RADIO

By H. F. Mickel

Police radio systems may be divided into two major classifications from an operational standpoint. The simplest type of system, designated "one way," permits communication in one direction only, from the headquarters station to mobile units. This type of operation requires a land station transmitter for the headquarters location and a receiver for each mobile unit. The "two-way" system provides communication from the headquarters station to mobile units and from mobile units to headquarters. The equipment required for a two-way system consists essentially of a land station transmitter, one or more land station receivers, and a mobile receiver and transmitter for each two-way vehicle. In certain installations where all equipment is on the same frequency, or where mobile transmitters are equipped for two-frequency operation, a "three-way" system is evolved permitting car-to-car communication in addition to the two-way previously described. Essentially all systems which have been placed in service since 1942 are of the two-way or three-way type.

Police radio systems may also be divided into two major groups on the basis of the kind of equipment used. Prior to 1940, practically all police radio installations employed a-m apparatus. Since that date, the vast majority of systems have made use of f-m equipment. The only activity in the installation of a-m apparatus is confined to the replacement or expansion of existing systems. New systems, almost without exception, are of the f-m variety.

The scope and complexity of police radio systems vary with the requirements of each particular installation. A small municipality may operate a single headquarters station and a small number of mobile units. If conditions at the system control point are not desirable for the local installation and control of the land station, a location providing advantages of increased elevation and improved noise-level conditions may be selected for this equipment. This requires remote-control apparatus at the control point and the interconnection of the control and station locations by means of wire line.

In larger cities where a great number of mobile units and a considerable coverage area are involved, fixed station equipments may be located at several points with individual control from one central dispatching station or from separate precinct control points.

In many cases, individual receivers of the type used in land stations are located at several advantageous points throughout a city with their outputs feeding back to the control station or stations over wire line. This greatly increases the talk-back range of the mobile unit to the fixed station.

State police systems normally involve a multiplicity of land station transmitters and receivers located strategically to cover desired troop or patrol areas.

A number of state and large city systems also incorporate CW telegraph stations for zone and interzone point-to-point communication.

In some instances, radio relay equipment is used for the control of remotely located stations, particularly where topographical conditions necessitate such remote installation of land station equipment and render impractical the use of wire line interconnection to the control station.

19. FREQUENCIES

The first police radio systems operated on frequencies just above the standard broadcast band with channels in two portions of the spectrum (1610 kc–1730 kc and 2326 kc–2490 kc) assigned for this purpose. The general plan was to place state systems in the lower band and city stations on the higher channels. A number of these systems are still in operation, and essentially all apparatus employing these frequencies is for land-station-to-mobile communication. These, doubtless, will be gradually replaced by equipment operating on higher frequencies.

The next portion of the spectrum assigned for police operation was the 30.1–40.1 megacycle band (now 30–50 megacycles). It was found that these frequencies possessed many operational advantages for police work: reduction of interference between stations, reduced atmospheric and man-made interference, lower transmitter power output requirements, and, probably most important of all, the ability to produce practical equipment for mobile talk-back operation. It was in this band that f-m apparatus for mobile communications made its appearance with its many attendant advantages.

During World War II the use of still higher frequencies by the Armed Forces disclosed many characteristics which pointed toward the desirability of their use for police communications systems. Some background of experience gained in the use of 116- to 118-megacycle equipment for relay purposes in police systems, starting about 1940, also gave added weight to this belief. Experimental work encompassing frequencies in the 160-megacycle area revealed very favorable performance characteristics for police use. Accordingly, the Federal Communications Commission has set aside channels in the 152- to 162-megacycle band for the police services. From actual data covering a representative number of systems in normal operation, it appears that sky-wave or "skip" interference, often causing considerable trouble in the 30- to 50-megacycle band, is greatly reduced in the 152- to 162-megacycle frequencies. Smaller antennas are a natural and desirable result of the use of 152- to 162-megacycle channels with the further advantage that high gain and directional antennas for land stations are entirely feasible at these frequencies. Atmospheric and man-made interference is still further reduced as compared to the 30- to 50-megacycle band. Coverage within the normal service area of a 152- to 162-megacycle system is more complete, with fewer dead spots, than with lower frequencies. It appears, also, that still lower transmitter powers will give satisfactory results.

The Federal Communications Commission has also made certain shared assignments for police service in the 72- to 76-megacycle band. Tests conducted on the 30- to 50-megacycle, 72- to 76-megacycle, and the 152- to 162-megacycle bands indicate that the extreme coverage range decreases somewhat as the frequency rises but that improved blanket coverage within the useful range is achieved as the frequency is increased. The 30- to 50-megacycle channels are characterized by a greater degree of "bending" of the transmitted signal and, for that reason, seem better suited for applications where greater coverage distance is required, particularly in hilly or mountainous terrain.

It appears, therefore, that 30- to 50-megacycle channels are best suited for state and county police systems and 152- to 162-megacycle frequencies for municipal use. The Federal Communications Commission has also provided bands for police service in various portions of the spectrum from 450 megacycles to 30,000 megacycles. Complete information regarding all allocations of frequencies for police use may be obtained from the May 6, 1949, issue of the Federal Register or from the new FCC Rules and Regulations, when published.

20. POWER AND RANGE

There is no fixed formula for the absolute determination of coverage which may be expected in a police radio system. Local conditions of terrain, antenna elevation, and noise level are some of the variables that influence such coverage. Transmitter power output is also a factor, particularly in the 1610- to 1730-kc and 2326- to 2490-kc bands. However, in the higher-frequency channels, antenna elevation and noise-level conditions are more influential than transmitter power. Table 1 indicates the normal limit of transmitter power in the various frequency bands (plate power input to final stage).

Since communications range is a function of so many variable factors, actual experience in the planning and installation of police radio systems is the most reliable means of predicting results. A single land station installation will afford satisfactory two-way communication for an average city county, provided that the antenna site is carefully selected from the standpoint of elevation and noise level. Two-way range up to 50 miles with 30- to 50-megacycle equipment is not uncommon with modern apparatus properly installed. A slight decrease in range may be expected with 72- to 76-megacycle and 152- to 162-megacycle equipment.

Table 1

Frequency, megacycles	Land Station Power, watts
1.61–3.0	2000
25–100	500
100–220	600
Above 220	To be specified in authorization

21. EQUIPMENT

Land station transmitting equipment is of conventional design using standard circuits and tubes. F-m equipment is normally of the phase-shift type. The same applies to mobile transmitters.

Land station and mobile receivers are of the superheterodyne variety and are fixed tuned to the assigned operating frequency. Squelch circuits are provided to quiet the receivers when the associated carrier is not on the air.

Crystal control has become standard for all transmitting and receiving equipment designed for police service.

Power for land station equipment is normally obtained from the regular public utility service. Frequently gas-engine generating equipment is provided for emergency operation in the event of failure of the regular power source.

Mobile equipment uses the car battery as the primary power source with either vibrator or dynamotor units for high-voltage d-c supply.

Since vertical polarization has become standard in police service (30 megacycles and up), mobile antennas are of the vertical whip type for either side or roof top mounting. Land station antennas vary somewhat in design but are usually of the J, coaxial, or ground plane type.

SECTION 17

TELEPHONY

BY

JOHN D. TAYLOR

TELEPHONY

By John D. Taylor

TELEPHONY is the art of electrically transmitting speech between two oi more points. Telephone facilities are also used for many other purposes, such as the transmission of broadcasting and public-address programs.

Transmission of speech and other forms of intelligence is accomplished over wire circuits or through the air (radio) or by a combination of both mediums.

The telephone circuit fundamentally consists of a device (transmitter) for transforming speech sounds into electrical currents, which traverse a connecting medium (line or channel) and react in another device (receiver) in such manner as to convert the electrical currents into the original speech sounds.

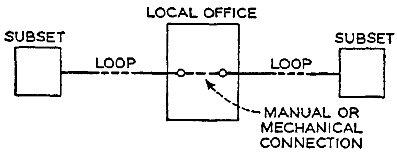

FIG. 1. Connection between Two Subscribers in the Same Office (Courtesy Bell System)

Switching arrangements of various types and capacities, either manual or mechanical,* are necessary to connect local or toll telephone circuits together, and a number of auxiliary circuits, in addition to the talking circuit, may be employed for a given connection, depending upon the types of systems involved and the length of the connection. The interconnection of two subscriber lines (loops) in the same office is usually quite simple, but for lines in widely separated offices the complete interconnecting circuit and associated apparatus may be very complex.

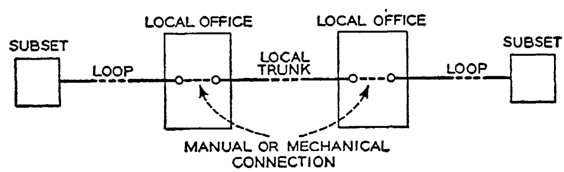

FIG. 2. Connection between Two Subscribers in Different Offices in the Same City (Courtesy Bell System)

Representative types of telephone connections between two subscribers are shown schematically in Figs. 1, 2, 3, and 4.

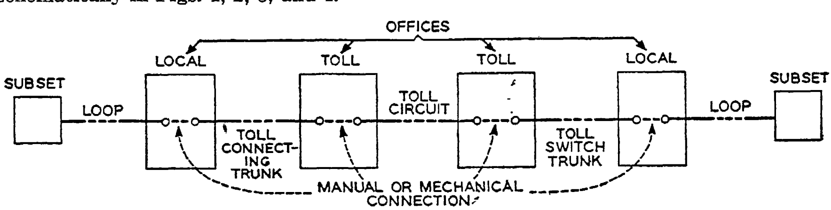

FIG. 3. Connection between Two Subscribers in Different Cities (Courtesy Bell System)

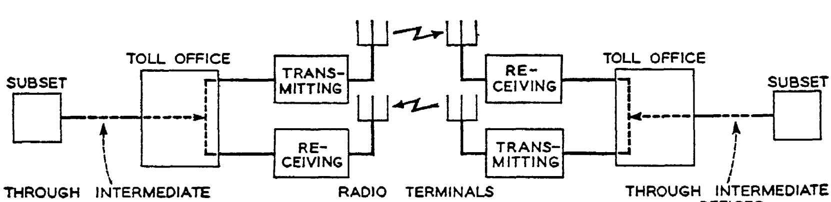

FIG. 4. Connection between Two Subscribers in Different Countries via Radio Channel (Courtesy Bell System)

* The word "mechanical" is used in this section in a broad sense to include all forms of non-manual switching.

In telephone practice the various facilities naturally fall under four main headings: (1) central-office equipment; (2) land and buildings; (3) telephone lines; (4) substation equipment.

CENTRAL-OFFICE EQUIPMENT

Central-office equipment, in general, embraces the various switching arrangements, including auxiliary units of equipment, which are necessary for the interconnection, disconnection, control, and supervision of telephone facilities. Usually, the larger the telephone system, the more intricate are the equipment requirements.

The evolution of telephone service has been from magneto to manual common-battery to mechanical common-battery operation. All these types of operation are now in use, but the trend in present-day engineering is to mechanize telephone service in order to obtain greater speed, ease, and efficiency of operation and to avoid higher operating costs.

Central-office equipment includes all types of switchboards, both manual and mechanical, switch frames and panels, terminating frames and racks, toll terminal equipment, testing units, power plants, and many auxiliary pieces of apparatus. The equipment is housed in suitable buildings, and each entire assembly is known as a central office.

Auxiliary circuits and apparatus, such as alarms and indicators, both visual and aural, designed to call attention to certain operating conditions, monitoring and supervisory circuits, timing and recording devices, emergency power and ringing circuits, test circuits, and many other devices, necessary for the proper operation of central offices, are common to all systems to a greater or less degree, depending on the type and size of system.

1. MANUAL SYSTEMS AND OPERATION

Manual systems include both magneto and common-battery systems, in which telephone operators manually establish and supervise connections at switchboards, using flexible cords or keying units.

Magneto operation, first employed in the United States, requires operation of a magneto or hand generator (associated with magneto telephone sets) by the subscriber to signal the operator for connections and disconnections, and the provision of local battery (dry cells) at each telephone. Present practice also provides for hookswitch signaling (with limitations) by the subscriber on magneto lines, if desired, similar to common-battery operation.

Common-battery operation provides for the subscriber to signal the operator by removing his handset * from or replacing it on the telephone set hook,* direct current for both signaling and talking being supplied to the telephone set from the central-office battery over the subscriber line.

Manual switchboards are of several types and are made by a number of different manufacturers for interconnecting toll, trunk, and subscriber line circuits.

Magneto switchboards employ simple cord and line circuits but, in general, provide the least desirable telephone service from the standpoint of speed and ease of operation. These boards are now built with capacities of up to 200 subscriber lines and are used principally in small offices, where the majority of the terminating lines extend into rural areas and have relatively high energy losses. Even here the present tendency is toward mechanical equipment in new installations and replacements.

Typical full magneto switchboard circuits of the latest type, for a board having a capacity of 150 lines and 15 cord circuits, are shown in Fig. 1.

FULL MAGNETO OPERATION of such a switchboard is as follows:

In placing a call, the subscriber turns the hand generator crank at his telephone, sending 20-cycle current over his line and operating the switchboard drop (or line lamp circuit, if furnished). The subscriber then removes his handset from the hook and listens for the operator to answer. The operator inserts the answering plug of an idle cord circuit in the line jack associated with the operated drop, opens her listening key, and requests the called number. Assuming that this number is also a local subscriber's line in this office, the operator inserts the calling plug (associated with the cord circuit being used) in the called-number line jack and operates her ringing key, using code ringing as may be required, to signal the called station. If ringing power is supplied to the switchboard by a hand generator, the generator crank must also be turned by the operator while operating the ringing key. The called station bell is actuated by the 20-cycle current sent out over

* The word "handset" is intended to include the older-type telephone receiver and the word "hook" to include the newer-type telephone-set cradle.

the line, and the operator awaits the called subscriber's answer with her listening key open; when she hears the subscriber answer she closes her key and disconnects her telephone set from the connection.

On completion of the call both subscribers place their handsets on the hook, the calling subscriber turns his generator crank, operating the answering cord ring-off drop and sig-

(c) Operator's circuit, including monitor, varistor, and grouping key circuits.

naling the operator that the conversation is completed. She then removes the plugs from the line jacks and restores the cord circuit to its idle position.

Central energy (common-battery) type telephones on magneto lines may be made to operate successfully, using a line circuit, as shown in Fig. 2. This circuit provides service to a subscriber in a magneto office similar to common-battery operation, but such service is limited generally to short town lines, not exceeding about 225 ohms conductor loop resistance. The subscriber removes his handset from the hook, sending a surge of direct current through the repeating coil windings (line side), the line, and the telephone set. This surge induces a surge of current in the drop windings of the repeating coil, which are in series with the line drop. The line drop is operated and the call is handled from that point in the same manner as other full magneto calls.

Magneto toll lines are terminated at magneto switchboards in the same type of line circuit, and the operating is similar to that for local circuits. In the local switchboard, two pairs of cord circuits are arranged so that the repeating coil can be removed by operating a key on toll connections, in order to reduce transmission loss, assuming that circuit

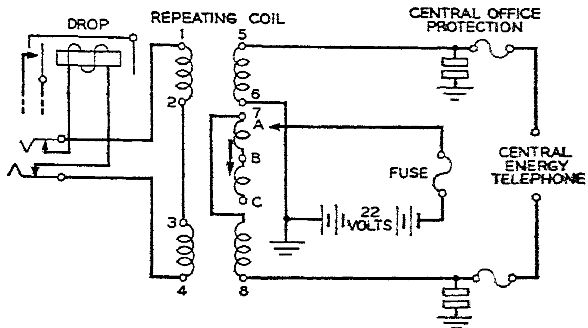

Fig. 2. Magneto Switchboard Subscriber Line Circuit Arranged for Common-battery Signaling and Talking by Subscriber (Courtesy Stromberg-Carlson Co.)

noise is satisfactory without the coil for a particular connection. Figure 3 shows typical loop and simplex dial trunk and cord circuits for use at magneto switchboards, which have trunks to a mechanical office.

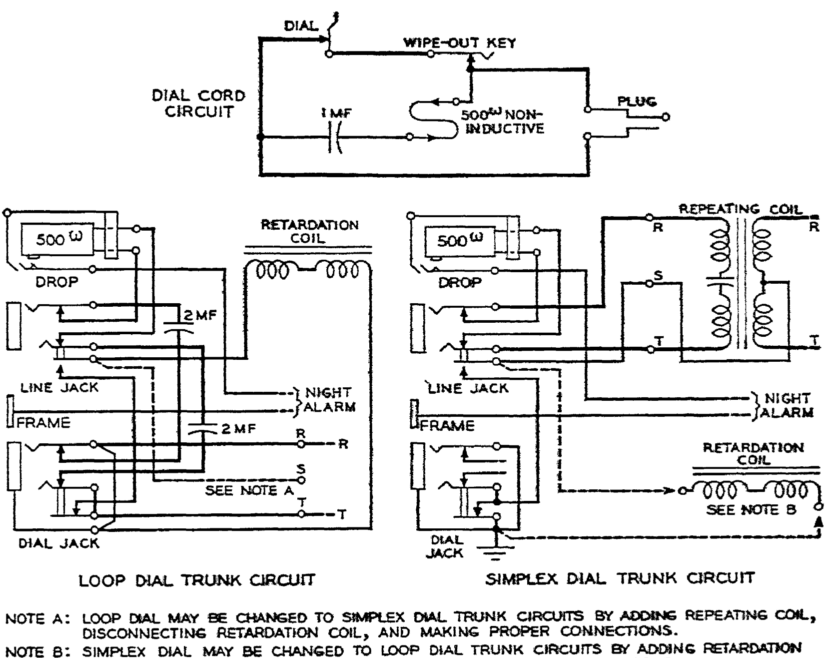

Fig. 3. Magneto Switchboard—Dial Trunk and Cord Circuits (Courtesy Stromberg-Carlson Co.)

COMMON-BATTERY SWITCHBOARDS are made in a variety of types and capacities, both single and multisection (multiple), to meet service requirements and are widely used throughout the United States and foreign countries. The subscriber signals the switchboard operator by operating the hookswitch (or cradleswitch) of his telephone. However, in order to provide this more convenient and faster service, the subscriber switchboard line, cord, and auxiliary circuits are more complex than for magneto equipment.

Single-section common-battery non-multiple switchboards are used principally in the smaller towns, where magneto service is not adequate. In this type of board each subscriber's line appears in the switchboard jack field only once, since one operator can reach

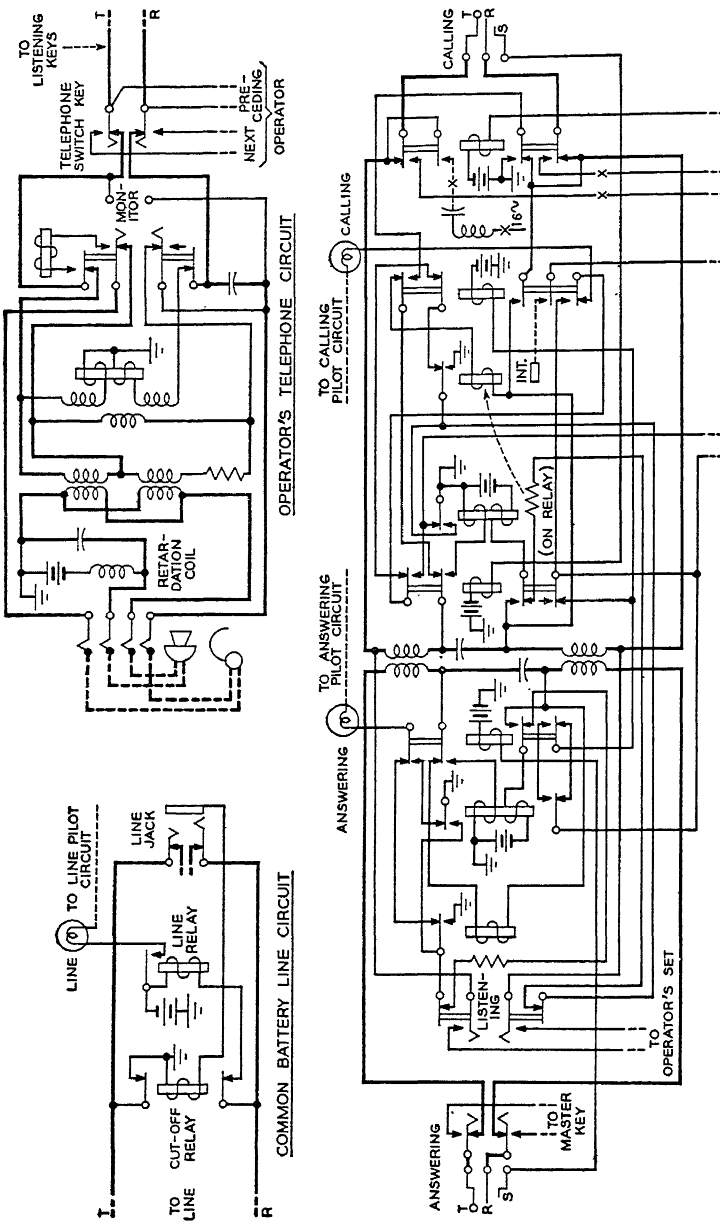

Fig. 4. Single Section Common-battery Switchboard Circuits—Common-battery Talking and Signaling (Courtesy Kellogg Switchboard and Supply Co.)

any jack in the board. Figure 4 shows schematic circuits of a typical board of this type. The capacity of such a board is up to 200 subscriber lines, 30 toll or rural lines, and 16 universal cord circuits. The capacity may be doubled by operating two such boards adjacent to each other.

Multiple common-battery switchboards are designed for single-office and multioffice cities, where single-section boards are inadequate to meet service requirements. The capacities of this type of board range from about 600 to about 10,000 lines, thus limiting the capacity of a single office to about 10,000 lines. For the large cities, requiring more than 10,000 lines, more than one office, each with its own switchboard, is necessary.

Single-office multiple common-battery switchboards are assembled by sections in one or more line-ups, each section being identically equipped with jack fields and cord circuits. The number of sections in an office varies from two to twenty or more, depending upon

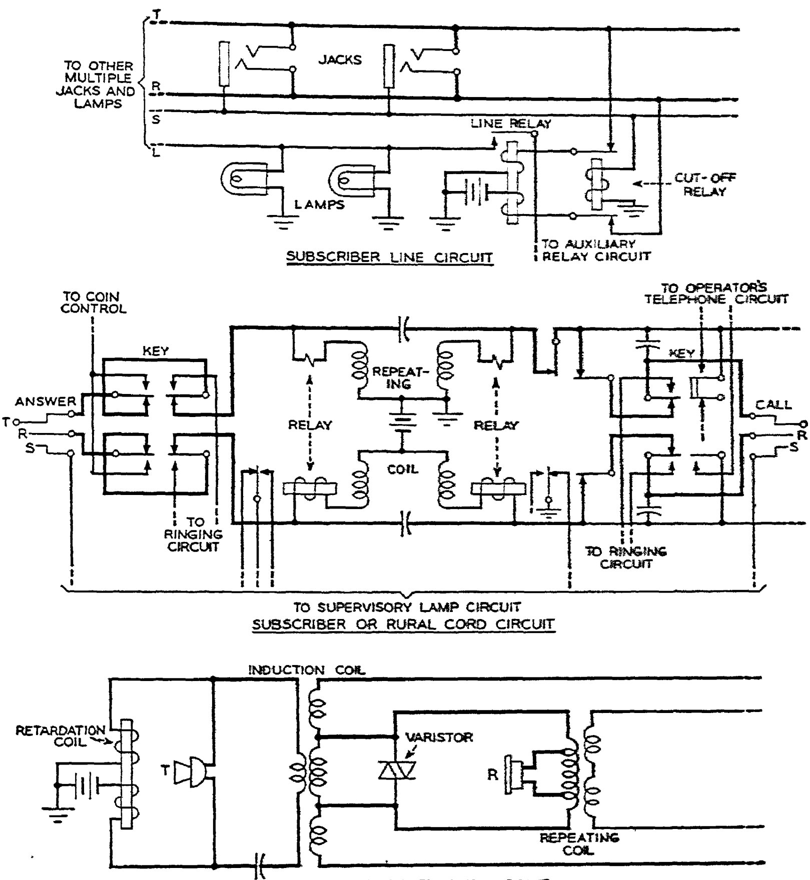

FIG. 5. Multisection Common-battery Switchboard Circuits—4000-line Common-battery Talking and Signaling (Courtesy Bell System)

the number of subscriber lines served and the traffic load. Each section of switchboard provides for from one to two and two-thirds operators and from three to eight panels, in which the multiple jack and lamp strips are mounted. Each subscriber line has one multiple jack with associated line lamp in each section, although in some of the older boards only one answering jack was provided per line. Thus, jack 100 and its associated lamp in the first section in the line-up are cabled to jack 100 and its lamp in the second section, and similarly throughout the board.

Since each subscriber line terminates in the jack and lamp circuit corresponding to his number, when the subscriber signals the operator to place a call all the line lamps associated with his line throughout the board light and may be answered by any available operator, but by only one at a time. When one operator answers a call, all jack sleeves associated with that particular line have potential placed on them, which causes a click in the ear of any operator who touches the tip of her plug to the sleeve of any jack associated with that line. This click warns the operator that the line is busy. The number of line lamps which are permitted to light on any one line is usually limited to five but may be less, depending on traffic loads and calling rates. Figure 5 shows the principal schematic circuits for a typical multiple common-battery switchboard with a capacity of 4000 subscriber lines, 360 toll lines or 720 outgoing trunks, and 17 cord circuits per position.

The provision of a trunking board and special arrangements of subscriber multiple in the various line-ups makes it possible to increase the capacity of the board to accommodate up to 5600, 7200, or 10,400 subscriber lines and to provide for a substantial complement of toll lines and trunks. However, when new central-office installations or sizable additions to existing manual boards are being considered, present practices require a careful study to determine the practicability and economies of employing mechanical operation, because of its many advantages, including integration with the general trend toward universal mechanized telephone service.

This board is capable of operating as a combined local and toll, local and trunk, or local, toll, and trunk board.

Multioffice multiple common-battery switchboards of modern design are similar to the single-office multiple board described above. Some of the older-type subscriber switchboards did not provide for multipling the line lamp as well as the multiple jack, so that the subscriber's lamp signal had only one appearance in the entire switchboard and answering time was considerably slower than with the multiple-line lamp arrangement.

INTEROFFICE TRUNKS are necessary in multioffice exchange areas to provide for extending a call from one office to another. In manual operation the calling-subscriber signal appears at the calling-subscriber switchboard (designated in trunking as the A board), the operator ascertains the called number and, either by the call circuit or straightforward trunking method, passes the called number to a terminating trunk board (designated in trunking as the B board) at the called office. An intermediate office (tandem) may be involved in establishing the trunk connection. The A operator connects the calling line to the selected outgoing trunk at the A board, the B operator at the called office connects the B end of the interconnecting AB trunk to the called B board multiple jack, and the ringing of the called subscriber automatically starts. The cycle of ringing usually consists of a 2-sec ringing interval followed by a 4-sec silent interval with d-c potential only impressed on the line. This cycle is repeated until the subscriber answers or the connection is taken down. When the subscriber answers in either the ringing or silent interval, relays in the B trunk circuit operate, disconnecting the ringing power and connecting the trunk circuit talking path through to the called subscriber. Upon completion of the conversation, a lamp disconnect signal appears before both A and B operators, in response to both the calling and called subscribers hanging up their handsets, and the connection is taken down.

Call circuit trunking is a procedure by which the A or toll operator passes a call to a B (or tandem) operator over a call (order wire) circuit, which is entirely separate from the trunk circuit being used for the call. When the A operator presses her call circuit key associated with the call circuit to the desired B (or tandem) office, she is connected directly to the distant operator's telephone set. After she passes the call to the distant operator, the distant operator assigns an idle trunk in the group between the two offices and the A and distant operators connect the trunk to the calling and called lines at their respective boards.

Straightforward trunking is now the generally accepted method in manual operation rather than the call circuit method, from which it differs in that the A operator selects the idle trunk to the called office. She then connects the calling subscriber to the trunk with an A cord circuit, causing a lamp to light at the distant operator's position. The distant operator connects her telephone set to the trunk by pressing a key, or the set is automatically connected and the A operator is so informed by hearing a two-tone signal on the trunk. The call is passed and the connection is established, and during the conversation the supervisory lamps at both A and B boards remain dark. When the subscribers hang up their handsets these lamps light and the operators disconnect.

2. MECHANICAL SYSTEMS AND OPERATION

Of the several types of mechanical switching systems now in operation, probably the Strowger (step-by-step) system, manufactured by the Automatic Electric Co. (and others under Automatic Co. patents) is most widely known. It was the first type employed commercially (in the year 1892) and is still used extensively today. Other well-known mechanical systems have been developed to meet the needs of the rapidly growing telephone industry, particularly the Relaydial (Stromberg-Carlson), Relaymatic (Kellogg Switchboard and Supply Co.), All-Relay (North Electric Manufacturing Co.), Panel Dial, and Crossbar

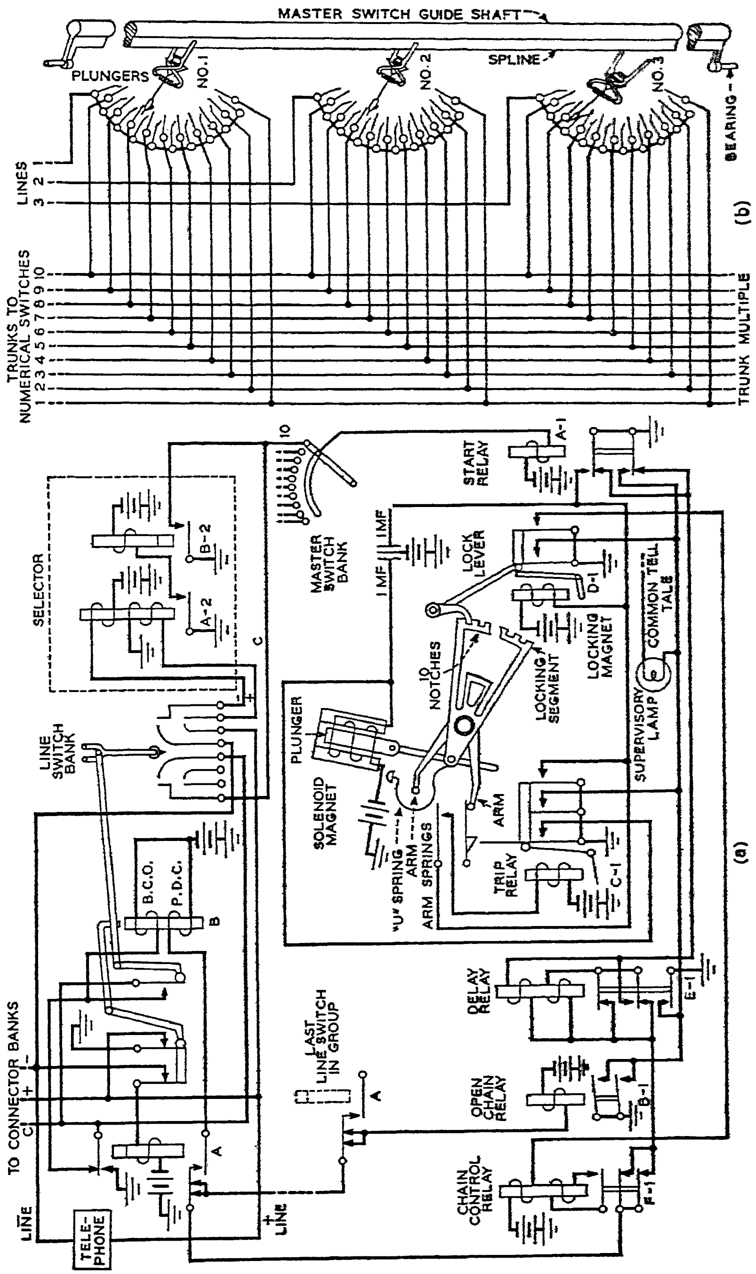

FIG. 6. Schematic Diagrams Showing (a) Self-aligning Line and Master Switch Circuit and (b) Relation between Plunger-type Line Switches and Trunks (Courtesy Automatic Electric Co.)

Systems (Western Electric Co.). All these systems have only one purpose, namely, to switch traffic quickly, accurately, economically, and in a manner satisfactory to the public, whether it be in a relatively small office or in the largest multioffice exchange area.

THE STROWGER SYSTEM employs the well-known step-by-step method of operation, so called because calls are advanced from the calling to the called subscriber step by step, as each digit of the called number is dialed by the calling subscriber.

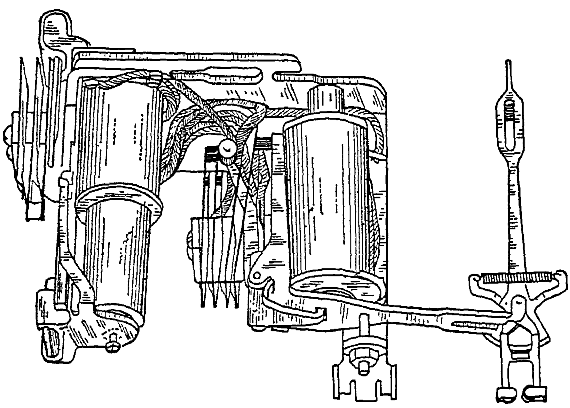

FIG. 7. Self-aligning Plunger Line Switch (Courtesy Automatic Electric Co.)

In step-by-step operation, the principal switching units involved in a connection between two local subscribers are a line switch or line finder, one or several ranks of selectors, and a connector. In addition, if the connection includes a trunk between two offices in the same exchange area, the outgoing end of the trunk will terminate in an impulse repeater.

The equipment which appears between the subscriber's line terminals and the first rank of selectors is classed as *non-numerical*, since it automatically functions as soon as the subscriber's handset is removed from its support and before any digits are dialed. Non-numerical switches are of two major classes—line switches and line finders. The line switch is individual to a telephone line and serves to extend the calling line to an idle selector or connector (forward selection), while a line finder is connected permanently to a selector or connector and serves to find the calling line (backward selection). Line switches are now seldom employed for public exchanges but are generally standard for private automatic exchanges of 100 lines or less.

The line switch may be of two types, *plunger* (10-trunk capacity) and *rotary* (10- or 25-trunk capacity).

The plunger line switch is a simple mechanism which automatically connects its calling line to any one of a number of trunks leading to *numerical* switches (the selector or connector, which are operated by dial pulses). Figure 6 shows a schematic diagram of the self-aligning plunger line switch and master switch circuit and of the wiring arrangement between trunks and line switches. Though only three line switches are shown in this latter arrangement, there may be from 25 to 100 such switches in one group. Figures 7 and 8 show views of the line and master switches.

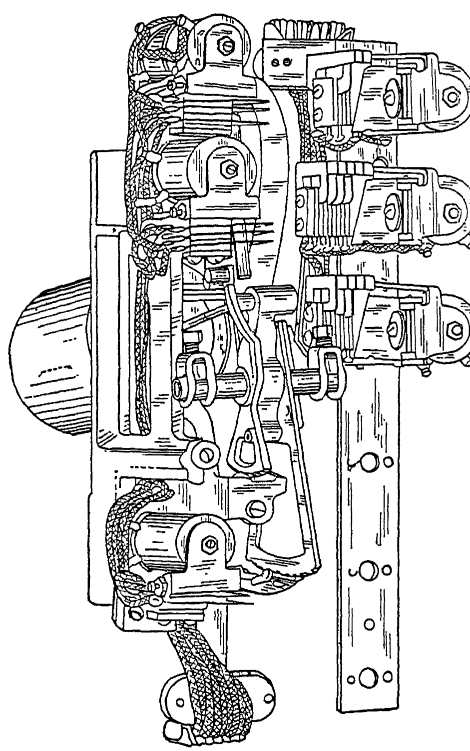

FIG. 8. Master Switch Associated with Self-aligning Plunger Line Switch (Courtesy Automatic Electric Co.)

When the handset is lifted at the telephone, the plunger is thrust into the line switch bank by operation of the A and B relays, closing the line and trunk spring contacts and extending the line through to the selector. The operation of the selector relays maintains the B relay and its plunger operated until the connection is released, the relays then returning to normal. Operation of the plunger starts operation of the master switch circuit, resulting in the moving of all idle line switch plungers opposite the next idle trunk. The self-aligning feature of the plunger reseats it on the master switch guide bar as soon as it is released. The connector bank terminal associated with the line is also made busy by the selector placing ground on the control lead.

The rotary line switch is a single-motion device, which may be associated with a telephone line for the purpose of extending the line to any one of a number of idle trunks. This switch has a shaft carrying wipers, which slide over bank contacts (arranged in a half circle) to which trunks to the numerical switches are connected. When the line and cut-off relays are energized by lifting the handset, the switch's driving magnet operates its

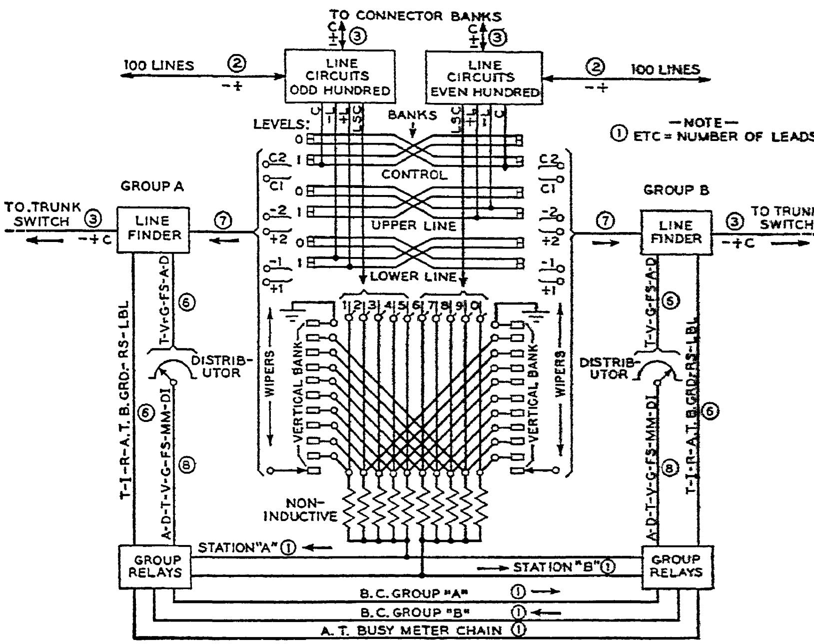

FIG. 9. Schematic Diagram of the 200 Line Finder Circuit (Courtesy Bell System)

armature against the action of a flat spring. At the end of the armature stroke the magnet circuit is opened, the spring forces the armature back, and the wipers are carried forward one step into the bank. This action continues until the wipers reach idle trunk contacts, where they remain until the next call is originated, when the wipers are moved to the next idle trunk. It is usually necessary to extend connections by means of wipers and bank contacts for several conductors which perform signal or control functions in addition to extension of the transmission path. Thus, each position of the wipers in the bank has from three to six or more bank contacts, which are simultaneously contacted by separate wipers when the selection is made. This type of switch is seldom used as a subscriber line switch since the plunger type is cheaper, but both operate satisfactorily.

Secondary line switches, rotary or plunger type, are now seldom used but were designed for larger step-by-step offices to combine the traffic from a number of primary groups of subscriber line switches and direct it to a relatively large common group of numerical switches capable of handling the combined traffic. Small trunk groups are less efficient than large trunk groups, and by employing secondary line switches the number of selectors required for the main trunk group need be only large enough to accommodate the peak load of the combined group instead of each small group requiring enough selectors to accommodate its own peak load, which usually will not occur at the same time as the peak loads of the other small groups.

The line finder switch seeks out the calling line from a group of subscriber lines connected to bank contacts and connects it to a trunk terminating in the first numerical switch of the switch train. The line finder switch permits the use of a simple, economical subscriber line circuit composed principally of a line and a cutoff relay comparable to those in common-battery manual systems. These relays function to *mark* the bank position of the calling line and to cause the allotted line finder to hunt the calling line.

As soon as the bank position of a calling line is marked by operation of the line relays, a relay of a common relay group (associated with each group of line finders) causes the proper line finder to hunt, first vertically and then horizontally, until the calling line is located, whereupon the finder connects its permanently associated first selector (or connector) to the calling line through the finder wipers and the bank contacts. The cutoff relay of the line circuit then operates to clear the line of unnecessary attachments and to free the common group of relays.

A number of line finders are grouped under the control of a single *distributor*, which preselects or allots the next line finder to be used in the next call as soon as the common relay group is released from the preceding call.

Line finder switches are of the two-motion (vertical and horizontal) type and usually have capacities for 50, 100, or 200 lines. In some small exchanges, line finders may be of the rotary (single-motion) type with capacities of 25 or 50 lines.

Figure 9 shows diagrammatically the switching arrangement between subscriber lines and trunks, and Fig. 10 a view of a line finder switch, for 200-line capacity. This switch has a group of relays mounted on a base, upon which is also mounted a frame supporting a shaft with ratchet mechanism for raising and rotating the shaft. The lower part of the shaft carries four sets of wipers (one single-conductor and three two-conductor), termed the *vertical, control* (upper bank), *upper line* (middle bank), and *lower line* (lower bank). The vertical and rotary stepping magnets and the release magnet (which permits the shaft to return to normal when the connection is released) are mounted within the switch frame.

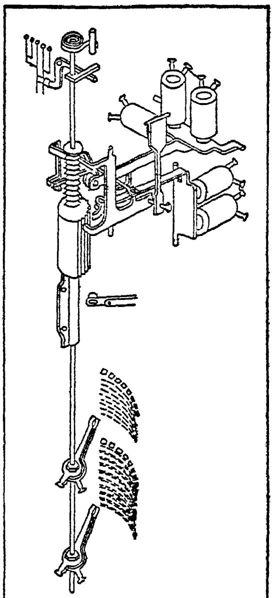

FIG. 10. Line Finder Switch for 200 Lines—Strowger System. (Courtesy Automatic Electric Co.)

A vertical interrupter (pulsing) circuit causes the vertical magnet (by its armature and pawl engaging the "vertical hub" ratchet) to elevate the shaft step by step to the marked level. A rotary interrupter circuit then causes the rotary magnet (by its armature and pawl engaging the "rotary hub" ratchet) to rotate the shaft step by step, until the marked control bank contact is engaged by the control wiper.

These motions cause the control, upper line, and lower line wipers to engage the corresponding contacts of their semicylindrical banks, each of which has 100 sets of contacts (10 levels and 10 sets per level). To the right of these banks is the vertical bank or commutator, comprising a single row of contacts, over which the vertical wiper moves until the marked level of the calling line is reached.

The release of the shaft is effected by the operation of the release magnet, which disengages the vertical, rotary, and stationary dogs from their ratchets, permitting the shaft to return to normal under spring and gravity action.

The impulse repeater is used in interoffice trunks in step-by-step exchange areas having more than one office. This repeater is required in the outgoing end of each trunk and functions (1) to make it unnecessary to provide a third (control) wire in each trunk, (2) to provide talking current to the calling subscriber, (3) to reverse battery to the calling subscriber when the called subscriber answers, and (4) to repeat dial pulses over the interoffice trunk so that the impulse circuit will not include both the subscriber's line and the interoffice trunk.

The two types of impulse repeaters are one-way and two-way. The first type is used at one end of one-way interoffice trunks; the second, at both ends of two-way interoffice trunks.

A diagram of the one-way impulse repeater circuit is shown in Fig. 11.

When the repeater is seized by the preceding switch, the A and B relays operate, and the B relay connects ground to the control lead C, to protect and hold the preceding switches in the train and avoid seizure by other switches. Relay B also operates relays A-1 and B-1 in the incoming selector at the distant office, establishing an impulse loop over the trunk. Relay A, responding to impulses from the calling subscriber dial, interrupts the impulse loop, according to the impulses received, thereby repeating these impulses over the loop.

When the called subscriber answers, operation of the back-bridge relay of the connector at the called office reverses the polarity of the current through the holding bridge (relay F) of the repeater at the calling office, causing relay F to operate. The operation of relay F causes relay D of the repeater to operate, which reverses the polarity of the current flow to the calling telephone, for the purpose of operating coin-collectors or message registers or of providing supervision of manual calls.

When the handset at the calling telephone is placed on its support, the relays release and the train of switches is restored to normal.

The selector is a switching device which became necessary for offices of over 100 lines. In a 1000-terminal system, only a single rank of selectors (first) is required, the first digit dialed operating the selector switch to connect to the desired hundred group of connectors.

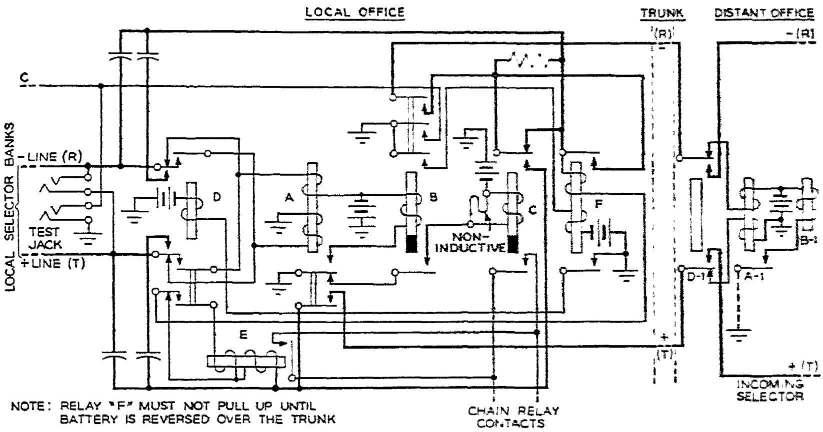

Fig. 11. One-way Impulse Repeater Circuit—Strowger System (Courtesy Automatic Electric Co.)

In a 10,000-terminal system, two ranks of selectors (first and second) are required. The first digit dialed operates the first selector to select the thousand group of trunks which terminate in second selectors, and the second digit dialed operates the second selector to select the desired hundred group of connectors. Thus, the selector is a numerical type of group-selecting, trunk-hunting two-motion switch, which requires but one digit for its operation.

Figure 12 shows a schematic diagram of the selector circuit. The selector has a group of control relays mounted on a base, which also supports a shaft and ratchet mechanism assembly for raising and rotating the shaft. The lower part of the shaft carries two sets of wipers, *control* (upper) and *line* (lower). The vertical and rotary (stepping) magnets and the release magnet are mounted within the switch frame. The bank contacts are in two groups of 100 sets of contacts each (10 levels and 10 sets per level).

When the selector is seized, it functions to hold all preceding switches in the train operated and guarded until the holding circuit is extended. It sends back dial tone to the calling subscriber if it is a first selector. It elevates the shaft and wipers in response to dial pulses and rotates them automatically to connect with an idle trunk in the selected bank level. It provides a busy signal to the calling subscriber when all trunks in the desired group are busy. The selector is returned to normal, when the calling subscriber places his handset on its support, by functioning of the control circuit and the release magnet of the selector.

The connector is a two-motion switch, similar to the selector, and, regardless of the size of the office, it is always employed as the final unit of step-by-step switch trains.

This switch operates in response to the last two digits dialed of the called number (directory listing). The first of these two digits is the "tens" and the last one the "units" digit. The only exceptions to this general principle are the 200-line connector and the frequency or code-selecting, party-line connectors, where a digit preceding or succeeding the "tens" and "units" digits is dialed for line group or ringing selection.

Figure 13 shows a schematic diagram of the connector circuit. The connector has a group of control relays mounted on a base, which also supports the shaft and ratchet

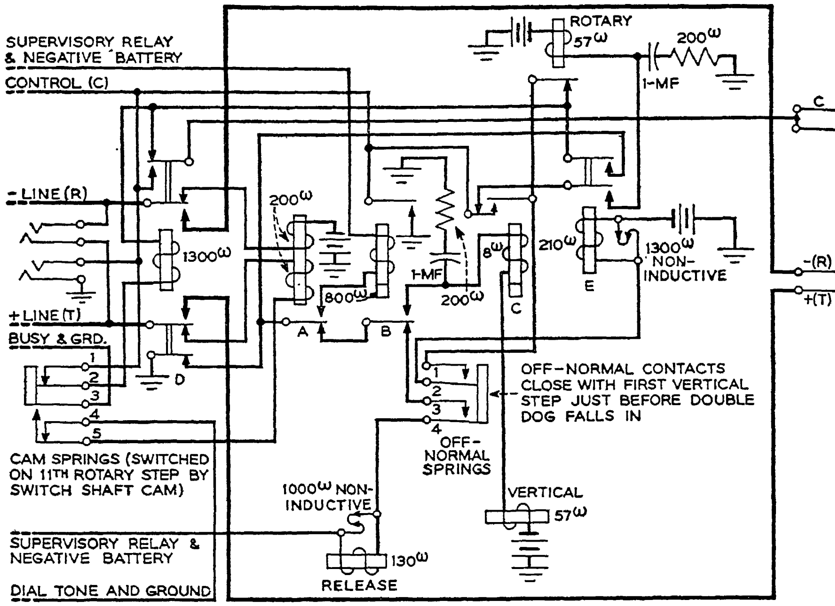

Fig. 12. Selector Circuit—Strowger System (Courtesy Automatic Electric Co.)

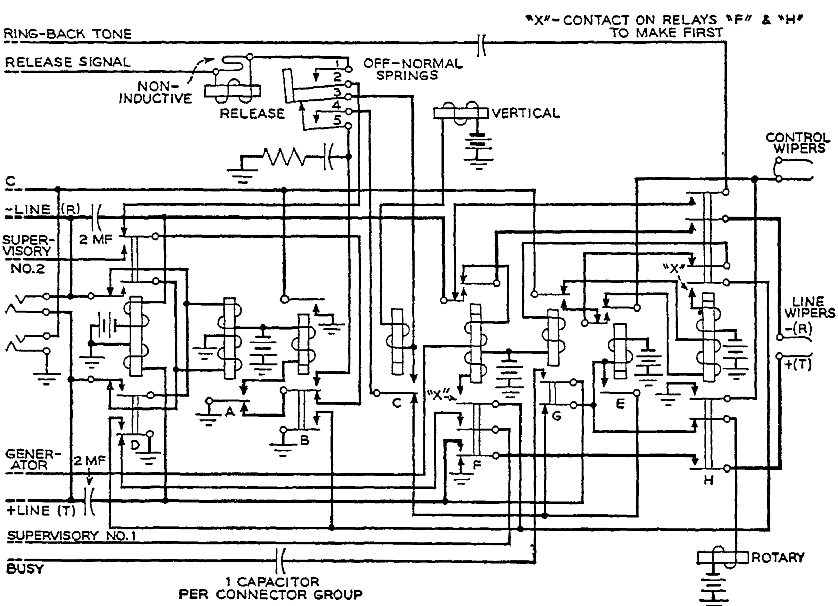

Fig. 13. Connector Circuit—Strowger System (Courtesy Automatic Electric Co.)

mechanism assembly for raising and rotating the shaft, step by step. The lower part of the shaft carries two sets of wipers, the *control* (upper) and *line* (lower), which engage respective semicircular banks of contacts of 100 sets each (10 levels and 10 sets per level). The vertical and rotary stepping magnets and the release magnet are mounted within the switch frame. One subscriber line is connected to each set of lower line bank contacts.

The pulses of the first digit received (except as mentioned above) step the shaft and wipers vertically as many levels as there are pulses. The pulses of the last digit received step the shaft and wipers horizontally, in accordance with the number of pulses received. This desired position of the shaft assembly is held by two movable detents, termed the "double-dog," and a stationary dog.

The release of the shaft is under the control of the release magnet, which, in operating, disengages the dogs, allowing the shaft assembly to return to normal.

The director system was originated and developed by Automatic Electric Co. for large and complex trunking networks of the Strowger system. Though not used in the United States to date, it has extensive application in Great Britain, particularly in the London metropolitan area. It is being considered in the Los Angeles area for certain S × S offices to meet extended service and automatic toll ticketing problems. The director is expected to play an important part in nationwide toll dialing, requiring register-sender equipment.

The director, itself, consists of standard A. E. Co. relays and switches, which store the subscriber dial pulses and perform various other functions. A director for simple functions occupies the space of two regular switches, but, being very flexible in design, it may be of various sizes for specific needs. Wherever used, this unit usually effects savings in selectors, repeaters, and floor space. It can be added to existing S × S equipments as desired.

In operation, an idle director is selected by a director finder and attached to a line finder-first selector trunk as soon as the line finder seizes the calling line. The director then functions as an "electrical brain" to:

1. Record the number (pulses) dialed by the subscriber.
2. Analyze the office code digits received and immediately determine the best routing for the call.
3. Substitute, if necessary, other routing digits, which may differ entirely from the received digits. This is known as translation, which permits automatically selected alternative routings with resulting trunk savings.
4. Send out pulses, corresponding to the routing code, which operate switches, as though operated by the subscriber dial.
5. Store the remaining digits, dialed by the subscriber, usually without translation, and send out corresponding pulses just after the routing code is sent.
6. Detach itself from the connection upon completion of operation 5 and await the next call.

The toll switch train, consisting of a toll transmission selector, a toll intermediate selector, and a combination toll and local connector, is designed to complete toll calls directly from the toll board to the subscriber. The *toll transmission selector* provides increased talking current to the called subscriber telephone through repeating coil windings and has increased capacity in the talking circuit. It also provides for complete supervision of the connection at the toll board, and it repeats the dial pulses from the toll operator dial through to the toll intermediate selector and the toll connector. It has a 400-point bank, required for additional functions. The *toll intermediate selector* is similar to the regular selector except that it also has a 400-point bank. The *combination connector* is not used for local calls unless all the regular connectors are in use.

Main distributing frames (MDF) and intermediate distributing frames (IDF) provide a means for properly terminating the outside cables, which carry subscriber lines and various types of trunks and toll circuits, and equipment within the office, and cross-connecting these various circuits and equipments as required.

Multipling of trunks and of switching equipment is so arranged as to provide maximum access to switches from subscriber lines and from switches to lines, and efficient operation of trunking and other equipment.

Figure 14 shows a schematic diagram of a trunk layout for a 100,000-line multioffice exchange. It will be noted that secondary line switches are employed between the primary line switches and first selectors and between the first selectors and impulse repeaters, the object being to concentrate the traffic loads in these sections and reduce to a minimum the number of first selectors and repeaters required. All manual board services are centralized at one office for efficient operation. A special switch train is provided to reduce wrong numbers which may result from careless removal of a handset or accidental jiggling of the cradle plunger switch. This equipment is not always warranted.

The *U* suboffice represents a telephone center of light load, located rather remotely from the other offices. Traffic does not justify a separate group of trunks to each of the other offices, so that the office is made tributary to office *U*. To reach a subscriber in the

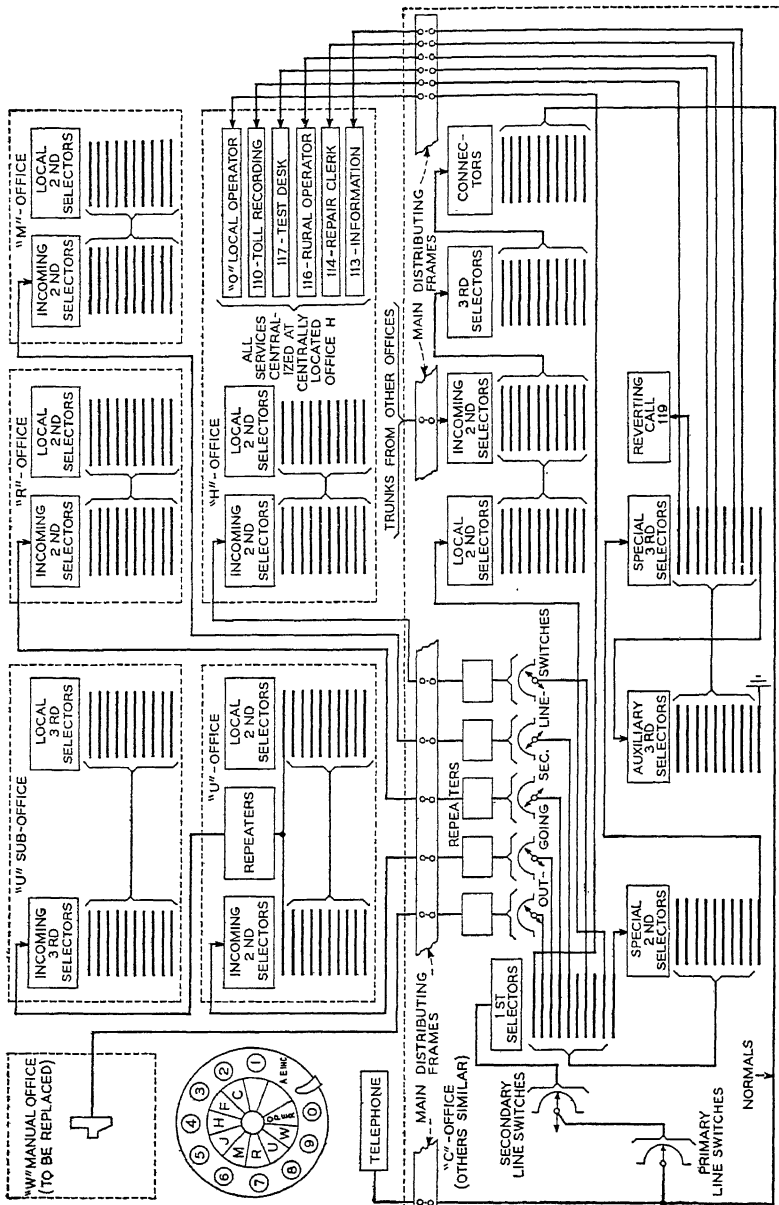

Fig. 14. Trunk Layout for a 100,000 Line Multioffice Exchange—Strowger System (Courtesy Automatic Electric Co.)

office, *U*0 is dialed, the first incoming switch in the *U* suboffice being a third selector. Outgoing calls from this office pass through the main *U* office.

Multioffice trunking and other switching in the Strowger system is accomplished, using in combinations the types of step-by-step switches and repeaters described above and, in addition, many other auxiliary circuits and devices which limited space will not permit discussing here.

THE PANEL DIAL SYSTEM is a radical change, both in mechanical and electrical characteristics, from the Strowger system and is employed generally in the largest metropolitan areas. Great flexibility of operation is permitted by this system as trunk groups and their sizes are for all practical purposes arbitrary. The time of establishing a connection is not dependent on the step-by-step dialing process of the subscriber, since, after all the dialing pulses are received from the subscriber by an intricate mechanism, the connection is rapidly routed to the called line, under control of this same mechanism, with great speed. The equipment as a whole is necessarily complex.

The principal mechanisms in the system are:

1. The panel-type selector with its banks of line or trunk terminals, which are selected by vertically moving brushes mounted on brass rods.
2. The sequence switch, which has a number of insulating disks mounted on a shaft. Each disk has a metal stamping on each side, and the entire assembly of disks turns a step at a time, as directed by the control circuit, with two brushes bearing on each stamping. By this means a large number of circuit arrangements may be made as required to establish the talking connection at the proper time, as determined by the control circuit.
3. The decoder sender is the "brains" of the system. It registers and stores the dial pulses from the subscriber dial by means of a dial pulse register circuit: it decodes the numerical digits dialed into a non-numerical selection scheme by choosing the proper route relay. The route relay controls the selection of an interoffice trunk. The sender then takes over control, sending out pulses to actuate a train of selectors which establish connection with the called line. The decoder sender is then released for other calls.

The panel-type selector, from which the system derives its name, performs the same function in this system that the line finder and selector switches perform in the Strowger system. The panel-type selector frame consists of several panel multiple banks of subscriber line or trunk terminals, over which the selector brushes slide vertically, and mechanism for moving and controlling the selector motion, as shown in Fig. 15.

The panel multiple bank consists of horizontally projecting terminals, arranged in vertically positioned, rectangular panels or banks, as shown in Fig. 16. Each terminal in the panel consists of a flat brass strip extending horizontally through the panel and having 30 projections on each side of the panel and also a soldering lug at each end of the strip for wiring. A set of three of these strips, mounted one above the other and insulated from each other with impregnated paper, constitutes the tip, ring, and sleeve terminals of one line. Thus, each line appears horizontally across the face of the panel 30 times, or 60 times for both faces. The number of lines or trunks provided in the banks varies in accordance with requirements, present practice with respect to subscriber lines being to provide 40 lines per panel and 10 panels per frame.

A selector is placed opposite each three vertical rows of line terminals; it consists of a hollow vertical brass tube on which are fastened ten sets of spring brushes, one set of brushes for each terminal bank. Each brush has three contacts, normally held apart by an insulator so as not to touch the lugs or terminals on the terminal panels. Each brush contact is connected in multiple with the corresponding contact of the other nine sets of brushes on the same brass tube or selector, so that any selector may reach any one of the 400 lines in the frame by tripping the proper brush, and the total selector movement will not exceed one of the ten banks of terminals. In practice, each bank of 40 lines is divided vertically into two identical banks of the same lines, but with the line numbering in reverse order (bottom to top and top to bottom of the bank). This arrangement of line numbering still further reduces the travel of the selector brushes to reach a particular line and reduces operating time of the selectors. A trip rod is provided with trip levers for each bank, so that the brush which is selected to make contact with the calling line is tripped as it starts upward in the calling line bank, the insulator between the brush contacts is withdrawn, and these contacts make the connection with the calling line terminals when they are reached.

The multiple wiring between the brushes is contained inside the hollow brass tube of the selector and terminates in another set of brushes at the top of the frame, which slide on bars in the commutator panel and control the selector movement.

The control mechanism of the selector is located at the bottom of the frame. There are two horizontal cork-covered rolls, extending the width of the frame and driven in opposite directions by suitable gears and a motor. Attached to the lower end of each selector tube is a flat bronze strip or rack, which is close to, but, in the idle position, not touching, the continuously revolving cork rolls. An electromagnetically operated clutch is mounted on the selector frame in front of each rack. Energization of either the up or down magnet presses the rack against the up or down cork roll, causing the selector to move up or down as desired. A pawl (not shown) engages in the horizontal slits of the rack and prevents the selector from slipping down after it has been elevated to the proper level. The selector returns to its normal position when released by the trip magnet. Figure 16 shows the control mechanism.

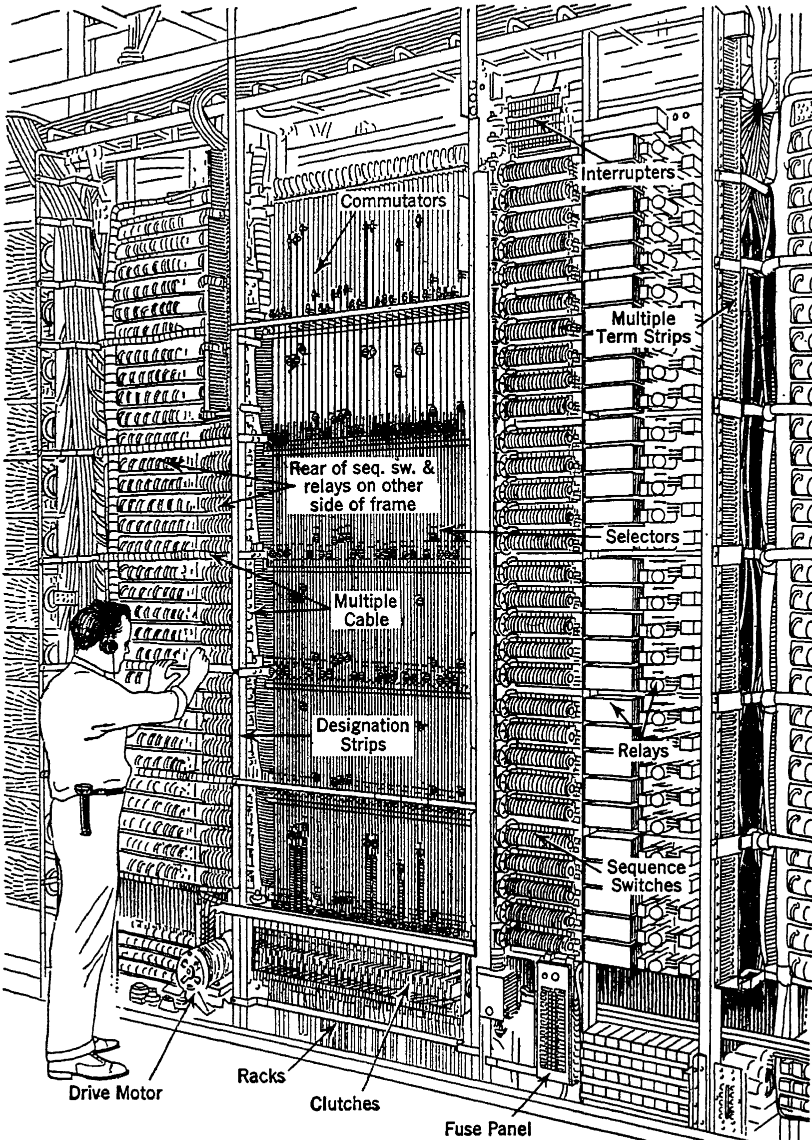

FIG. 15. General View of Panel Frame—Panel Dial System (Courtesy Bell System)

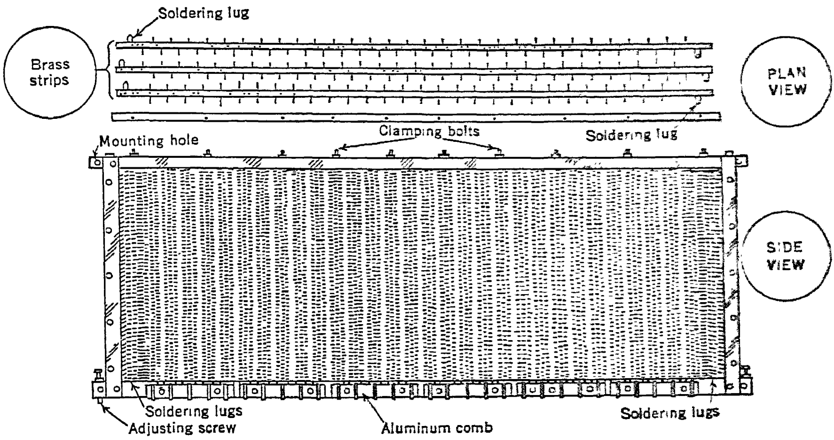
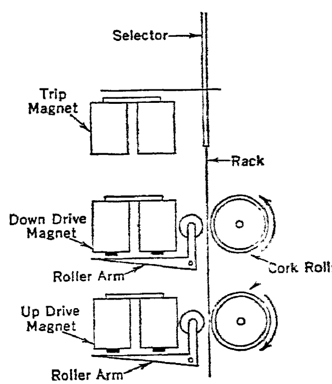
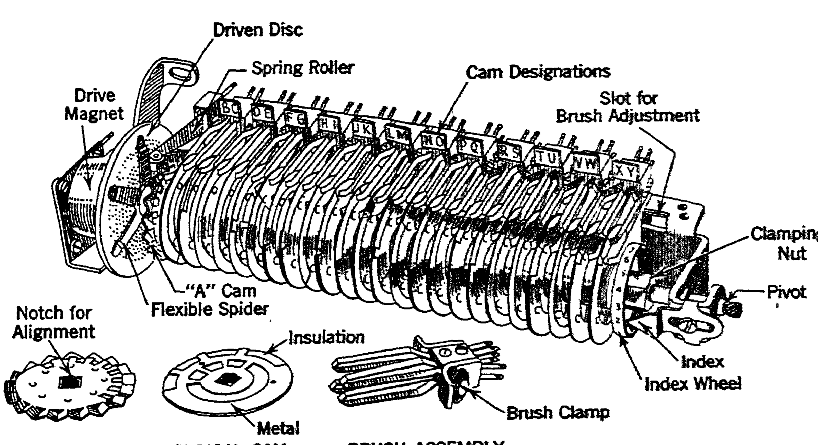
Control of the up-and-down movement of the selector is obtained either from impulses coming from the sender or from connections made on the commutator at the top of the frame. Panel selector equipment may vary in construction details and wiring, depending on its assigned function in the system.



Panel Multiple Bank



Selector Control Mechanism



Sequence Switch

FIG. 16. Panel Frame Units, Showing Details—Panel Dial System (Courtesy Bell System)

The sequence switch is vital to panel operation. The control circuits for panel-type selectors are necessarily complex and must be set up in sequence to cause the various operations for establishing a connection to take place at exactly the right time. This switch (Fig. 16) has 24 disks or cams mounted permanently on a shaft, and each disk consists of insulation with a specially shaped metal stamping attached to each side of the disk. Two brushes bear on each side of each disk. The metal stampings are of different shapes, so that as the disks turn each brush may rest on the stamping or on the insulation, in accordance with the position of the switch. This provides a means of establishing connections between brushes or opening and closing circuits in various combinations, as desired. A fluted metal disk, on which a spring roller rides, is mounted at the end of the shaft, so that the shaft may be revolved and held in any one of 18 positions. An electromagnet, when energized, pulls this disk against the edge of another continuously revolving disk and thus causes the shaft to turn one step at a time for each energization of the electromagnet.

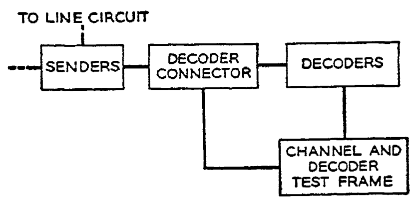


FIG. 17. Interconnection of Decoder Sender Units—Panel Dial System (Courtesy Bell System)

One sequence switch is associated with each selector and is located on the right of the terminal bank, as shown in Fig. 15.

The decoder sender records the pulses dialed by the subscriber, translates and decodes the first group of pulses (office code), resulting in selection of the proper central office trunk or trunks, and finally controls the brush selection and functioning of the various selectors and the sequence switch. The major units consist of a sender, decoder connector, and decoder, as shown in Fig. 17.

The dial pulse register circuit of the sender consists of a group of relays so connected as to record the dial pulses and subsequently control the operation of the decoder and selectors in establishing the connection. Figure 18 shows the portion of the dial pulse register circuit which registers the first three series of pulses comprising the office code. The connection of the sender to the subscriber's line operates the *AC* relay, so that the *P* group of relays is connected to the *A* group. The *P* group counts the pulses as received from the subscriber dial. The release and reoperation of the *L* relay, under control of the dial, operate the *P* relays. The *A* recording relays are operated by the action of the *P* relays in such manner that the sum of their numbers is equal to the figure dialed. Thus, if the first letter of the office name is *S*, causing seven pulses to be sent, relays *A*-2 and *A*-5 will operate. When the first figure has been recorded, the *RA*-1 relay supplies ground to the *A* recording relays, locking them, and releases the *P* relays. The *P* relays are then connected to the *B* recording relays, which are ready to record the next figure dialed. This operation is similar for each of the remaining figures dialed by the subscriber.

There are eight groups of recording relays, three for the office code and five for numerical digits. The last five groups are not shown in Fig. 18, but they are similar to those shown.

When three digits have been dialed, relay *CL* operates (relay *Az* operates in place of relay *CL* if the first figure dialed is zero). The operation of either of these relays indicates that the sender is ready for translation. The sender is now automatically connected to a decoder, through the decoder connector, by connection of the *A*, *B*, and *C* groups of leads shown in Fig. 18 to the corresponding groups of leads shown in Fig. 19.

The decoder register relay groups, *A*, *B*, and *C*, shown in Fig. 19, then register the hundreds, tens, and units digits of the office code, stored in the sender. The setting of the *A* register relays causes one of the multicontact relays, *H*-2 to *H*-9, to operate; the setting of the *B* relays causes operation of the proper *T* relay, and the setting of the *C* relays grounds one of the 10 leads shown at the right in Fig. 19.

Each *H* relay has 100 armatures and contacts as indicated in Fig. 19. The 800 contacts are connected to terminal strip punchings, called code points. The operation of an *H* relay connects the proper hundred code points to the hundred contacts of the *T* relays (ten to each relay). The operation of the proper *T* relay connects ten code points to the ten leads from the *C* relays, and the setting of the *C* relays connects ground to one code point.

The code points are cross-connected to route relays (Fig. 19), one of which is provided for each possible path, which a call may take. Since a particular route relay may be cross-connected to any code point, so that the selection of a particular route relay is numerical, the selection operation from this point on need not be on the decimal basis as indicated above.

A particular route relay is so designed that it requires certain operations of the district and office selectors independently of the code point to which it is connected, and thus of the number dialed in securing it. If the position of a group of trunks is to be changed on the selector, the route relay must be changed accordingly, but no further change in the system need be made. Only one route relay is required in each sender for each outgoing

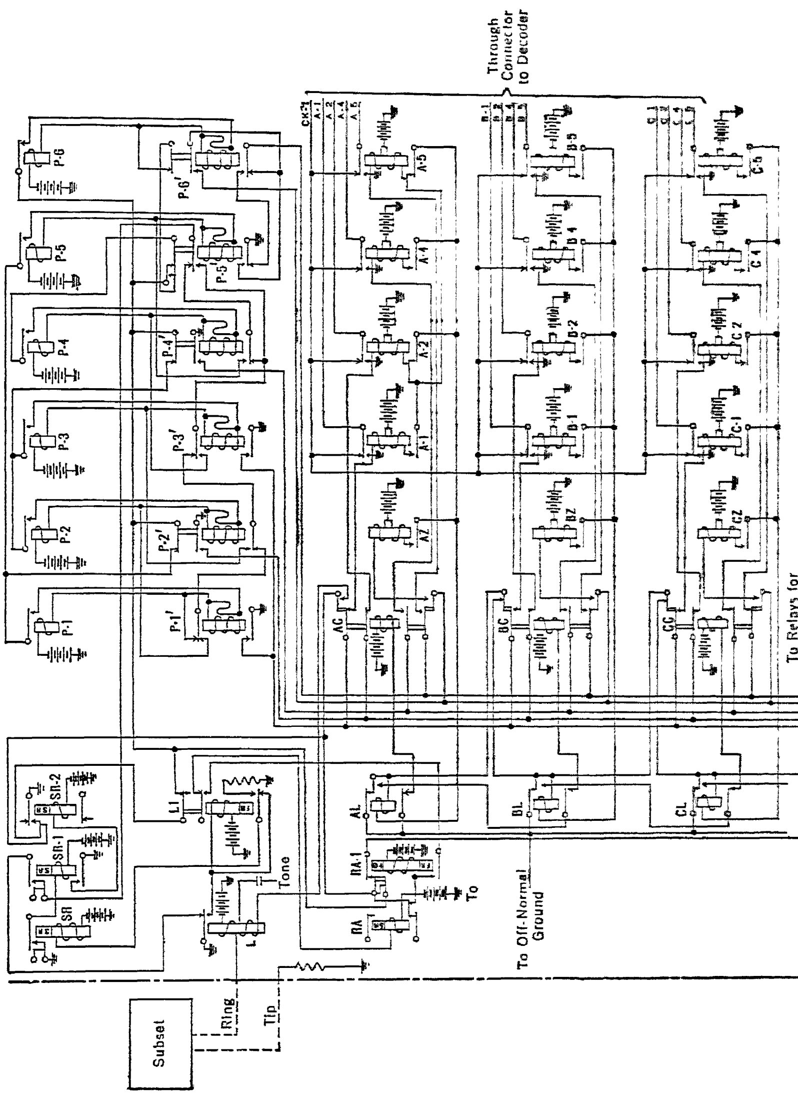

FIG. 18. Dial Pulse Register Circuit of Sender—Panel Dial System (Courtesy Bell System)

trunk group from the district and office multiple, that is, one for each dialing combination used in the particular exchange. The route relay, through a combination of registering relays, determines the brushes to be tripped and the movements of the selectors which choose the proper office. Once the proper route relay is selected, the remaining operation of obtaining the proper office is straightforward. All vacant code points are strapped together and connected to a single route relay, which will cause the sender to complete the call to an operator, who will explain to the subscriber that an incorrect number has been dialed.

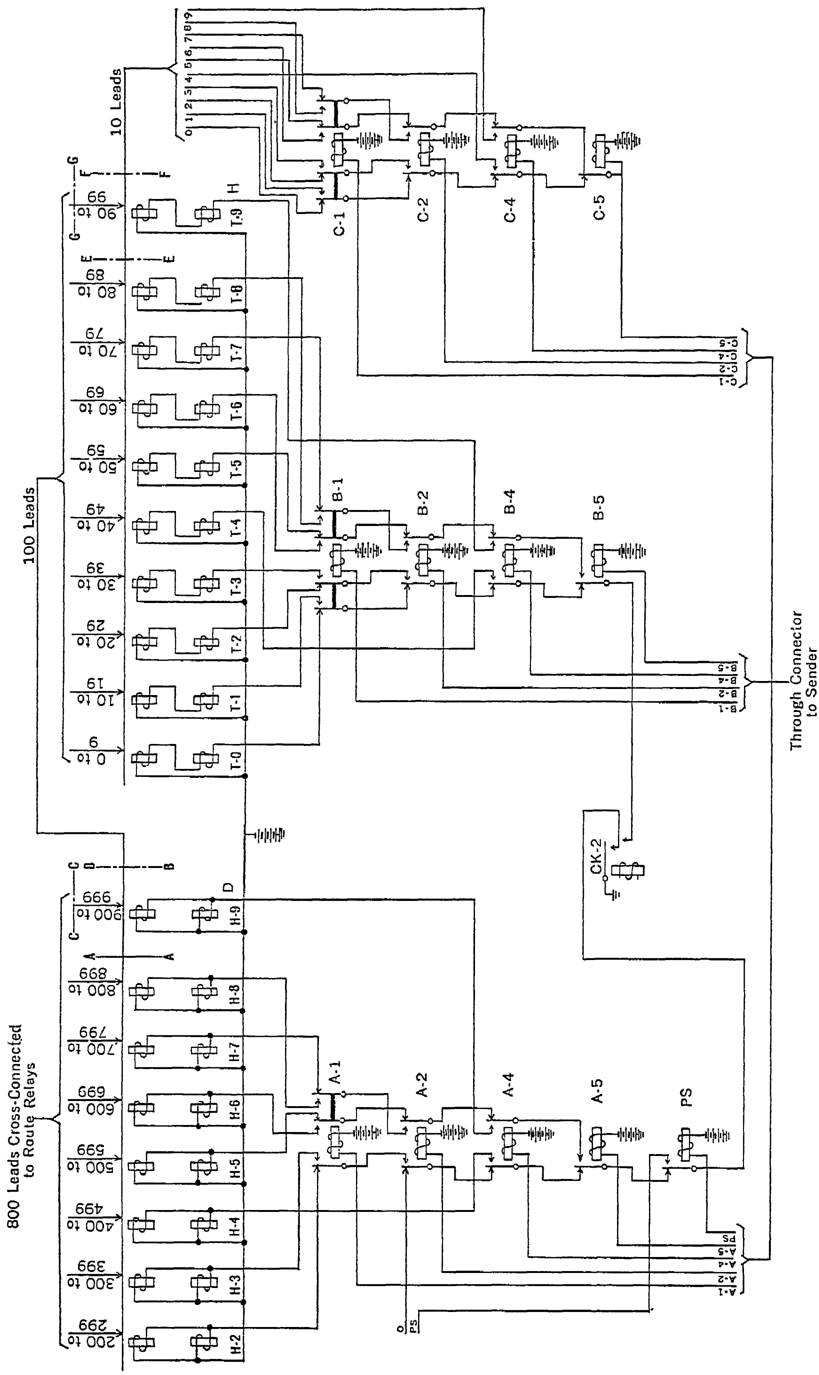

FIG. 19. Decoder Register Relay Circuit of Decoder—Panel Dial System (Courtesy Bell System)

When the decoder has completed translation, or if translation cannot be completed owing to trouble, the decoder signals the sender, which releases the decoder. Thus, the decoder is needed only during the time the office trunk is being chosen, but the sender is needed in the connection until the called subscriber line is connected. More senders will be required than decoders, the usual ratio being about 400 senders to not over 10 decoders, although this ratio varies with the traffic load.

IN PANEL DIAL OPERATION each subscriber line terminates on a line finder frame for handling outgoing calls, and a final frame for handling incoming calls, as shown in Fig. 20. When a subscriber lifts his handset to call, direct current from the central-office battery flows through his line and operates the associated line relay, at the same time making his line busy to any selector on the final frame. The operation of the line relay causes an idle line finder selector associated with the bank of terminals in which his line appears to move upward until it finds the calling line; this relay also causes the trip rod in that bank to trip the proper brush of the moving selector, after which the trip rod is immediately reset.

Simultaneously with the motion of the selector, the panel link circuit is selecting the district selector associated with the line finder selector, and also an idle sender. The panel link frame is also similar to the panel type selector frame, but with different details to suit its functions. The frame is divided into two equal parts vertically with the sender selectors on the left and the district selectors on the right. Each district selector is wired directly to its corresponding sender selector.

In practice, the district selector when released from a call selects the next idle line finder, while the sender selector remains where it is unless near the top of the bank, in which case it returns to normal position.

When the line finder reaches the calling line and the sender selector has found an idle sender, dial tone is sent back to the calling subscriber.

The action of the sender is described in detail. The dial pulses are stored in the dial pulse register circuit, the first three digits serving to connect the proper route relay to the sender and thus set the proper registering relays in the sender, at which point the decoder is disconnected from the circuit.

The sender is then prepared to cause the district selector to choose an interoffice trunk to an incoming frame. The district selectors are typical panel-type selectors, except that every eleventh terminal and an additional one between the two groups of five at the top of each bank is arranged as an overflow terminal to stop the motion of the selector when all ten trunks below it are busy. The trunks can be used in larger groups than multiples of 10 by making the intermediate overflow terminals busy, in which case the selector will pass over them, or groups of five trunks are available at the top of each bank.

If 450 trunks are not enough to provide the necessary trunks to all the offices in the exchange area, a group of office selectors is employed to care for all the trunks outgoing from the office. The calls are then routed by the district selector to the proper office selector and thence to the incoming selector of the called office.

The movements of the selectors on both district and office frames are guided by a reverse control method. As the selector is driven upward by the cork roll, it sends back one pulse to the sender each time a brush moving on the commutator (at the top of the frame) makes contact. Commutators for the various types of selectors are shown in Fig. 21. The pulses are counted by the sender, and, when the number of pulses indicates to the sender that the selector has moved to the proper position, the sender opens the up-drive magnet circuit, stopping the selector motion.

The first selection on either the district or office frame involves the tripping of the proper brush. If, as shown in Fig. 20, the desired trunk appears on the fourth panel from the

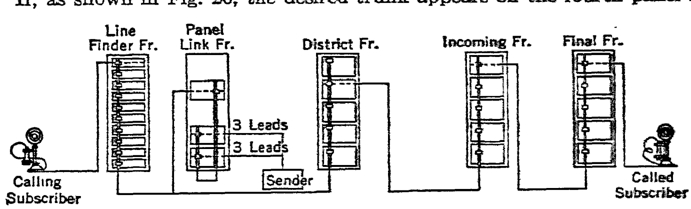

Fig. 20. Typical Panel-type Connection—Panel Dial System (Courtesy Bell System)

bottom, the district selector will first move up a distance of four segments on the *A* bar of the commutator (Fig. 2 in Fig. 21). At that point the selector will be stopped, the sequence switch will be turned two steps (from position 4 to 6 in Table 1), changing the fundamental circuit to prepare for the next operation, and the trip rod will be rotated into position to trip the fourth brush. The selector is now started upward again by the sender, and sends back a pulse for each bar on the *B* bar of the commutator, each of which represents a distance of ten trunks. Thus, the upward movement of the selector to the proper trunk group is controlled by the number of pulses sent to the sender from the *B*

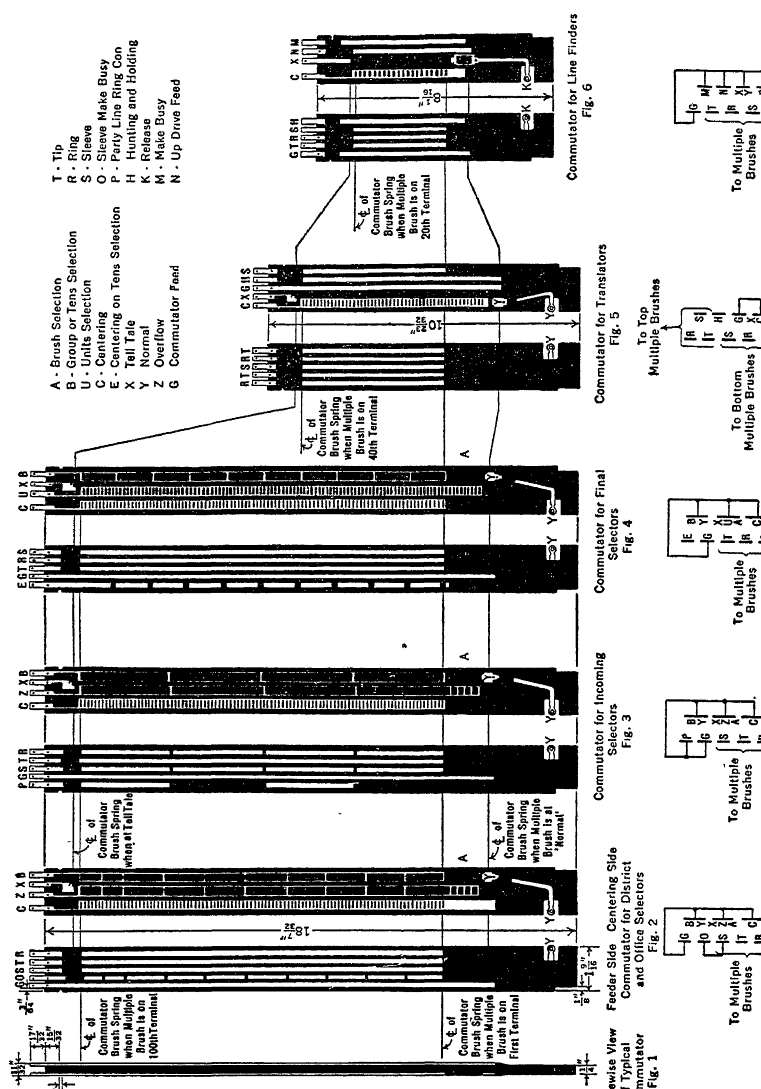

FIG. 21. Commutator Brush Connections for Selectors, Translators, and Line Finders—Panel Dial System (Courtesy Bell System)

bar. When the selector reaches the proper group, the sequence switch is again turned two steps (position 6 to 8 in Table 1) and the selector moves up slowly, testing each trunk in the group to find an idle one—a process known as hunting.

The hunting process is common in panel operation. The connections are shown in Fig. 22, all connections marked 8 being closed, since the sequence switch is on position 8 (Table 1). If the *L* relay is operated, the up-drive clutch is energized by current flowing to ground through the *L* relay left-hand contact, and the selector moves up. As long as the sleeve contact of the selector brush is grounded, the L relay is operated through contact 7 1/2/8. Since the sleeve contacts of busy trunks are grounded and those of idle trunks are not grounded, the selector will move a small distance beyond the last busy trunk. However, even here the L relay is grounded through the commutator brush and the G bar of the commutator. The reason for this slight extra movement is to allow the holding pawl on the selector rack to engage the correct slot.

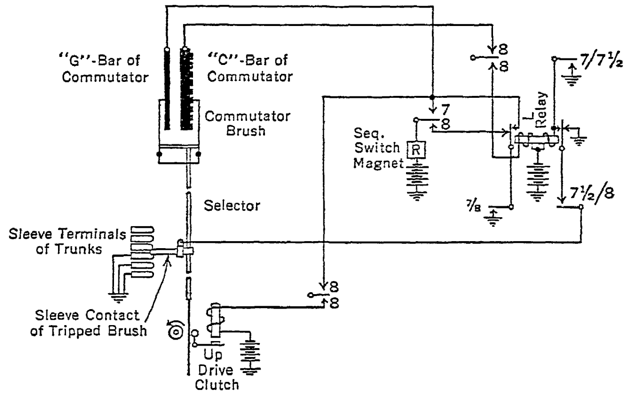

FIG. 22. Selector Circuit for Hunting Idle Trunk—Panel Dial System (Courtesy Bell System)

When an idle trunk is found, the sequence switch turns to position 10, until the connection is completed, the changes necessary in the control circuits being made by other sequence switches located on the incoming and final selector frames.

Table 1. Operations of District Sequence Switch

Position	Corresponding Circuit Condition	Position	Corresponding Circuit Condition
1	Normal	10	Selection of brushes, groups, etc., beyond the district selector
2	Selecting an idle sender		
3	Waiting for sender	11	Waiting for sender
4	Selecting brush	12	Talking (non-loaded trunk)
5	Waiting for sender	13	Talking (medium-loaded trunk)
6	Selecting group	14	Waiting for operator to answer
7	Waiting for relays	15	Talking to operator
8	Hunting idle trunk	16	All trunks busy
9	Waiting for sender	17	Operating message register
		18	Returning apparatus to normal

These selectors are also of the panel selector type, differing only in details. The final selector frame has capacity for 500 lines, thus requiring 20 final frames for a 10,000 subscriber line office. The incoming selector frame must then hold 20 groups of trunks, which can consist of 24 trunks and an overflow terminal. This arrangement, which is employed in all offices, is shown in Fig. 23. The sender circuit is so arranged that either 0 or 1 in the thousands digit causes brush 0 to trip, while the combination of the first two numbers determines the proper group for the selector to hunt in. When an idle trunk to the final selector is found, the second or hundreds digit determines which brush will be tripped, while the tens digit determines in which group the called line appears. Final selectors are directed rapidly to the proper group of ten; when the proper group is reached, the clutch on the up-drive roll is released by a change in the setting of the sequence switch and 1/4 usual speed is substituted as the motive power. The final selector tests the line on which it stops, and if it finds the line busy it returns to normal and sends back a busy tone to the calling subscriber.

If the called subscriber has a private branch exchange (PBX) with several trunks, the final selector will hunt for an idle line if the called number is busy exactly as it hunts for an idle interoffice trunk.

Many special provisions must be made in any installation for party lines, message rate service, rapid testing, and other special conditions that arise, but such arrangements will not be considered here.

THE CROSSBAR SYSTEM is the latest Bell System development in mechanical switching. It differs radically from the Strowger (step-by-step) and the panel dial systems in construction, operation, and control, but it is so designed that it functions satisfactorily with all other types of switching, whether mechanical or manual. The crossbar system offers important improvements in switching, both in operation and maintenance, over the step-by-step and panel systems, but it does not necessarily replace existing installations or additions to these older systems.

Only the most important functions of the crossbar system can be discussed in this handbook, owing to space limitations.

The crossbar system has two outstanding features, *the crossbar switch* which is used for all major switching operations, and *the marker system* of control which is used in establishing all connections throughout the crossbar office. The apparatus consists principally of crossbar switches of the relay type and multi-contact and other type relays generally employed in telephone systems. The switching circuits are wired to the contacting springs of the switches, and the circuit closures are made when the contacts are pressed together by operation of the electromagnets.

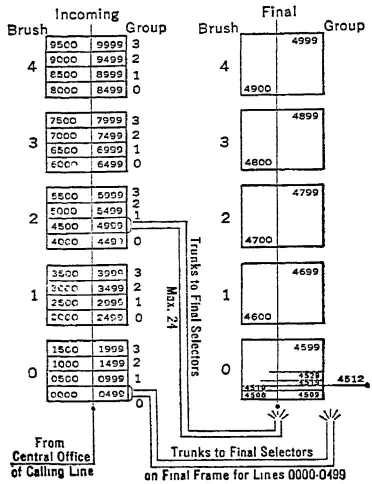

FIG. 23. Trunk and Subscriber Multiple on Incoming and Final Selectors—Panel Dial System (Courtesy Bell System)

The use of relay-type apparatus economically permits having twin contacts of precious metal throughout, insuring reliable operation for the low values of speech and signaling currents inherent to telephone systems. The very short mechanical movements and small operating time intervals required in crossbar switch operation permit a reduction in control equipment over the slower-moving, older-type systems, thus resulting in the use of large switch and relay assemblies on unit-type frames, factory wired and tested. In the design of the switching frames and associated control circuits, it has been possible to standardize a relatively few types of equipment units, thus simplifying manufacture, merchandising, and operating company engineering.

The marker, composed mainly of relays by means of which it controls switching operations, has many advantages, one of the most important being the completion of its complex functional processes in establishing a call in less than one second. The markers are connected momentarily, by means of multicontact relays, to various switching units of the office to guide the completion of calls through the crossbar switches. The marker system provides for an attempt automatically to establish a call over alternative paths when all the normal routings are busy or trouble is encountered; the marker will detect, record the location and nature of such troubles, and indicate their presence to an attendant by operating an alarm. The marker design also facilitates the introduction of new service features and operating changes as desired, since the main control features of the entire system are incorporated in a small number of markers.

The crossbar switch, which gives the system its name, is the basic switching unit of the system. Figure 24 shows a front view of a 200-point switch. Fundamentally, this switch contains (1) 10 separate horizontal circuit paths, (2) 20 separate vertical circuit paths, and (3) an electromagnet for each horizontal and each vertical path, so that the operation of any horizontal and any vertical magnet in sequence will connect a horizontal and a vertical path together at one of the 200 cross-points. The 10 horizontal paths are controlled by 5 horizontal bars each actuated by a selecting magnet, and the 20 vertical paths are controlled by 20 vertical bars each actuated by a holding magnet. Any set of contacts may be closed by first operating the selecting magnet corresponding to the horizontal row in which the contacts are located, and then by operating the holding magnet associated with the particular row of vertical contacts. The holding magnet will hold the contacts closed until the connection is released, but after it is energized the selecting magnet returns to normal until called upon to operate on another call. Thus, 10 sets of contacts may be made at one time through the switch, one for each horizontal path.

Figure 25 shows in detail a portion of the selecting mechanism of the crossbar switch. The 10 sets of contacts in each vertical row are associated with the vertical or holding bar of that row. Each horizontal or selecting bar has 20 flexible wire selecting fingers, mounted at right angles to the bar, one finger for each vertical row of contacts. When a selecting bar is rotated through a small arc by its magnet, the selecting fingers move up or down into position, depending upon the direction of rotation of the bar. When a holding bar in a

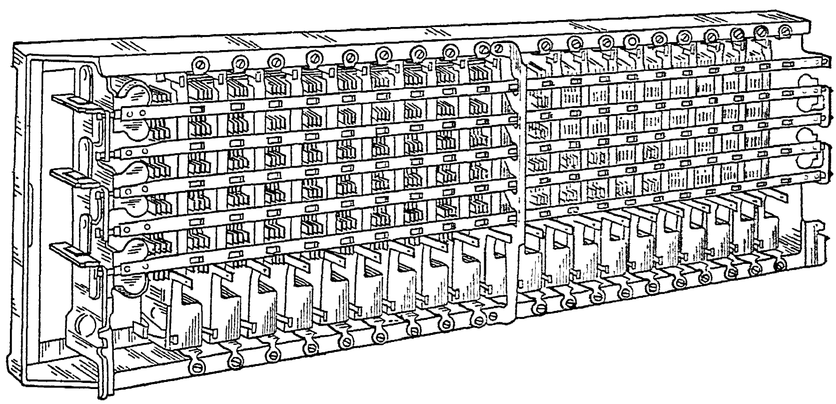

FIG. 24. Crossbar Switch—Front View—Crossbar System (Courtesy Bell System)

particular vertical row is operated by its magnet, it will bear against the particular selecting finger which has been moved into position in its row, and the finger will be pressed against the operating spring horizontally in line with it. Thus, the operating spring will be pressed against the contact multiple (fixed contact spring) and the circuit path will be closed at that point.

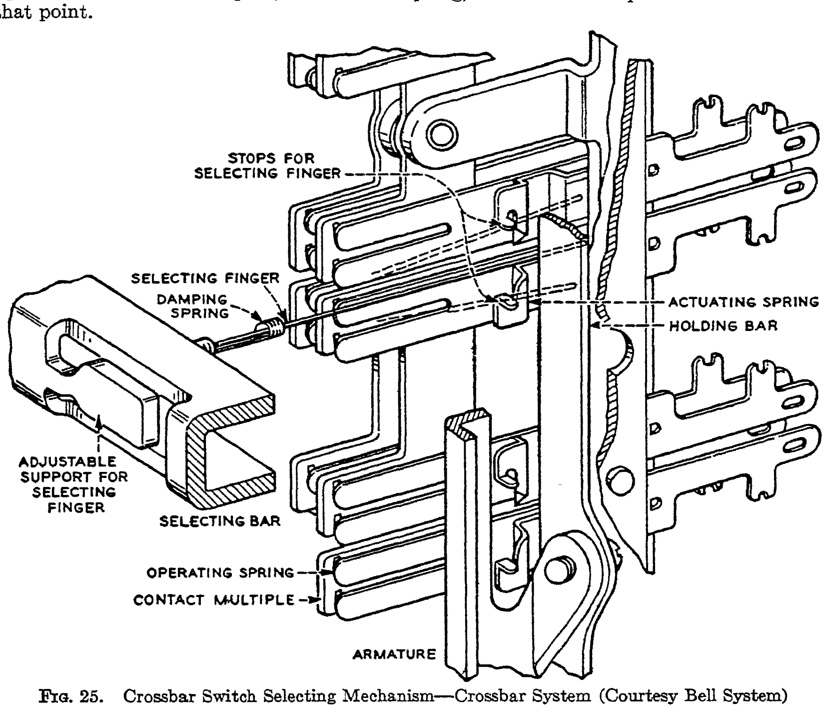

FIG. 25. Crossbar Switch Selecting Mechanism—Crossbar System (Courtesy Bell System)

The selecting bar and all its fingers except the one being held against the operating spring will be released as soon as the holding bar operates. When the connection is released, the holding bar returns to normal and the held finger returns to its idle position midway between, but slightly to the right of, two sets of operating springs. At those points along an operated vertical bar where the fingers are not operated by the horizontal bar, the fingers are pushed in between each two sets of operating springs and thus do not bear against these springs. Only one finger is operated at one time for a given vertical bar.

The selection operation is performed by five horizontal bars, each of which will select one of two horizontal rows of operating springs, depending on the direction of rotation of the bar and consequently the selecting fingers. Figure 24 shows two magnets at the end of each horizontal bar, one causing the fingers to move upward and the other causing them to move downward. After release, the horizontal bar is restored to its mid or idle position by centering springs at the ends of the bars and adjacent to the magnets.

The vertical units of the crossbar switch each have 10 sets of operating springs in vertical rows with one vertical or holding magnet at the bottom of the row which actuates one vertical bar or armature extending the height of the 10 sets of contacts. Each set of contacts may consist of three, four, five, or other numbers of pairs of springs in horizontal spring pile-up or assembly, depending on circuit requirements. Figure 24 shows four pairs of springs per set of contacts. One twin contact spring of each pair is stationary and designated contact multiple; the mate or operating spring of the pair is pressed against the contact multiple, when operated. This contact multiple spring is made of one piece of metal, insulated from the mounting and extending the full length of a vertical row of contacts. Wiring lugs are formed at the lower end of these vertical metal pieces, facing the rear, to which are wired the lines or trunks of the vertical circuit paths. On the front and at the lower end of these pieces projections are provided for testing purposes. The mate or operating springs extend to the rear of the switch, where wiring lugs are provided and may be strapped horizontally to the corresponding springs of adjoining vertical units, thus extending the horizontal paths across the switch verticals, or to adjoining switches.

The switch may have "off normal" contact spring assemblies, if required, associated with each selecting magnet which operates them to perform various circuit functions.

The 200-point crossbar switch is 9 1/4 in. high and 30 1/2 in. long. A 100-point switch with 10 verticals is also available.

The multicontact relay used in the crossbar system and shown in Fig. 26 resembles in design the vertical unit of the crossbar switch. The relay is provided with 30, 40, 50, or

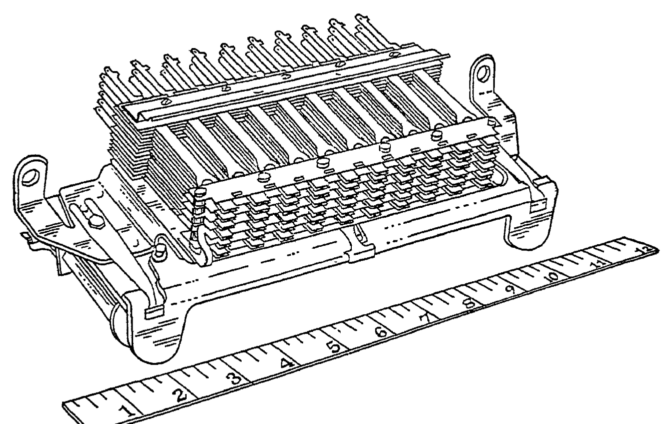

FIG. 26. Multicontact Relay—Crossbar System (Courtesy Bell System)

60 sets of individually insulated contacts, normally open, but closed when the relay magnets are operated. Each relay has two separate magnets, armatures, and associated groups of springs. By operating the magnets independently, the unit can be operated as two separate relays, each closing 15, 20, 25, or 30 sets of contacts, or if both magnets are energized in parallel the full number of contacts of the unit are closed. All contact springs have twin contact surfaces of solid bars of precious metal because of heavy duty requirements. This relay is used mainly in the common connector circuits, where a large number of leads must be connected simultaneously to a common circuit.

New and improved general-purpose small relays of the U and Y types are used in the crossbar system. These relays permit the use of up to 24 springs in one assembly, providing for various combinations of transfer or simple make and break contacts. The springs are equipped with twin contacts of various contact metals, depending on the characteristics of the circuits controlled by them. The Y relay has a slow release action obtained by copper or aluminum sleeves over the relay core.

CROSSBAR OPERATION may be more readily understood from the block diagram of the functional arrangement of the principal equipment units of the system which are involved in a connection between two subscribers, as shown in Fig. 27. The three main

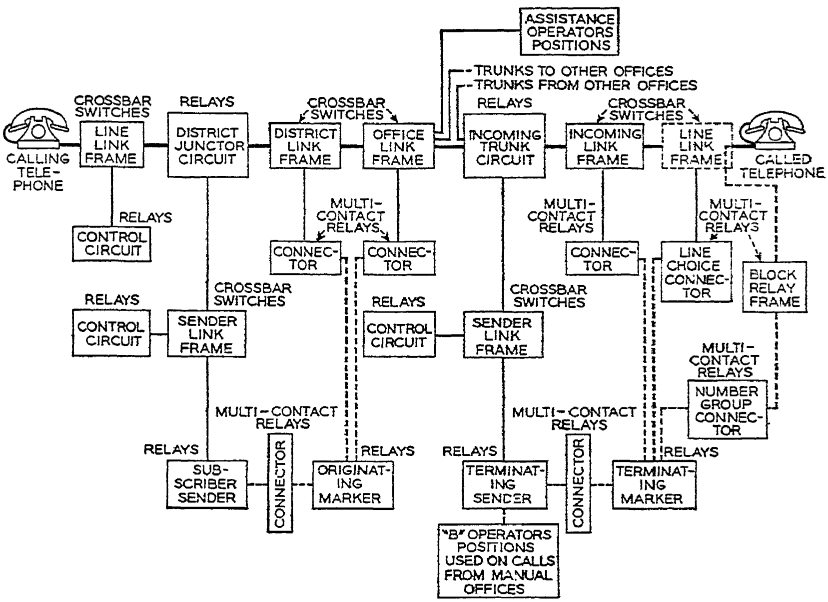

FIG. 27. Functional Arrangement of Equipment Units—Crossbar System (Courtesy Bell System)

types of equipment units are: (1) the district junctors and incoming trunks, which supply battery to the transmission and supervisory circuits; (2) the crossbar switch frames; (3) the common control circuits and the senders and markers.

The district junctor and incoming trunk circuits are composed mainly of small relays. The district junctor furnishes talking battery for the calling subscriber and supervises the originating end of the connection. The incoming trunk circuit controls the ringing of the called subscriber bell, furnishes talking battery for the called line, and supervises the terminating end of the connection.

The switch frames, consisting principally of crossbar switches, provide the means for switching between the subscriber lines, district junctors, and incoming trunks, and also for switching these district junctors and trunks to senders.

The senders consist chiefly of small relays, and their function in crossbar is comparable to that of an operator in manual operation. The subscriber sender registers the called number from the subscriber dial pulses and transmits the necessary information to the markers, to the terminating sender, and to the manual operators (in manual offices) for completing connections to the called line. This sender also controls operation of the selectors in distant panel offices. The terminating sender receives the numerical digits of the called number from the subscriber sender of any panel or crossbar office and transmits the required information to the terminating marker for setting up connections to the called line.

The markers are the most important control circuits in the crossbar system. They comprise both small and multicontact relays and are of two types, one for originating and one for terminating traffic. Since their operating time is less than 1 sec, only three or four markers are needed in the average size office.

The originating marker determines the proper trunk routes to the called office. It has access to all outgoing trunk circuits and all crossbar switch frames used in establishing connections to the called office trunks. The marker records pulse information, tests the trunk group for an idle trunk to the called office, tests for and marks or reserves an idle path through the switch frames, and finally operates the proper crossbar switches to establish a path from the calling subscriber line to the outgoing trunk circuit. The lowest-numbered available paths are always selected in order to reduce selection time and increase operating efficiency.

Trunk selection is made by the marker through route relays, of which there is one for each called office routing. This relay is so wired as to direct the marker to the called office trunk group and indicate the number of trunks in the group; also to indicate the office link switch frame on which the trunk group appears and the type of called office, which is also indicated to the sender. Route relays may be assigned to any office trunk group, and other changes may be made, as required.

The terminating marker performs similar functions in the terminating office, establishing a path between the incoming trunk circuit and the called subscriber line. This marker has access to all the subscriber lines terminating in the office and to all crossbar switch frames used for connecting to subscriber lines. It records pulse information, tests the called line to determine whether it is idle, tests for and marks an idle path through the switch frames, and finally operates the proper crossbar switch magnets to establish connection to the called line.

The marker, in testing and connecting the called line, employs a marker group connector circuit and block relay frame in which the called line appears. Each subscriber line has three test terminals on the block relay frame, and a number group connector will usually have access to the test terminals of several hundred lines. The marker determines from these test terminals whether the called line is busy and the identification of the proper line link frame and horizontal group of line links which have access to the called line; also the type of ringing required is determined from circuit conditions on the test terminal.

There are also *common control circuits*, associated with the line link and sender link frames, for controlling the operation of the switches on these frames. In addition, there are *common connector circuits*, composed mainly of multicontact relays, which are used to connect the markers (1) to their respective senders, (2) to their associated switch frames, and (3) to the subscriber line test terminals.

The line link frames, although shown separately in Fig. 27, are, in a given office, used for both originating and terminating traffic. After the talking connection has been established between subscribers (see Fig. 28), all the common control circuits, including senders, markers, connectors, line link control circuits, sender link frames, and their associated

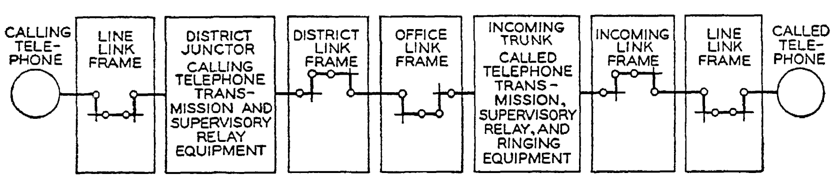

FIG. 28. Completed Talking Connection—Crossbar System (Courtesy Bell System)

control circuits, will have been released, and the talking path will be maintained by the holding magnets of the crossbar switches, which are used on the link, district, office, and incoming link switch frames. These holding magnets are held operated under control of the supervisory relays in the district junctor and the incoming trunk circuits and are released only when the subscribers hang up their handsets.

The establishment of a connection with the crossbar switch is shown schematically in Fig. 29, in which 20 vertical units are connected to 20 subscriber lines and 10 trunks are strapped horizontally across the switch. With this arrangement, any one of the 20 lines may be connected to any one of the 10 trunks by closing the contacts at the proper cross point. By adding a second 200-point switch with 20 additional lines connected to its verticals, and extending the trunk strapping through both switches, 40 lines are given access to the 10 trunks. Thus, by adding other switches in this manner, the number of lines having access to these 10 trunks may be further increased.

A line link frame comprises primary bays and secondary bays. Each primary bay terminates 200 subscriber lines (10 primary switches with 20 lines each), but the number of primary bays per frame may be varied within limits to meet traffic requirements. The secondary bay contains secondary switches; the bay is divided vertically in the center, so that there are 10 switches, each with 10 verticals on the left of center and the same arrangement on the right of center of the bay. The switches on the left have their verticals connected to line junctors which are used for terminating traffic, and those on the right have their verticals connected to district junctors which are used for originating traffic. At the bottom of the secondary bay is a cabinet containing control circuit relays, and just above this cabinet are the multicontact relays which connect the control circuits to the crossbar switches.

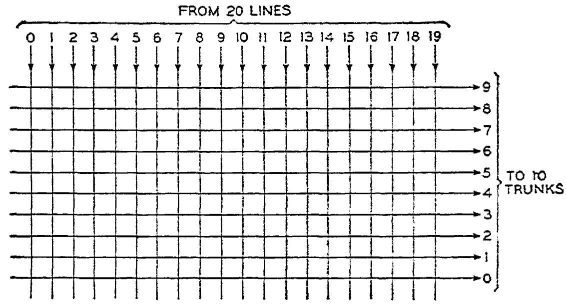

FIG. 29. Simple Trunking Arrangement with a Single 200-point Crossbar Switch—Crossbar System (Courtesy Bell System)

Since each subscriber in an office has only one crossbar appearance and that on a vertical unit of a primary crossbar switch, both originating and terminating calls are completed by means of the same line link circuits serving that particular switch. Thus, all originating traffic from any of the 20 lines on a primary switch flows through the associated 10 line links to the 100 district junctors, and all terminating traffic to these 20 lines flows through the same 10 line links from the line junctors, as shown in Fig. 30.

The arrangement shown in Fig. 30 is also used in the originating and terminating sender link switch frames, where the circuits reached are non-directional, that is, where any one of the circuits wired to the frame and available for selection can be used for establishing a connection.

Where it is necessary to provide greater flexibility and efficiency in trunk groups than is possible with the arrangement shown in Fig. 30, two primary and secondary switch

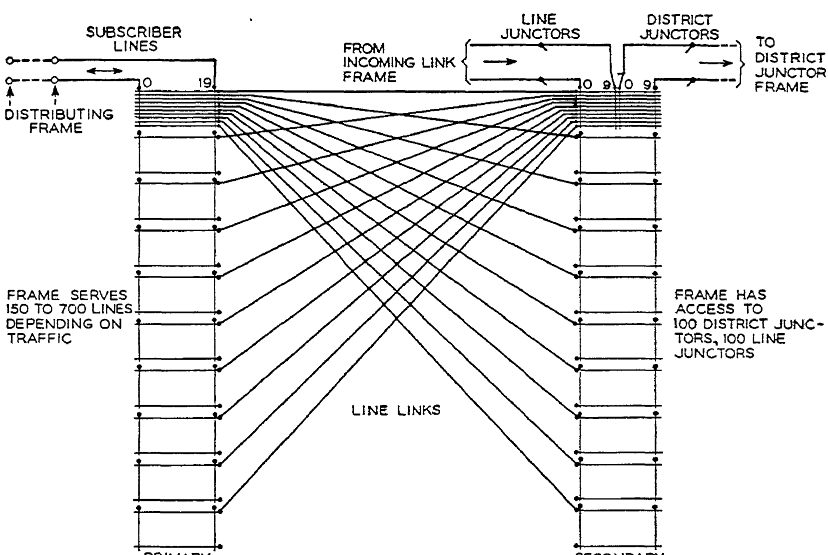

FIG. 30. Single Primary-secondary Trunking Arrangement—Crossbar System (Courtesy Bell System)

frames are employed, as shown in Fig. 31. This layout shows an incoming link frame to which incoming trunks are connected, and a line link frame to which subscriber lines are connected. These two frames are operated in tandem for establishing the terminating connections between the incoming trunks and are called subscriber lines. As shown, 100 incoming trunks are connected to the 100 horizontal paths of the 10 incoming link frame primary switches, 10 trunks per switch. Although only 200 lines (20 lines on each of 10 primary switches) are indicated in Fig. 31, 150 to 700 subscriber lines mav appear on the verticals of the primary switches of the line link frame.

Referring to Fig. 31, the connection of a particular incoming trunk to a particular called line requires the selection of an idle path through the incoming link and line link frames. This path will consist of an incoming link, a line junctor, and a line link. The incoming trunks on each of the primary switches have access to 20 incoming links appearing on the 20 verticals of the switch. These 20 incoming links are distributed over the 10 secondary switches of the incoming link frame, two links to a switch and one link to each half switch. In order to provide for the distribution of the 20 incoming links over the 10 secondary switches, the horizontal paths of the secondary switches are separated between the tenth and eleventh verticals, thus providing 20 instead of 10 horizontal paths on each switch. The incoming links on each half of these secondary switches have access to line junctors appearing on the verticals of these switches. These junctors are, in turn, distributed over

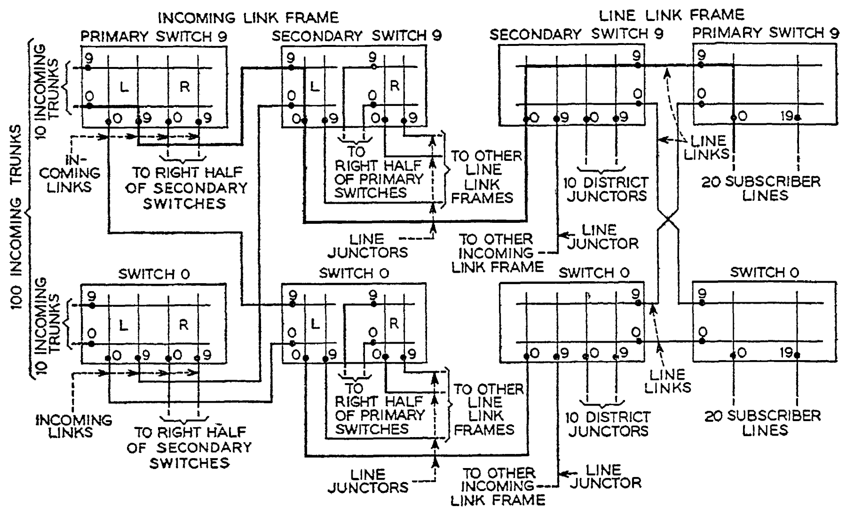

FIG. 31. Double Primary-secondary Trunking Arrangement—Crossbar System (Courtesy Bell System)

the secondary switches of all the line link frames in the office. There will be at least one junctor from each secondary switch on an incoming link frame to a secondary switch on every line link frame in the office, or a minimum of 10 line junctor paths between any incoming link frame and any line link frame, the number of paths varying, depending on the number of frames required in an office.

The line junctors on the verticals of each of the line link frame secondary switches have access to 10 line links on the horizontal paths. The 10 line links are distributed over the primary switches of the line link frame, one to each switch, giving each link access to the called subscriber lines appearing on the verticals of the primary switch with which the link is associated.

With the Fig. 31 arrangement of switches and the three groups of interconnecting link paths, any incoming trunk can be connected to any called line appearing on the line link frame or, by means of other groups of line junctors, to a called line on any other line link frame in the office. This trunking arrangement is also employed for connecting district junctors to outgoing trunks in the originating office.

Establishing a call from one crossbar subscriber to another crossbar subscriber requires four stages of operation, two at the originating and two at the terminating office:

1. The calling subscriber is connected to a subscriber sender through the line link frame, district junctor, and sender link frame, and the sender registers the dial pulses of the called number.

2. The subscriber sender is connected to an originating marker through the marker connector, and the marker then selects the switch frames for establishing a connection between the calling subscriber line and an outgoing trunk.

3. The outgoing trunk (incoming at the terminating office) is connected to a terminating sender through the terminating sender link frame, and the sender registers the pulses corresponding to the called number.

4. The terminating sender is connected to a terminating marker through a marker connector, and the marker then selects the switch frames for establishing the connection to the called subscriber line.

Future developments in crossbar equipment point toward simplification of equipment and circuits and reductions in the number of units required, wherever possible. An improved system of crossbar is now under study, in which it may be possible to establish connections with one marker instead of the two markers now used, and in which other simplifications may be secured.

OTHER RELAY SWITCHING SYSTEMS developed by various manufacturing companies include Relaymatic, by Kellogg Switchboard and Supply Co.; Relaydial, by Stromberg-Carlson Co.; All-Relay, by North Electric Manufacturing Co.

These systems operate on the principle of (1) finding the calling line when the calling subscriber takes his handset from the hook, (2) selecting and closing groups of contacts by relay action under control of dial pulses, subdividing the groups of contacts closed, until the contacts of the called line are reached, after which ringing power is applied to the called line by a link circuit. Since no moving parts are involved except the operating springs or reeds, which are equipped with precious-metal twin contacts, maintenance is simplified and operating costs are reduced over other types of automatic switching employing motors and step-by-step type switches with base-metal contacts and sliding brushes.

The line circuits may be assigned for common-battery local and rural, trunk or pay station service. Local lines may have individual stations or multiparty service up to 10-party selective (for metallic lines) or 16- to 20-party code ringing (for grounded lines). Local lines are of the metallic type, and line adapters are used for grounded rural lines, as required. By the addition of a trunk adapter, any line circuit may be converted to a trunk circuit. All link (connector) circuits have access to all lines, are assigned in rotation, and automatically release from any line in trouble or as soon as the subscribers hang up. A line lockout feature is generally provided with these systems which prevents tie-up of a link equipment if a line is in trouble or a handset is left off the hook or if the link fails to release after a predetermined time. As soon as the line in trouble is restored to normal, the lockout of the line from access to the link circuits is automatically discontinued.

These systems are made in capacities from 10 to 10,000 lines and may be operated as unattended small dial offices, if desired, with trunks to a nearby manual or mechanical office. In such cases, suitable alarms are provided which indicate at the attended office when the equipment needs attention and the type of trouble at the unattended office. Some systems of more than 200 lines employ relay-type selectors to distribute calls from one group of 100 line finders to the desired 100-line group of connector links and connectors.

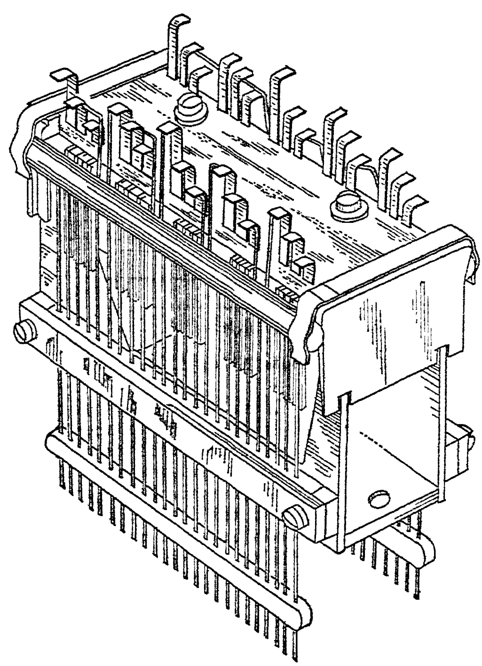

Fig. 32. McBerty Relay (Courtesy North Electric Mfg. Co.)

McBerty Automatic Telephone System (North Electric Manufacturing Co.). The important unit of this system is the McBerty relay, Fig. 32, a new design consisting of an integral reed spring-armature-contact structure having no pivots or hinges, which are common to most relays. The basic mounting structure may be used as a single multicontact relay or as a group of three, four, or five separate relays, the entire unit being light and compact. The relay coils are of the molded bobbin type, which slip over the steel-alloy cores welded to the mounting frame. Gold-alloy contacts are used throughout. Bare wire is used for multipling relay contacts.

This system employs a link circuit consisting of a line finder, connector control relays, and a connector for establishing a connection between a calling and called subscriber. As many links are provided as are required to handle normal traffic loads. Figure 33 shows a single link circuit layout for a 100-line system, but for purposes of illustration only three of the ten tens relays are shown. Also for clarity each single line shown represents two wires outside of and three wires within the switchboard.

When a calling subscriber removes his handset from the hook, the line relay in his line circuit operates, causing the proper line finder tens and units relays of an idle link circuit to operate, closing the calling line through to the connector control relays of this link. The calling subscriber then dials the called number, and the dial pulses are registered by

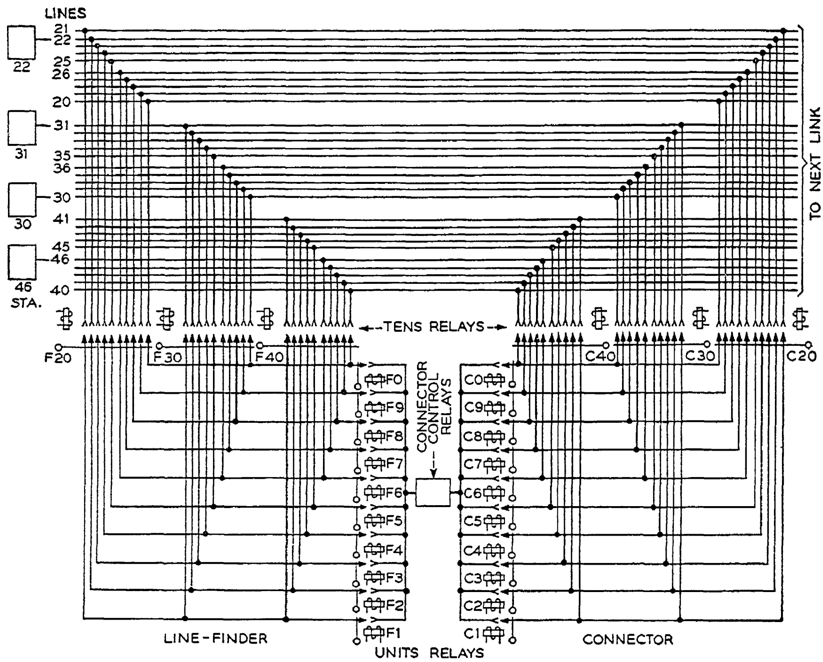

FIG. 33. Diagram of North 100-line All-relay System (Courtesy North Electric Mfg. Co.)

the control relays. These relays cause operation of the connector tens and units relays (corresponding to the called number) connecting the called line to this link.

The above operations complete the connection between the calling and called subscribers through the link circuit, which applies ringing power to the called line. This link is not released for other connections until the subscribers hang up. While the tens relays close through ten lines in both the line finder and connector each time they are operated, only one units relay is closed through in each line finder and connector for a given call, and thus all lines except the calling and called lines remain open to the control relays and may be seized by other links when calls are originated by such lines.

The XY dial telephone system, developed by Stromberg-Carlson Co., employs for its basic unit the XY selector-type switch, a view of which is shown in Fig. 34.

The XY switch, used in the line finder, selector, and connector circuits, is radically different in construction from the Strowger step-by-step switch. The switch is assembled on a metal base plate, which is mounted horizontally on a switch frame. The switch has a carriage with four separate wipers, tip, ring, sleeve, and hunt, and the carriage is moved as a unit in two horizontal directions, one paralleling the front edge of the base plate, called the X direction, and the other at right angles to the X direction, called the Y direction, under control of two magnets, X and Y respectively. The carriage is driven by a cog roller (tubular shaft) assembly, which slides along a shaft during the X motion and rotates during the Y motion. The cog roller is a double-cut tubular gear, with ratchet teeth cut parallel to its length and rack teeth cut as rings. The annular rack teeth mesh with and are driven in the X direction by a sprocket actuated by the X magnet. The Y magnet actuates a pawl which engages the ratchet teeth of the cog roller, turning it around the shaft.

Since the switch is 100 point, the X motion is given 10 steps (plus one for overtravel) and the Y motion 10 steps (plus one for overtravel), thus providing for selection of any one of 100 lines. Since four wipers are involved and each wiper has its own set of 11 wire banks (each 11 wires deep), 44 rows of wires are lined up in front of the wipers. An X wiper is also provided, which is operated by a pinion and rack assembly actuated by the X magnet and which has access to a 23-wire bank to mark the level of X travel.

When the X wiper finds the proper level, thus positioning the wipers, on the carriage, before the proper wire banks, the X magnet is de-energized and the Y magnet, assuming control, moves the wipers into the wire banks until the proper line wires are reached.

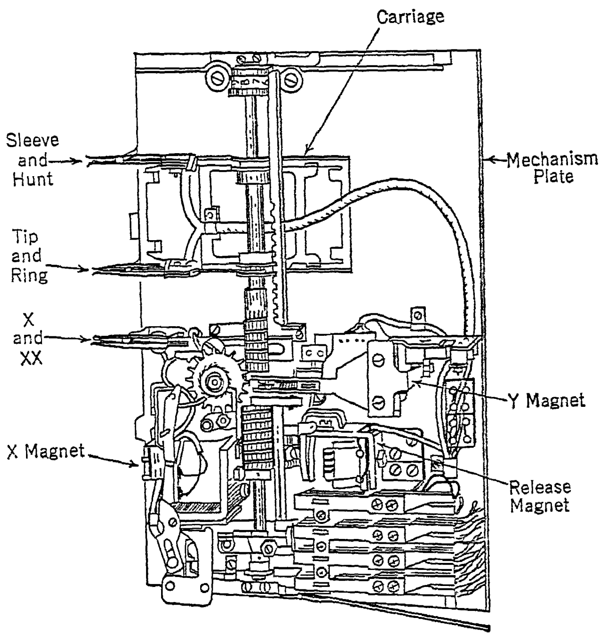

FIG. 34. The XY Switch (Courtesy Stromberg-Carlson Co.)

A number of unique features are built into the XY switch assembly, such as bare wire multiple for line terminations, a new mechanical design for magnet current interruptions to avoid armature chatter, and flexibility to function as a line finder, selector, or connector; the fact that the common wire banks need be wired only once, for up to 50 switches, results in large wiring economies.

The system requires line finders, selectors, and connectors, as in other step-by-step systems, but the XY switch functions for each of these three units.

In operation, the calling subscriber removes his handset from the hook, thereby causing his line relay to operate and an idle line finder, which is permanently associated with a selector, to find and connect to the calling line. The calling line is thus extended through to a selector which returns dial tone and supplies talking battery to the calling subscriber. Assuming that the called number is 234, the first digit dialed is 2, which causes the selector to move two steps in the X direction and into its wire bank automatically in the Y direction until an idle connector serving the 200 group of lines is found. When the second digit, 3, is received by the connector, it moves its wipers three steps in the X direction, and when the third digit, 4, is received, these wipers move into the wire banks in the Y direction to the fourth wire, thus connecting the calling to the called line. This connection is not completed, however, until the connector applies ringing power to the called line and the called subscriber has answered.

3. TOLL SYSTEMS AND OPERATION

Toll systems, as distinguished from local systems, are designed to handle toll traffic over toll circuits. Toll traffic differs very materially from local traffic, since toll circuits may extend from one toll office to a nearby toll office or to an office in this country or in almost any other country in the world, involving many thousands of miles of circuit.

Toll circuits must be of a grade suitable in all respects for the traffic they are required to handle. For the very long circuits, expensive equipment and complex arrangements are necessary to meet all requirements.

In the smaller offices the toll and local positions are identical or in the same lineup; the same line and cord circuits may be used for both local and toll service. In the larger toll centers, involving a number of toll circuit groups, separate manual toll boards are provided for concentrating in one switchboard, for a given toll area or center, all the toll circuits serving that area. Such switchboards require special circuits and auxiliary equipment for properly recording, ticketing, timing, and supervising toll connections.

MANUAL TOLL SWITCHBOARDS now in use in large metropolitan centers provide outward positions for outgoing toll calls, inward positions for incoming toll calls, and through positions for toll calls switched through the board from one toll circuit to another, or, if desired, toll positions may be designed to handle both inward and through toll calls.

One type of manual toll switchboard (Western Electric Co. No. 3C) now in use is equipped to handle all types of manual toll switching and, in connection with step-by-step offices, may be arranged to handle those local dial calls requiring the assistance of an operator.

The functions of this particular type of board are (1) to establish outward toll connections while holding the calling subscriber on the line (combined line and recording [CLR] traffic), or to establish connections later, if for any reason the call cannot be completed on the first attempt; (2) to connect inward toll calls to the called subscriber line if in the local or tributary office area; (3) to interconnect toll circuits (through traffic) upon request of a distant operator; and (4) to handle miscellaneous local calls.

Outgoing calls from local or tributary (small office, having toll connections to its larger toll center office) offices reach the toll board over recording-completing trunks from local manual or mechanical offices or over tributary toll circuits from tributary offices. Inward calls reach the toll operator over toll circuits (between toll centers) and are completed to the local called subscribers over toll switching trunks, either on a straightforward basis through manual B boards or by dialing or key pulsing over mechanical trunks through a mechanical office.

This switchboard has nine jack panels and three operator positions, each equipped with ten pairs of high-impedance toll cord circuits, per section, and by adding sufficient operator positions to handle the traffic load as many toll and trunk circuits as required can be terminated in the switchboard.

These boards are equipped with calculagraphs for stamping the tickets with the elapsed time of calls for billing purposes, electric clocks, ticket conveyors, ticket holders and compartments, and many other auxiliary devices for handling toll traffic. Transmission gain may be introduced in the toll circuits, as required, when the operator inserts the plug of her cord circuit into the toll line jack. Idle circuits and circuits busy may both be indicated by lamp signals, and automatic listening equipment may be provided at inward positions for incoming plug-ended toll circuit operation.

MECHANICAL TOLL SWITCHBOARDS OR SYSTEMS have been in use for some years in a number of comparatively small toll networks, the first systems being of the dial or step-by-step type.

The step-by-step system of toll dialing, though useful and economical for a small group of interconnected dial offices, presents sizable operating problems where intertoll dialing is attempted over an extensive area involving a large number of intermediate offices.

The mechanical switching of toll traffic requires that the digits dialed by a calling subscriber or originating operator at a given office, to reach a particular subscriber in another part of the country, must be different from the digits dialed to reach any other subscriber. In step-by-step toll dialing offices, the originating toll office is reached by the subscriber dialing zero (0), tributary offices by dialing the figure one (1), and two more digits are generally required to select the proper outgoing toll or tributary circuit. Thus, when a call is dialed through a number of step-by-step toll offices, three digits must be dialed for each office passed through in addition to the digits required for the terminating office and called subscriber line. This requirement results in a long series of dialed digits for a call that passes through a number of intermediate offices. Figure 35 shows that 19 digits are required for a call from Portsmouth, N. H., to Vinland, Kans., involving only four intermediate offices. Additional intermediate offices, in this connection, would increase the digits to be dialed, so that not only would there be delays in ascertaining the proper codes to dial in order to extend the call through the various intermediate offices, but also the dialing of a long series of numbers would retard operating time, would hold expensive facilities unnecessarily long, and would tend to increase operating errors. Also, if delays

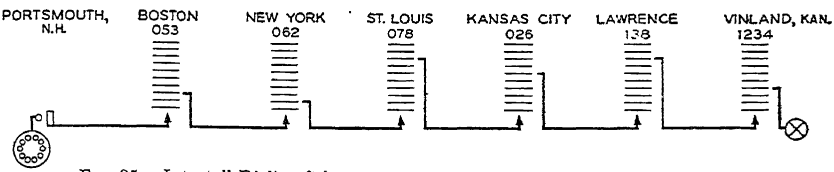

FIG. 35. Intertoll Dialing Scheme—Step by Step System (Courtesy Bell System)

were encountered in securing any intermediate link or if the called line was busy, the complete dialing process would have to be attempted again.

THE NO. 4 CROSSBAR TOLL SYSTEM, a development of the Bell System, was first placed in service in Philadelphia in August 1943. This system was developed primarily to provide for ultimate toll dialing on a nationwide basis and was designed so that it could be introduced gradually throughout the country on an economical basis without immediately displacing existing manual or mechanical systems except as desired.

The No. 4 system is arranged, as shown in Fig. 36, to complete (1) outward calls from local subscribers to outgoing toll lines, (2) inward calls from incoming dial or manual lines

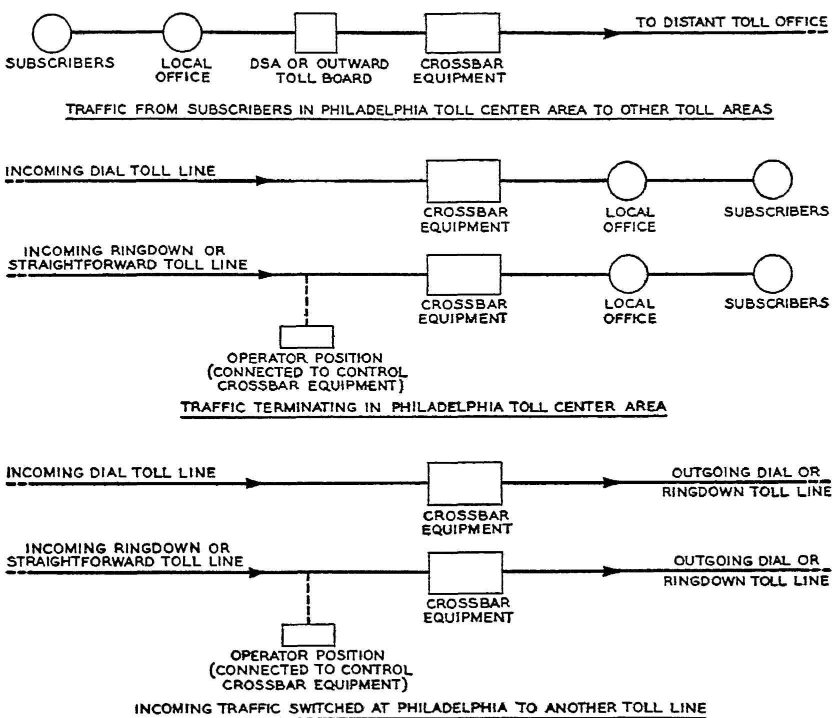

FIG. 36. Types of Calls Handled by the Crossbar System (Courtesy Bell System)

to local subscribers, (3) through calls between incoming and outgoing dial or manual toll lines.

Outward calls, and incoming calls from toll lines equipped for toll-line dialing, are automatically switched under control of dials or keysets at the originating end of the lines.

Incoming calls from other types of toll lines (ringdown or straightforward) are routed to operator positions.

In the No. 4 system, crossbar switches with senders and markers are used in the same general way as in the local crossbar system, with such variations as are required for toll traffic. The operator positions which supplement the mechanical switching system for handling terminating and through calls from toll lines not equipped for toll-line dialing are of the cordless type, but cord positions may also be used to facilitate handling calls over congested toll-line groups. This system permits toll-line dialing into a city having panel or crossbar offices.

Figure 37 shows a block schematic of the main circuit components of the No. 4 crossbar system. *Five types of senders* which act as automatic operators are provided, three for incoming and two for outgoing trunks. For each incoming call, an *incoming sender* is connected, and, unless the call is to be completed over a manual trunk or one equipped to receive multifrequency pulsing at the distant end (in which case only an incoming sender is required), an *outgoing sender* is also connected, as shown in Fig. 37. When an outgoing

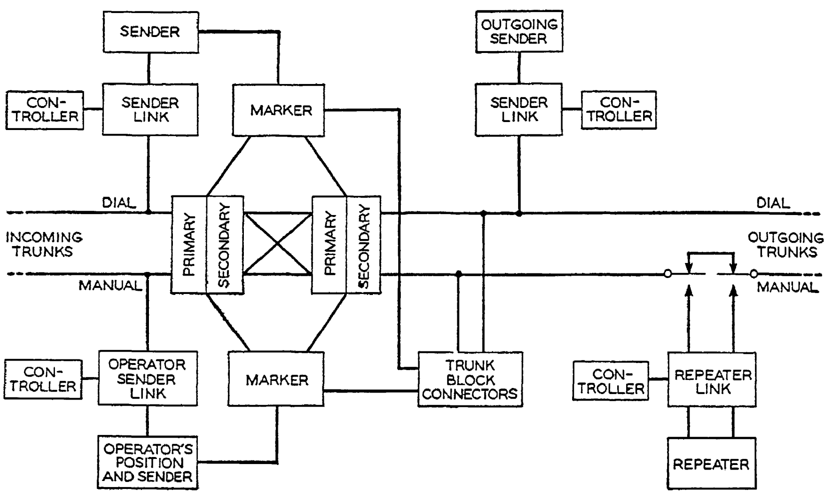

FIG. 37. Block Schematic of Main Circuit Components of the No. 4 Crossbar Toll System (Courtesy Bell System)

sender is used, the incoming sender transfers, through the primary and secondary frames, all the digits received except the first three, which are used by the marker to control the connection within the office. Incoming senders are designed to transmit d-c key pulses and outgoing senders to receive them, the transfer of digits being at the rate of 8 per sec. All incoming senders are also arranged to send out multifrequency pulses, so that outgoing senders are not required when the terminating points have senders capable of receiving this type of pulse, such as at local and toll crossbar offices. Ultimately, when multifrequency pulsing becomes general, outgoing senders may be eliminated. While incoming senders are arranged to send either d-c or multifrequency pulses, the *dial incoming sender* is designed to receive dial pulses (10 or 20 per second) recorded on crossbar switches, and the *key pulsing incoming sender* to receive d-c or multifrequency pulses, as may be indicated by a signal from the incoming circuit, as recorded on relays, four relays for each digit. The third type of *incoming sender* (*position*) is associated with each operator's position; on an outgoing call from the position, the sender connects to a marker, into which it passes the first three digits received, for the purpose of establishing connection to the desired outgoing trunk. When this trunk is selected an outgoing sender is attached, except when the trunk is on the manual or multifrequency basis.

Both types of *outgoing senders* receive d-c key pulses, but each type sends out different signals, depending on the signal the sender receives from the outgoing trunk. *One type* receives four or five digits and controls the sending of either revertive or call-indicator pulses. Revertive pulses are used for completing calls to panel or crossbar offices; call-indicator pulses, for calls to manual offices in panel areas. *The other type* of outgoing sender receives up to 11 digits, and either sends them out as dial pulses into a step-by-step office or connects itself to a call-announcer and controls the sending of the latter's voice announcements, which are limited to five digits.

Figure 38 shows the types of connections that incoming and outgoing senders are required to control. For a call to a local office within the crossbar toll office area, only the called office code and four or five digits are required to reach the subscriber from the crossbar toll office, since the trunk selected by the crossbar equipment connects directly with the called office. For a call to another switching area through an intermediate point, one, two, or three additional digits for use at the intermediate point must be dialed or keyed following the switching code, requiring up to 14 digits maximum.

All senders are safeguarded from being held too long on a connection by timing circuits, which, after a predetermined time, signal the originating operator to start the call again, and are then released. When trouble involving the sender exists, the sender is automatically held for inspection and the maintenance forces are notified by alarm circuits.

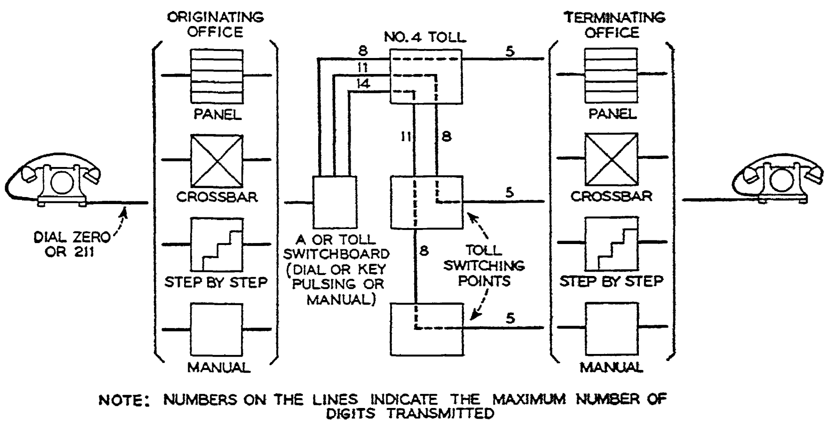

FIG. 38. Representative Types of Calls Switched by the No. 4 Crossbar Toll Office (Courtesy Bell System)

TELEPHONE REPEATERS are essentially voice-frequency amplifying devices with suitable talking and monitoring features designed for use in voice-frequency toll circuits which would, without amplification, be greatly restricted in their length. By means of such devices, properly spaced and controlled, toll circuits may be extended to any practical length desired.

In the early designs, telephone repeaters were basically of two types, those in the Bell System being designated 22-type for two-wire circuits and 44-type for four-wire circuits. Present Bell System practices employ a single type of amplifying device for either two- or four-wire circuits, and suitable connecting arrangements to connect it into the two- or four-wire circuits or any combination of such circuits.

Figure 39(*a*) and (*b*) shows a schematic diagram of the two- and four-wire arrangements, respectively. Where a repeater is employed at the junction of a two- and a four-wire circuit, the two-wire arrangement is used for connection of the repeater to the two-wire circuit and the four-wire arrangement for connection of the repeater to the four-wire circuit.

In the *two-wire arrangement*, the separate branches of the amplifiers are joined electrically through *repeating coil hybrids* for a repeater at an intermediate point in the telephone circuit. For a repeater at the terminal of a circuit a *resistance hybrid arrangement* (see Fig. 39[*c*]) usually takes the place of the repeating coil hybrid on the switchboard (drop) side of the repeater. In the *four-wire arrangement* repeating coil hybrids are not used, except where required at the junction of two- and four-wire circuits. Four-wire terminating sets are employed on the drop side of four-wire repeaters.

The repeating coil hybrid arrangement (Fig. 39[*a*]) consists of two repeating coils, *A* and *B*, with low-inductance windings so related and connected as to form, with associated equipment and the line, a balanced bridge circuit when the line and balancing equipment impedances are equal and the impedances connected to terminals 2–5 of each coil are equal. Coils of different ratios to match various line circuit impedances, and with phantom circuit taps for securing a phantom circuit, if desired, are available.

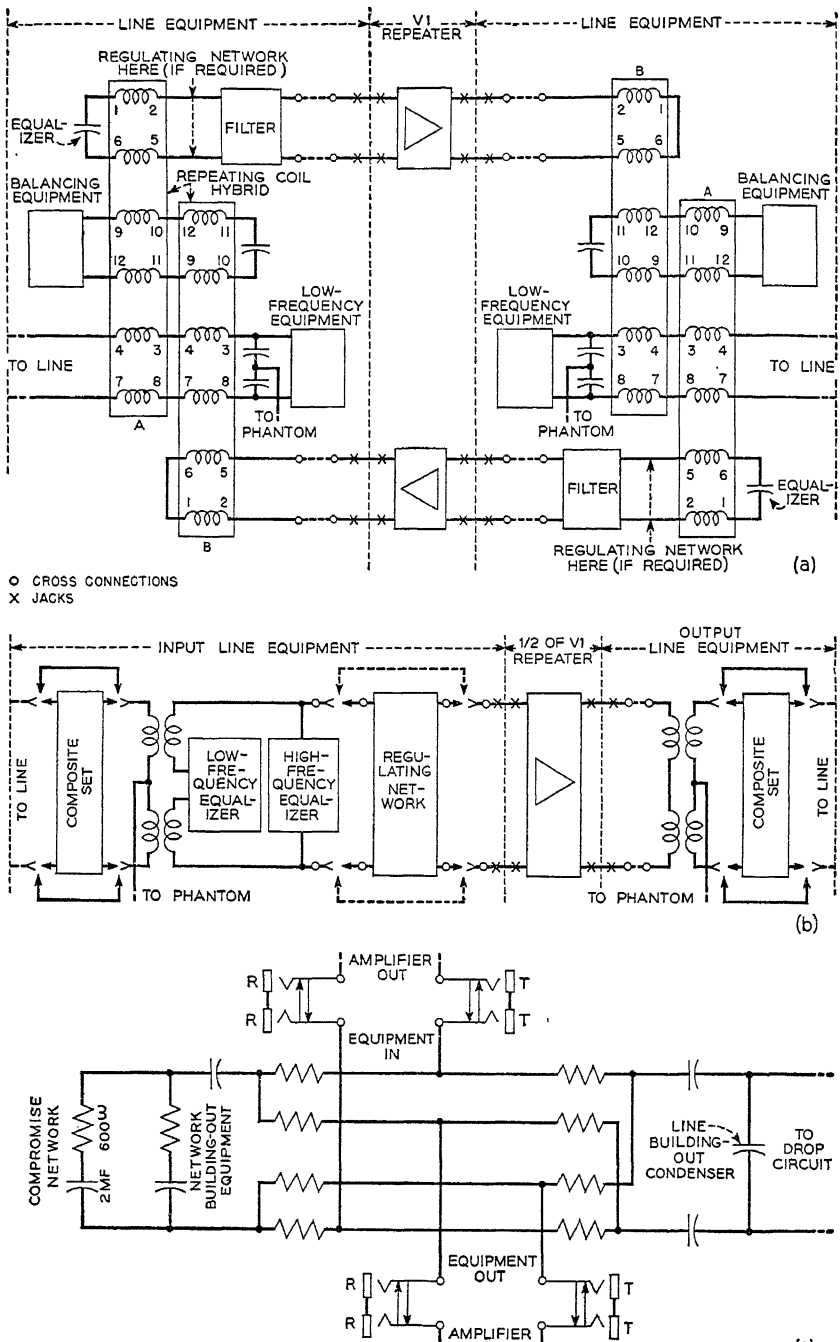

Fig. 39. Terminating Arrangements used with Telephone Repeaters (Courtesy Bell System)

Incoming current from the line flows through the line windings of both coils and induces equal voltages in the network windings 9–10–11–12 of both coils. Since the poling of the network windings of coil *A* are reversed with respect to the network windings of coil *B*, the resultant voltage across the network (balancing equipment) is zero. The voltages induced in the 2–1–6–5 windings of both coils are likewise equal, and the power received from the line (deducting coil losses) divides equally between the impedances of the amplifier branches connected to 2–5 of each coil. Since these branches transmit in opposite directions, the power received from the line from a given direction by one of the branches and its amplifier is effective, while that received by the other branch and its amplifier is ineffective.

Outgoing current from the effective amplifier flows through the 2–1–6–5 winding of coil *B* and induces equal voltages in the line and network windings of coil *B*. The resulting currents in these windings also flow through the corresponding windings of coil *A* to the line and balancing equipment, respectively. The currents in the line and network windings of coil *A* induce equal voltages in the 2–1–6–5 winding of coil *A*, but these voltages are opposing in phase because of the reversed poling of the network windings, and the resultant voltage is zero. The power received from the amplifier (deducting coil losses) thus divides equally between the line and the balancing equipment. The power received by the line is useful, while that absorbed by the balancing equipment is wasted.

In order to secure a satisfactory trans-hybrid balance, the windings of a given coil must be mutually balanced to a high degree of precision, but separate coils need not be so highly balanced with respect to each other.

The resistance hybrid arrangement (Fig. 39[*c*]) is composed of resistances, condensers, and the necessary terminating jacks connected to form a four-branch balanced lattice type network. This network joins together the amplifier branches on the terminating (drop) side of the repeater and terminates them in the required 600-ohm two-wire drop. The network presents a 600-ohm impedance in all four directions. The 1000-cycle loss through this network is 10.7 db for each direction of transmission.

In the *four-wire arrangement*, one-half of an amplifier unit is employed in each side of the four-wire circuit, transmitting in one direction only. Single repeating coils, of the type used with two-wire arrangements, are provided to match the impedances of the line and amplifier. Phantom taps are provided in these coils, and the coils must be matched for balance when phantom circuits are employed.

The amplifier circuit of the repeater is shown in Fig. 40. This circuit has a nominal input impedance of 600 ohms, and the input transformer impedance ratio (windings 9–8 to 1–7) is 300 to 357,000 ohms. The output transformer has four windings, of which winding 9–10 is for the negative feedback feature. The output impedance ratio of this transformer (windings 7–8 to 1–2) is 21,000 to 600 ohms.

The *amplifier vacuum tubes* are heater-type pentodes, 310 A for regulated and 328 A for non-regulated battery supply.

Grid bias on the tubes is obtained from the voltage drop in resistances *B* and *C* and in the *potentiometer* through which the total cathode current flows.

The total gain of each amplifier is about 35 db; the secondary winding of the input transformer is tapped to provide a total gain adjustment of 20 db in 4-db steps; and the potentiometer serves as an additional gain control with a range of about 5.4 db. The power-carrying capacity of the amplifier is such that the transmission level at the *amp out* jacks may be as high as +10 db with respect to the transmitting switchboard. The nominal d-c battery supply is 24 volts for the filament current and 130 volts for the plates.

Attenuation equalizers for two-wire repeaters are associated with the line equipments and are connected to the amplifier inputs at intermediate repeaters and to the receiving amplifier line input at terminal repeaters (terminals 1–6 and 2–5 of coils *A*, Fig. 39[*a*]). They are of the fixed type and designed for repeater sections of average length. The *low-frequency equalizer* for equalization in the low-frequency range consists of capacitance or a combination of capacitance and resistance, depending on the line characteristics. At two-wire circuit terminals, this equalizer is omitted in the transmitting side of the terminal repeater. *High-frequency* equalization on two-wire circuits is obtained by the effects of the various equalizer units mentioned and by interaction effects between the filter and the impedances between which it is inserted.

Equalization for four-wire circuits (see Fig. 39[*b*]) is provided by a low-frequency equalizer consisting of a condenser shunted by a resistance, and a high-frequency equalizer consisting of a combination of resistance, inductance, and capacity.

Low-pass filters of nominal 600-ohm impedance are provided, to limit currents above the voice range to be transmitted, in the four-wire branches of the line equipment, associated with the amplifier input for the two-wire arrangement, as shown in Fig. 39(*a*). Three types of filters are provided, having nominal circuit cutoffs of 2450, 2850, and 3500 cycles per second. The filter is omitted from the transmitting branch of terminal repeaters.

Regulating network equipment is provided for insertion in the repeater circuits (see Fig. 39[*a*] and [*b*]), as required, to compensate for changes in line attenuation due to temperature variations. This equipment functions under control of a pilot wire regulating system which actuates relays, causing resistance-type loss pads to be cut in or out of the repeater circuit, as required, to maintain circuit transmission levels. This equipment is more fully described in another part of this section.

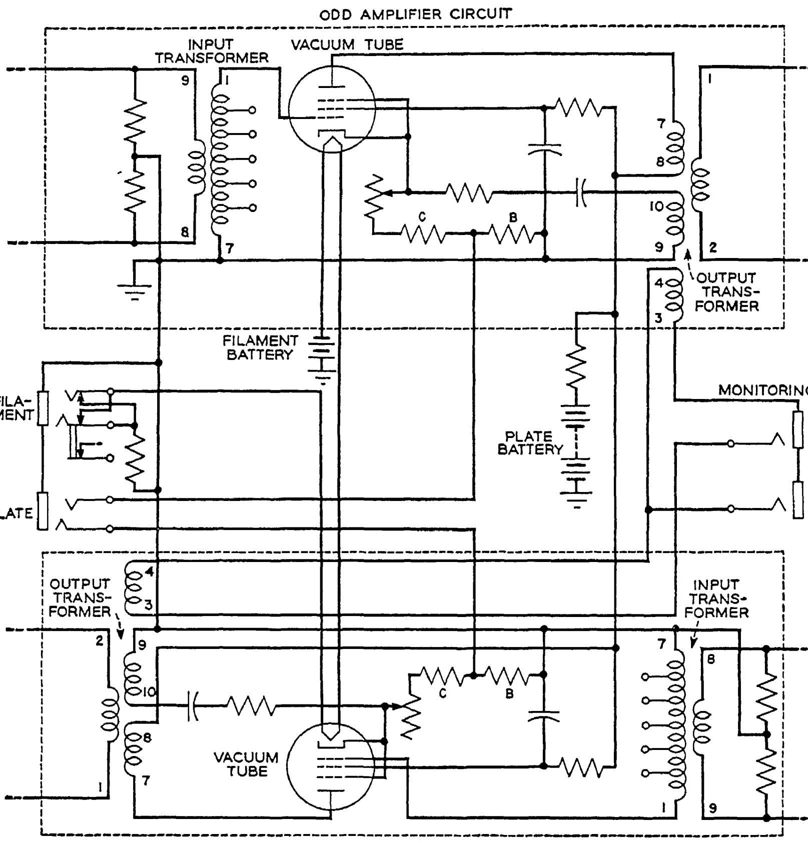

Fig. 40. VI Telephone Repeater Circuit (Courtesy Bell System)

The balancing equipment, connected to 9–12 of each *A* coil (Fig. 39[*a*]), is required to balance the line and its equipment (up to the repeating coil hybrid) in each direction of transmission for two-wire arrangements but is not required for four-wire arrangements, at intermediate points. At both the two- and four-wire terminal repeaters, a simple compromise network is employed on the drop side with the resistance hybrid (Fig. 39[c]) and four-wire terminating sets, respectively. Balancing equipments are designed in various combinations of resistance, capacitance, and inductance to closely match the impedance of their various associated lines.

Signaling over repeater-equipped circuits requires the use of auxiliary signaling circuits employing 20, 135, or 1000 cycles or composited d-c signaling on *two-wire circuits*. The 20- and 135-cycle and composited d-c signals are by-passed around intermediate repeaters, through which such signals will not pass, but 1000-cycle signaling will pass through the repeaters in the same manner as voice-frequency currents. For *four-wire circuits*, in which there are usually a number of repeaters, 1000-cycle signaling is generally employed as the most economical and satisfactory arrangement.

CARRIER TELEPHONE SYSTEMS permit the securing of additional telephone channels between two toll centers by superimposing carrier frequencies on voice-frequency wire circuits between these points. At the terminals of the carrier channels, carrier equipment is required which is capable of converting voice frequencies to modulated carrier currents, transmitting them over the wire circuit, and reconverting or demodulating them at the receiving end to voice frequencies. This equipment must operate in both directions of transmission. Carrier equipments (carrier repeater or transfer units) are also employed for amplifying carrier currents and for transferring the carrier channels where the wire circuit does not, but the carrier channels do, extend through the intermediate office.

Carrier telephone systems are in operation in many countries, but they are in use to the greatest extent in the United States because of its vast network of toll circuits. These systems are manufactured by a number of different companies, both Independent and Bell, the number of two-way channels provided in the various systems ranging from one to twelve, excluding the L-type carrier system. The Bell System is the largest manu-

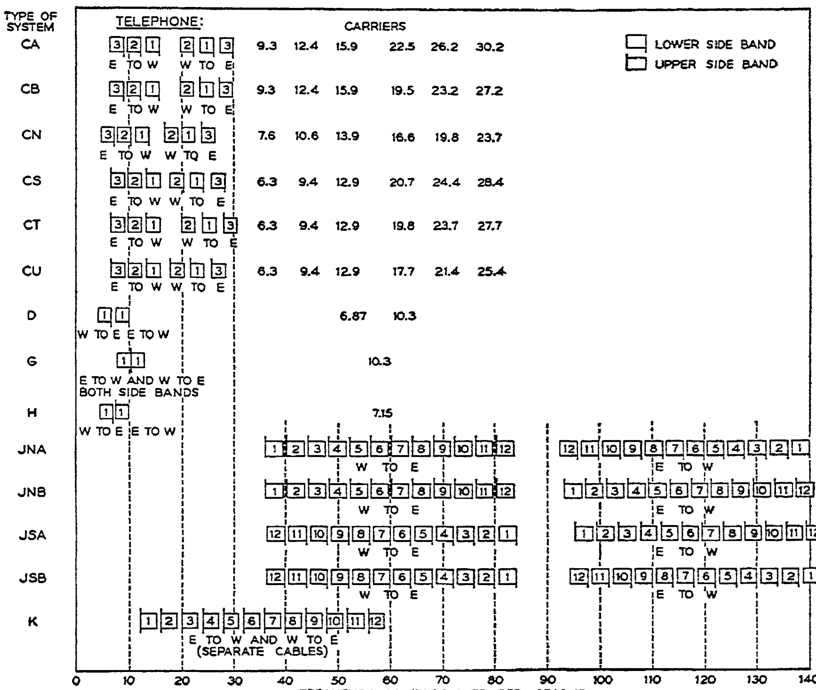

FIG. 41. Channel Frequency Allocations for Telephone Carrier Systems (Courtesy Bell System)

facturer and user of carrier telephone equipment in this country, and the frequency allocation chart shown in Fig. 41 applies to carrier systems of Western Electric Co. (Bell System) make. From this figure, it is seen that the D, G, and H systems provide a single channel, the C series three channels and the J and K systems twelve channels, all two-way.

In operation, the basic principle is the same, regardless of the type of system or the number of channels provided. Figure 42 shows a block schematic of a type C carrier telephone system with one intermediate carrier repeater.

It will be noted that each of the three channels has identical equipment units at both the east and west terminals, and that identical common equipment is provided at each terminal to serve each of the three channels. The carrier repeater also serves all three channels. Voice-frequency transmission over the wire circuit is not interfered with by, nor does it interfere with, the carrier currents, because of the low-pass and high-pass filters associated with the wire line at each terminal and at the repeater or transfer points. The low-pass filter will pass only voice and the high-pass filter only carrier frequencies.

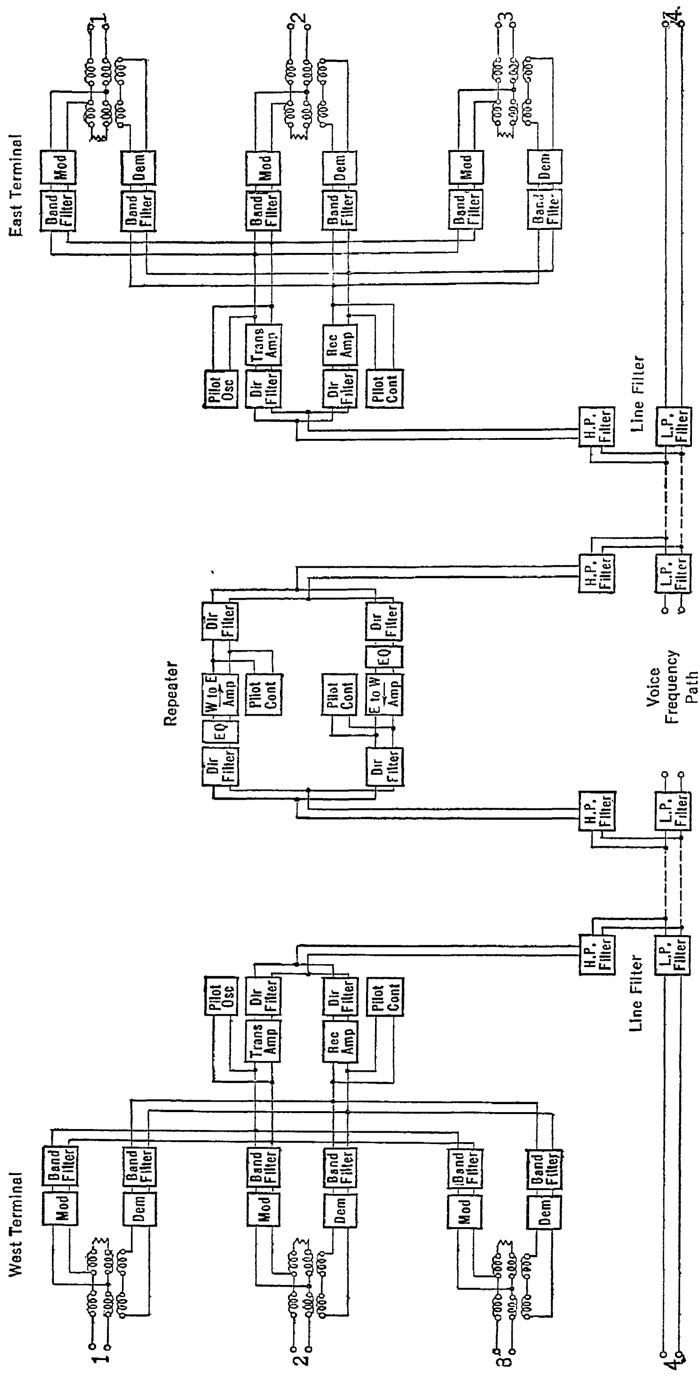

FIG. 42. Type C Carrier Telephone System (Courtesy Bell System)

Incoming voice frequencies (about 250–2750 cycles) into channel 1 (Fig. 42) at the west terminal pass to the modulator, where they modulate a carrier frequency. The lower sideband only (assuming this system is of the CS type) is transmitted through the band filter, transmitting amplifier, and directional and high-pass filters to the wire line. At the intermediate point the sideband frequencies pass through the high-pass and directional filters, equalizer, west to east amplifier, directional and high-pass filters, thence to the line. At the east terminal the sideband passes through the high-pass and directional filters, receiving amplifier, band filter, and demodulator to the voice terminal of channel 1. Transmission takes place similarly in the opposite direction. The band filters pass only the band of frequencies intended for their particular channels, blocking out all frequencies of other channels which travel the common paths. The directional filters separate the incoming and outgoing bands of frequencies. The amplifiers, which are of the high-gain, negative-feedback type, are necessary to maintain proper levels of transmission for the carrier currents. The pilot equipment indicates and controls the transmission levels automatically, so that manual adjustments are not required. The three-winding transformers (hybrid coils) separate the transmitting and receiving voice paths at the voice-frequency terminals of each carrier channel.

For *open-wire operation,* present practices make use of the G system for single-channel very short circuits (under about 25 miles), the H system for single-channel medium-length circuits (up to about 300 miles, with repeaters about every 125 miles), and the C system for three-channel groups ranging from about 100 miles to any length desired with repeaters about every 150 miles. The G system equipment does not have an amplifier, but one may be associated with the system externally. The CN allocation of the type C system and the D system are not used for new installations. All these systems are considered to be in the *low-frequency* group of carrier systems (up to about 30 kc), and they provide about 2500-cycle voice bands.

The *broad-band* carrier systems operate in a range from about 12 to 2000 kc or more and provide about 3000-cycle voice bands. As may be noted in Fig. 41, the K system, for toll cable use, functions between 12 and 60 kc; the J system, for *open wire,* between 36 and 140 kc; and the L system (not shown), for *coaxial cable* use only, between 60 and 2000 or more kc. The J and K systems may be operated any distance desired but require repeaters about every 70 and 16 miles respectively.

The L type carrier system, operating over specially designed conductors, known as coaxial cable, because of their construction, is capable of providing up to 480 two-way circuits per pair of coaxials (depending on the make-up of the cable) if coaxial amplifiers are spaced about 5 to 8 miles apart. Practically, however, the number of circuits to be provided in any L system will depend upon traffic requirements, since circuits can be added as desired at any time in groups of 12.

Figure 43 shows the frequency translations which take place at an L type carrier telephone system terminal. *Three steps of modulation* are employed to change an individual voice-frequency channel of 0 to 4 kc to its proper line frequency assignment. The *first step of modulation* occurs in the channel bank and translates a group of 12 voice channels to the 60 to 108 kc frequency band. The *second step of modulation* occurs in the group modulators and moves each fundamental group of 12 channels each (60 to 108 kc) to one of five frequency assignments (each 48 kc wide) within the 312 to 552 kc band. This band, designated a basic supergroup, is 240 kc wide and accommodates 60 channels of 4 kc each. The *third step of modulation* occurs in the supergroup modulators and translates each basic supergroup of 60 channels each (312 to 552 kc) to one of eight frequency assignments (each 240 kc wide) within the 68 to 2044 kc band. The 480 voice-frequency channels take line frequency positions within the 68 to 2044 kc band, and the four pilot channels are assigned to frequencies of 64, 556, 2064, and 3096 kc. The supergroups are separated by 8 kc each, except that 4 kc and 12 kc separate the first and second supergroups and the second and third supergroups, respectively.

All long-haul carrier systems, including the C, J, K and L systems, have regulating and pilot channel equipment which automatically adds transmission gain or loss as is necessary to maintain the channels within predetermined transmission equivalents. For *cable facilities* the normal transmission changes are due to temperature variations, being greater in aerial than in underground cable. Flat gain regulators with master controllers are employed in every repeater section for K systems. However, the amount of attenuation variation in cable pairs with a given change in temperature is not the same for all frequencies, an effect known as *twist.* To overcome twist effects, correcting circuits are also provided about every 100 miles for aerial and 200 miles for underground cable.

Large economies are possible with carrier systems, principally to provide additional toll circuits between toll centers. Their usage avoids, in many cases, the stringing of expensive wire circuits or possibly building a new pole line for open wire or cable or placing underground cable. In any event, studies will indicate the economies involved.

The basic 12-channel equipment units of the J, K, and L systems are similar, the channel modulators elevating the voice-frequency bands for 12 channels (4 kc per channel) from 0–48 kc up to 60–108 kc for these systems. Similarly the channel demodulator receives the 12 channels at 60 to 108 kc. The K system operates over separate toll cable pairs in separate cables with carrier repeaters, using the 12 to 60 kc band in each direction in the

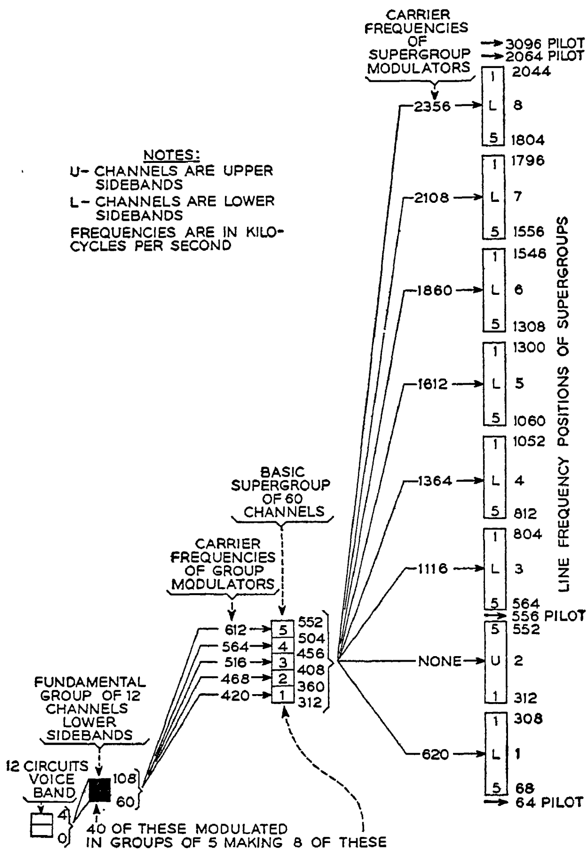

FIG. 43. Frequency Translations at an L-type Carrier Telephone System Terminal (Courtesy Bell System)

cables. The J system employs the same open-wire circuit in both directions, using line frequencies of 36 to 84 kc west to east and 92 to 140 kc east to west. The L system employs two coaxial units for the two directions of transmission, hence the same frequency band, from 60 to the required top kilocycle frequency, in each direction. Group frequency modulators move 12-channel groups from one frequency range to another, as required.

Figure 44 shows a block schematic of a type J carrier telephone terminal; Fig. 45, a type K carrier telephone terminal in more detail; and Fig. 46 a frequency translation diagram for the type J system.

The particular range of frequencies, 60 to 108 kc, to which the voice frequencies are first elevated in the J, K, and L systems was chosen, because (1) high-grade crystal filters can be most economically built for operation in this general range, (2) the second harmonic (120 kc) of the lowest frequency (60 kc) lies well above the highest frequency (108 kc), precluding the possibility of interference between the second harmonic (from any channel) and other channels, and (3) manufacturing economies are achieved by using the same

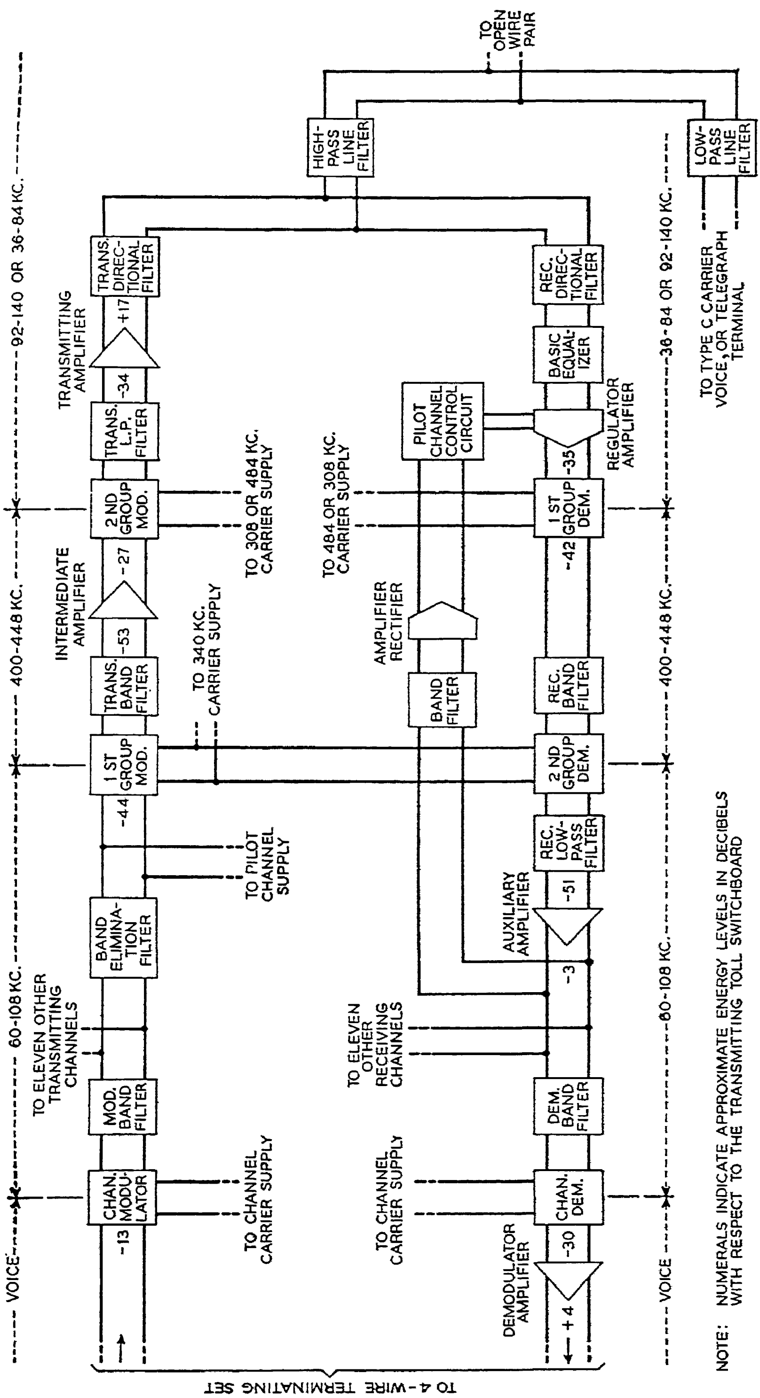

Fig. 44. Type J Carrier Telephone System Terminal (Courtesy Bell System)

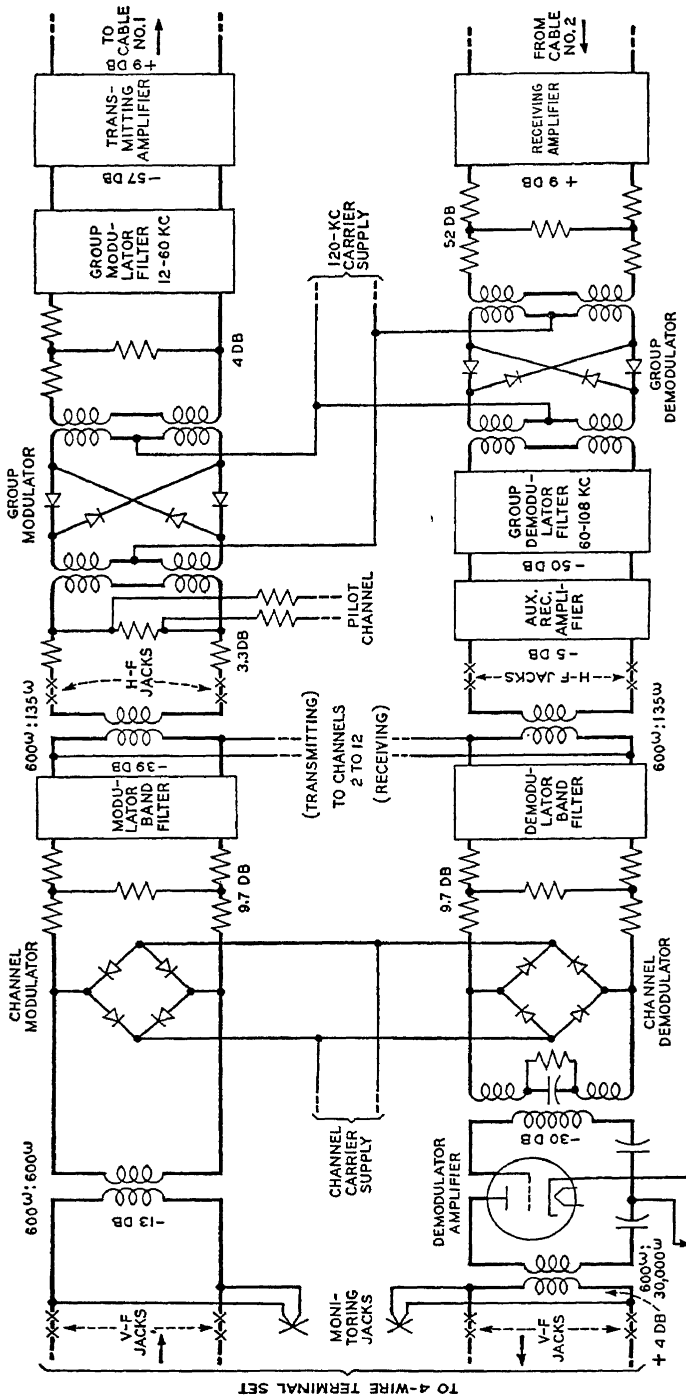

FIG. 45. Type K Carrier Telephone System Terminal (Courtesy Bell System)

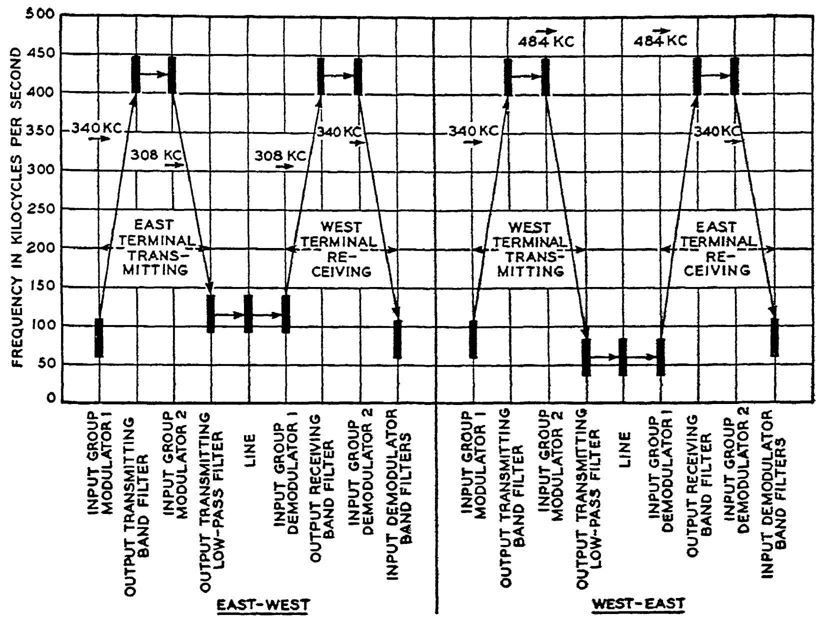

FIG. 46. Frequency Translations in Type J Carrier Systems (Courtesy Bell System)

group of channel carrier frequencies for all the broad-band systems. The line frequencies 12 to 60 kc were chosen for the K system because, for non-loaded cable pairs (loading not being available for these frequencies), the attenuation increases with frequency and in the frequency range chosen the attenuation-frequency increase is about uniform.

4. TANDEM SYSTEMS AND OPERATION

Local tandem offices are provided, usually one to each extensive multioffice area, where a large number of offices are located within and adjacent to city boundaries. The tandem office is generally centrally located to the offices it serves and has direct trunks to all these offices and also to attended PBX (private branch exchange) switchboards having a number of pay stations, to the toll board, and to various special service boards. It is neither economical nor practical in large metropolitan centers to provide a group of outgoing and a group of incoming direct trunks between each pair of offices in the center, since cable plant and the terminating trunk equipments required would be too costly. For many combinations of two offices some distance apart the traffic is usually so light as to preclude the use of expensive cable pairs between them for trunk purposes. Thus, the tandem office provides an economical means of trunking calls in the larger centers because a common trunk group is provided between each office served and tandem.

Although the introduction of a tandem office in the call trunking system of a given area adds another office to the system and may materially lengthen the trunk mileage between certain pairs of offices, depending on the geographical location of the tandem office with respect to the surrounding offices, it is evident that two groups of trunks (one outgoing and one incoming) between each pair of offices in a large center of, say, 50 offices would result in an uneconomical trunk network and equipment layout and a more complex arrangement of handling traffic. Also, the greater number of calls handled by the tandem trunk groups increases their efficiency and may largely offset the tandem layout costs. Tandem offices are warranted, however, in any particular case only if a comprehensive study of all the various factors involved indicates their need.

One system of tandem trunking now in use provides for trunking from a local manual office to a *panel sender tandem office* on a straightforward basis. The local A operator, upon receiving a call, inserts the calling plug of an A cord circuit into an idle outgoing trunk to tandem, causing selection to be made at the tandem office of an idle operator and a tone to be sent back to the A operator indicating that the tandem operator is ready to receive the call. The A operator passes the called office name and number over the trunk to the tandem operator, who registers this information on a keyset (a unit composed of individual keys having office code and number designations), with which each tandem position is equipped. The operation of the keys in the keyset causes pulses or number announcements to be sent out over the tandem to called office trunk, thus reaching the called office.

If the called office is of the step-by-step, panel, or crossbar type, the incoming pulses from tandem reach selector (in step-by-step) or sender equipment (panel or crossbar) in the called office, which completes the connection to the called subscriber in the regular manner, as previously described for these systems.

If the called office is of the manual type, the incoming pulses reach call announcer equipment at the tandem office before passing out over the trunk where they are converted from pulses to spoken numbers which reach an idle B operator's ear at the called office; or, where call announcer equipment is not provided, the tandem sender equipment sends out pulses over the trunk to call indicator equipment at the called office, which causes the called number to be displayed before the B operator. In either case the B operator connects the plug-ended trunk circuit over which the call is being routed into the called subscriber multiple jack, and ringing automatically starts on the called line. Supervision of the call at the local, tandem, and B boards is by means of the usual lamp signals.

If the calling subscriber is in a mechanical office (step-by-step, panel, or crossbar), the call is usually routed to a special board in the calling office. The special operator passes the call to tandem on a straightforward basis, and the connection is then completed by the tandem operator in the same manner as described for a calling local manual office.

Crossbar tandem equipment is now standard for new tandem offices, rather than the manual tandem arrangement, just described, where it is applicable. This equipment handles calls over two-wire trunks from panel or crossbar offices to other panel, crossbar, or panel indicator manual offices by means of crossbar switches in a marker system of operation. Calls from a manual office through crossbar tandem would reach a tandem operator over straightforward trunks and be completed as described for the panel sender tandem office.

The major switching frames in crossbar tandem offices correspond somewhat to the frames in a local crossbar office. Incoming trunks, terminated on incoming trunk frames, connect through trunk link frames, an office junctor grouping frame, and office link frames to outgoing trunks, which terminate in incoming trunk equipment in other offices as shown in Fig. 47.

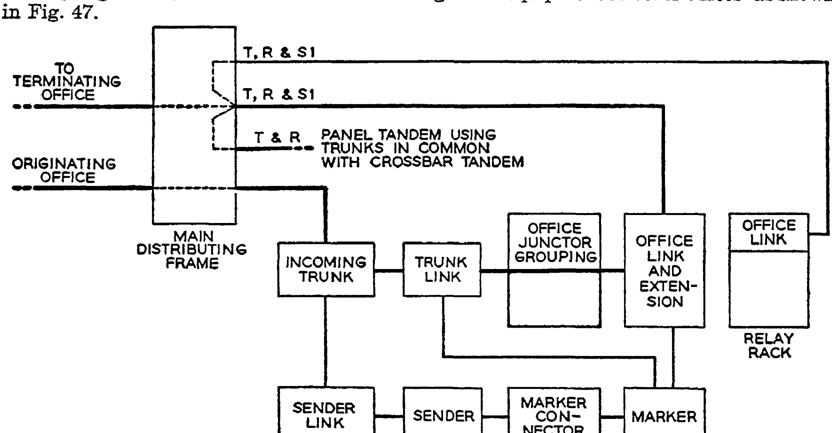

FIG. 47. Crossbar Tandem Office Units—Crossbar System (Courtesy Bell System)

When a call reaches the tandem office incoming trunk equipment, tandem sender and marker units are caused to associate with the trunk and link frames involved in the call. The sender receives and registers the incoming pulses from the originating sender on a revertive (pulses sent back) or dial pulse basis, and it controls the tandem switch selections and the selections in the called office. The marker which is associated with the sender through the marker connector frame routes the call through the tandem equipment under control of the tandem sender registrations.

5. AUXILIARY SERVICE EQUIPMENT

SERVICE OBSERVING DESKS are provided, where required, at individual offices or at a central location for observing the performance of switchboard operators and switching equipment.

One type of service observing desk is intended primarily as a non-centralized observing bureau for use with toll or local crossbar, step-by-step and manual, or combinations of toll and local plant. This desk is generally employed where not more than one desk position is required, and observations are confined to circuits at the same location as the desk. This desk is equipped with a cord circuit, operator's telephone circuit, jacks, lamps, keys, and other equipment for observing on lines and trunks.

For mechanically operated systems, pen registering equipment is also employed to record the subscriber dial and line registering pulses, as required.

Central observing desks require direct lines to the various offices which are to be observed, and as many desk positions as necessary to make the desired observations.

The information obtained by means of these desks is a very important aid in improving operator and equipment efficiency and in bettering service generally to the public.

INFORMATION DESKS are provided at individual offices or central locations to furnish subscribers with information about telephone numbers not listed in the telephone directory or changed from the directory listing and about many other items essential in assisting the subscribers to secure a wholly satisfactory telephone service. Up-to-date files of telephone listings are maintained at the information desks accessible to each information operator. Centralized information desks require that subscribers in each office be routed over the trunking system, provided for such service, to the centralized desk. Individual office information desks are reached over direct intraoffice trunks.

CHIEF OPERATOR DESKS are, if required, located one in each office. Various types of calls are referred to the chief operator, who is in direct charge of the operating forces. Complaints from the subscriber about the service rendered or any other items regarding the wishes of the subscriber in connection with calls the handling of which is not the operator's function are referred to the chief operator or a supervisor.

Trunks are provided from manual or DSA boards to the chief operator desks, over which these calls are routed.

REPAIR SERVICE DESKS are required in all but the very small offices to receive subscriber complaints of service or reports of trouble encountered with the substation equipment or telephone plant in general. Many other types of reports from the public are also referred to these desks, which are convenient contact points for subscribers. Records are maintained of troubles reported and cleared on subscriber lines, and valuable data are secured from them for studies of troubles and their elimination.

Repair trunks are provided at individual offices or to a central point for receiving these calls except in small offices where such calls are usually received at local testboards.

6. COMMON SYSTEMS

MAIN DISTRIBUTING FRAMES (MDF) are required in central offices for terminating the outside local and toll lines, which are usually brought into the office on cable pairs. These pairs terminate directly on protector strips, mounted vertically on the vertical side (VMDF) of the frame. In the smaller offices local and toll MDF are usually combined; in the larger installations, involving a number of toll and toll entrance cables, separate local and toll frames are provided. Terminal strips with insulated metal terminals are mounted horizontally in rows (shelves) on the horizontal side (HMDF) of the frame, and these terminals are cabled to an intermediate distributing frame (IDF). Cross-connecting wire (jumpers) may be run between any vertical protector strip and any horizontal terminal strip so that any incoming line on the VMDF may be connected to any pair of terminals on the HMDF. Other arrangements of protector and terminal strips are also used, depending on the needs of the individual office.

INTERMEDIATE DISTRIBUTING FRAMES (IDF) are usually employed in both manual and mechanical offices for local and toll lines. These frames have terminal strips on both the horizontal (HIDF) and the vertical sides (VIDF) of the frame. For *manual local lines* cabling from the MDF is terminated on the HIDF terminal strips, to which cabling from the manual A and B boards is also multipled. For small subscriber lamp multiple and single office boards, the B board and its cabling are omitted. The subscriber answering jacks in the A board and the line circuit equipment are cabled to the vertical terminal strips (VIDF). Cross-connecting wire may be run between any horizontal and any vertical terminal strip, thus providing a means of connecting any outside line to any subscriber A and B board multiple jack and to any answering jack and line circuit. By properly distributing heavy and light calling lines throughout the switchboard, traffic loads can be more uniformly spread over the operator positions.

Relay racks are also provided for mounting various types of apparatus, such as relays, repeating coils, apparatus mounted on panels, testing equipment, and many other equipment units.

PROTECTORS are provided at the vertical side of the MDF in all central offices having exposed outside cable or open wire plant in order to protect the equipment from damage due to excessive voltages and currents from foreign sources such as lightning and power lines. Figure 48 shows a typical protector used at main frames. Where the outside cable enters aerially and is exposed to these foreign sources, as it may be in small offices, fuses are also required in the circuits, unless the entering cable has at least 6 ft of 24 or finer gage cable inserted in it in such manner that no power line contacts can occur between the point of insertion and the MDF.

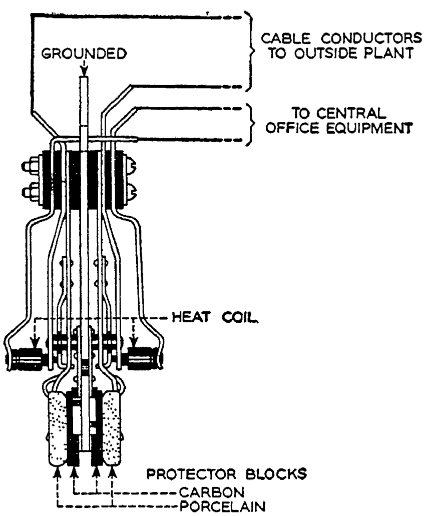

FIG. 48. Main Frame Protector with Heat Coils and Protector Blocks (Courtesy Bell System)

The protector consists principally of a spring assembly, arranged to hold two heat coils and two sets of protector blocks, one of each for each side of a metallic line. The heat coils designed to protect delicate central office equipment usually operate if 0.35 amp flows for 3 hours or longer or if 0.54 amp flows for more than 210 sec. This coil consists of a small coil of wire wound around a copper tube, into which is inserted a metal pin held in place by easily melting solder. The coil of wire is placed in series with the line conductor, and if sufficiently heated the solder melts, releasing the metal pin, which is forced against a grounding spring by the outside line spring of the protector. Several types of protectors and heat coils are available; some of the heat coils open the line conductor when they operate and may be reset mechanically without replacing or resoldering the coil. The protector blocks consist of a porcelain block with carbon insert and a solid carbon block, a pair to each side of the line, the air gap between the insert and carbon block being about 0.003 in. This gap will, on the average, break down at about 350 volts potential.

The protector ground bars are bonded to a main-frame ground bar which is connected to the office ground.

TESTBOARDS are provided in all attended central offices, and testing equipment of suitable design in all offices, for the purpose of determining the condition of lines and equipment, either because of reported or indicated trouble or as a trouble-preventive measure.

Many types of test cabinets and testboards have been made available to meet the needs of the particular location in which they may be installed.

In *small manual local offices* test cabinets, equipped with voltmeter (with batteries), test keys and cords, trunks, and in some cases an external Wheatstone bridge, are employed. In *large manual installations* a number of positions of testboard may be used, depending on the volume of repair and subscriber installation work involved. Each of these positions usually has a voltmeter, test keys and cords, trunks, and access to one Wheatstone bridge, as required. Lines and equipment are tested on reports of trouble or after installation work is completed, and, in case of trouble, its location is determined and the trouble is cleared by outside repairmen.

In *manual toll offices* testboards (primary, secondary, or both) are arranged with a group of jacks for each toll circuit, which is wired through these jacks before reaching the toll switchboard. The test positions are provided with voltmeter, Wheatstone bridge, test keys and cords, and trunks for testing lines and equipment and locating and clearing troubles. The testboard jacks also serve to patch lines and equipment to spare lines and equipment when the regular layout is in trouble or to make temporary circuit changes.

In *step-by-step local or toll offices* the testboard equipment is comparable to that provided in manual offices except that the positions are equipped with dials and dialing trunks for connecting to the various lines and equipments.

In *panel dial and crossbar local offices* a local test desk test selector frame is employed, consisting of a bay for sequence switches and a bay for relays, with terminal strips located at the side of the frame. This frame is used to associate the local test desk with the final selectors which are arranged for testing subscriber lines. The operation of the cutoff relay in the subscriber line circuit may be controlled from a key in the test desk. The six first selector circuits which connect to trunk circuits in the test desk have access to any one of 15 second selectors, which terminate in final test selectors. Test trunk ringing circuits are furnished as required. The test desk is equipped with voltmeter, test keys and cords, trunks, Wheatstone bridge if desired, and other necessary apparatus for checking the condition of and locating and clearing trouble on lines and equipment. In addition to the test desk there are various frames for testing the operating condition of the equipment, such as the outgoing trunk test frame, decoder test frame, and multiple registration test unit.

In *crossbar toll offices* a toll test board is provided for making overall tests on the toll trunks in order to locate troubles and restore the trunks to normal. A jack field is provided through which the intertoll trunks are wired, and miscellaneous trunks are terminated in this field. The circuits in this testboard are four-wire, requiring twin plugs. For talking and monitoring, the circuits are reduced to two-wire by means of a hybrid coil. A transmission-measuring system with the readings projected on screens at the ends of the testboard, a noise-measuring unit, and a variable oscillator are provided as part of the testing equipment. Outgoing toll trunks may be locked out (made busy) and tested by dialing through the *trouble tracing frame*, which seizes the incoming trunk connected to the outgoing trunk in trouble or to be tested and lights a lamp associated with that trunk at the testboard. The desired outgoing trunk may also be seized by plugging a test cord into the test jack appearance of the incoming intertoll trunk and operating the lockout relay in the outgoing trunk through the connecting switches.

In addition to the toll testboard a *maintenance center* is provided for each No. 4 crossbar toll system, in which various testing frames are located with a chief switchman's desk and files in front of the frames.

The maintenance forces at this center are occupied with responding to alarms, making tests, following up trouble reports and assistance requests, and maintaining records of the operations.

7. POWER SYSTEMS

Power equipment for central offices is required to provide direct current for talking and signaling and alternating and pulsating current for signaling and for many other auxiliary needs in telephone operations.

Power equipment for *magneto offices* usually consists of dry cells or a battery eliminator to supply direct current to the operator's telephone set and a hand generator and power-operated ringing device for ringing subscriber bells. Magneto subscriber telephones are supplied transmitter current by dry cells at each telephone or other power sources.

Power equipment consists of motor-generator sets and rectifier units (in *common-battery offices*) for supplying direct current for the energization of subscriber telephone transmitters, private branch exchanges or private automatic exchanges, central office cord and operators' circuits, relays, switches, alarms, carrier systems, telephone repeaters, and many other central-office units. Continuity of service is insured by the provision of storage batteries which float across the d-c office power supply and, in case of commercial power failure, will carry the office load for a short period of time, and by duplicate charging units operated by other than commercial electric power.

The types of charging and load supplying power units (including storage batteries) and of the signal supply units vary over a wide range of equipments, which have different capacities, functions, and characteristics depending on the office power load demands and the purposes for which the units are designed.

All common-battery offices, both local and toll, require 24- and 48-volt d-c supply, which may be provided by regulated rectifiers (mercury vapor, tungar, copper oxide, or selenium types) for the smaller loads; and motor-generator sets, singly or in multiple units, for the larger loads. In all cases, storage batteries of suitable capacity to provide for the 24- and 48-volt demand are bridged across the d-c power supply leads on a float basis; that is, the office load is carried by the generating units, the batteries serving as an emergency source of power. These offices may also require a 130-volt plate supply for carrier systems, telephone repeaters, and other vacuum-tube devices, which supply may be furnished from regulated rectifiers for small loads or from motor-generator sets for the larger loads. Storage batteries of the proper capacity are also required across this supply on a float basis for emergency reasons. Figure 49 shows a typical central-office power-plant arrangement with a single floating battery and automatic control. Although only one motor-generator set is shown, it is the usual practice to add these units for multiple operation as required.

Ringing and signal supply units may be of the vibrator or subcycle converter type for small offices or motor-generator sets for the larger offices. These units are designed to supply the usual 20-cycle, 75 to 175 volt ringing power, but certain multifrequency sets

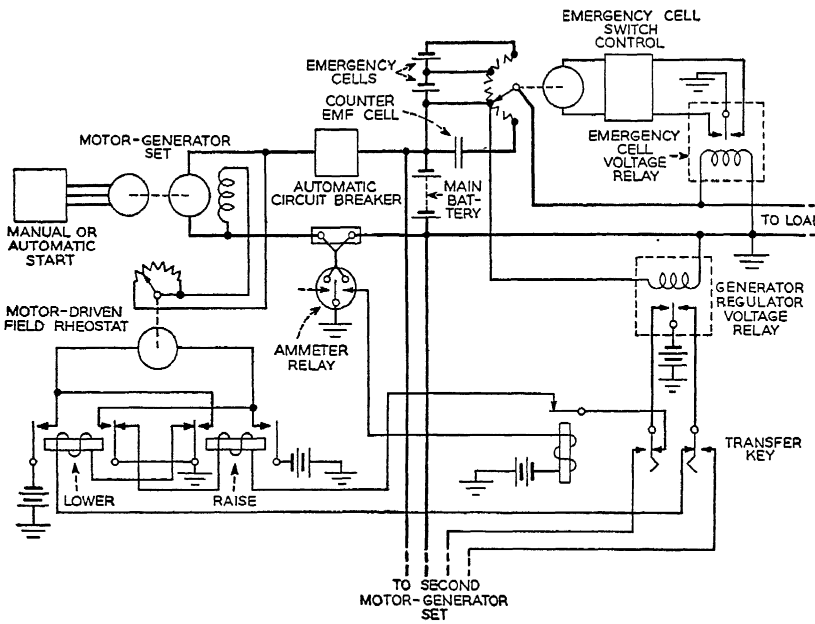

FIG. 49. Typical Central Office Power Plant Arrangement with Single Floating Battery and Automatic Control (Courtesy Bell System)

are also available for supplying harmonic frequencies of 16 $^2/_3$, 33 $^1/_3$, 50, 66 $^2/_3$, and, if desired, 25 cycles, at from 75 to 175 volts, for selective party-line ringing. These units also provide 110 to 120 volt d-c coin control supply, superimposed ringing with 46 to 52 volt silent interval tripping battery supply, howler tone (applied to lines with receivers left off the hook), interrupter tones of various frequencies for operator and subscriber signals, such as busy, trouble, or operating procedure.

In addition to the above types of signaling units there are several different types of single and multifrequency generators producing frequencies for signaling, such as 135 and 1000 cycles, and for vacuum-tube oscillators.

All power equipment is automatically regulated to close limits.

RADIO TELEPHONE SYSTEMS

Radio telephone systems have been in operation for over 25 years, but with the growing need for such systems in recent years, accelerated by World War II, they are rapidly coming into use for many purposes in the communications field. Many of these systems are arranged for connection to wire telephone plant, so that subscriber stations may be interconnected over radio channels and wire line extensions to give local, national, and world-wide service.

8. APPLICATIONS

Radio telephone service is being employed today (1) between all of the larger and many small countries, (2) within individual countries, (3) between ships at sea and fixed land stations, (4) between coastal harbor and inland waterways ships and fixed land stations, (5) between mobile vehicles of various classes and stationary points or other mobile units, (6) between planes and ground stations or other flying planes, (7) directly between persons (walkie-talkie), and (8) for special and emergency use, such as for fire, police, emergency repair units, and for temporarily bridging gaps in telephone lines that have sustained major damage.

Development work and trial tests are in progress for the use of radio channels (1) between and within trains and railroad operating control points, and (2) for rural line telephone service. An important activity, now in the experimental stage, is the use of super high-frequency (microwave) radio systems for toll telephone, television, facsimile, and other services. Undoubtedly many other applications of value to the public will be found for radio telephone systems.

Radio telephone systems may be listed at present under the following general classifications:

1. Long-haul toll.
2. Short-haul toll.
3. Coastal harbor and inland waterways.
4. Highway mobile.
5. Urban mobile.
6. Airways mobile.
7. Railway mobile.
8. Rural subscriber.
9. Special emergency.

Table 1 lists some of the principal operating data regarding these systems.

A new *microwave radio relay system*, using frequencies between about 2000 to 12,000 or more megacycles, is installed between New York and Boston. This system, using "line-sight" frequencies, requires seven intermediate relay stations, spaced on the average about 30 miles apart and located on relatively high elevations, as shown in Fig. 1. This trial of

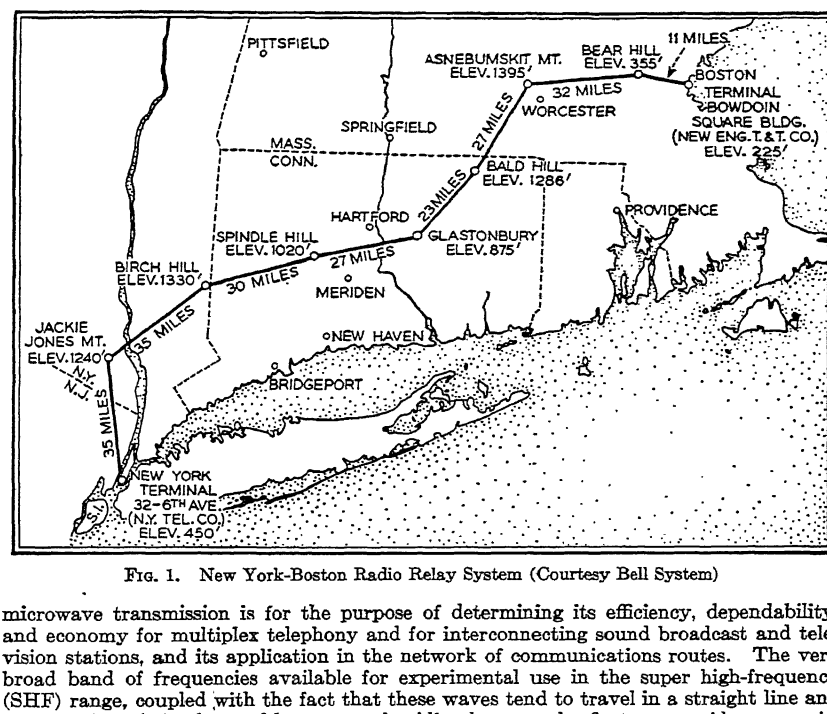

FIG. 1. New York-Boston Radio Relay System (Courtesy Bell System)

microwave transmission is for the purpose of determining its efficiency, dependability, and economy for multiplex telephony and for interconnecting sound broadcast and television stations, and its application in the network of communications routes. The very broad band of frequencies available for experimental use in the super high-frequency (SHF) range, coupled with the fact that these waves tend to travel in a straight line and are capable of being beamed by means of guiding lenses and reflectors, provides a promising field for experiments in communications, with the probability of eventually securing

large groups of telephone, telegraph, television, sound broadcast, and other useful channels.

The multicavity magnetron, a high-frequency power generator developed for radar, has made possible 10,000-Mc frequency currents with peak powers ranging from 10 to 1000 kw for very short intervals of time.

The microwave radio relay system has been given a valuable tool in the *lens-antenna*, consisting of an array of small metal plates mounted in a frame about 10-ft square. This lens employs the same principle in focusing radio waves into a pencil beam as an optical

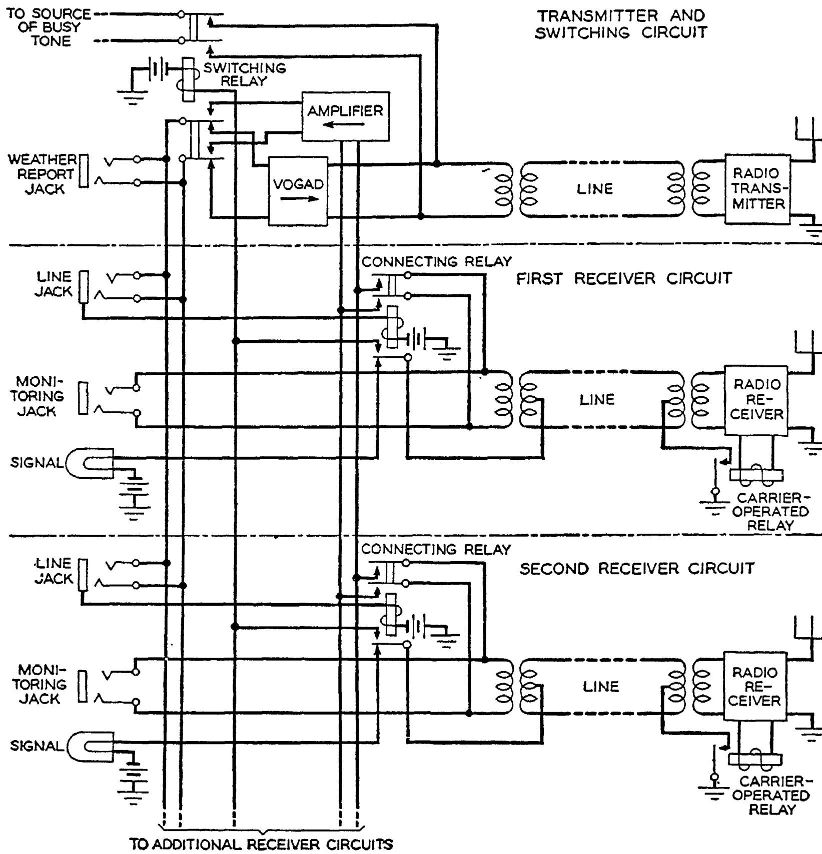

Fig. 2. Shore Circuit for Coastal Radio Service (Courtesy Bell System)

lens does in directing light waves. The radio waves are fed into this new lens-antenna through a hollow-tube wave guide and horn at the rear, the waves spreading out along the hornlike shields to the lens plates, which bend the waves and direct them out of the front of the lens to produce an emergent wave front parallel to the front of the lens. This type of antenna causes less wave distortion due to dimensional variations than would result from such variations in a parabolic reflector, and greater manufacturing tolerances therefore are permissible. Also, the horn-type shield at the rear of the lens reduces rearward radiation, present in reflector antennas, and the front of the lens may be protected from weather by a plastic covering.

Multiplex operation over microwave radio channels was developed by the Bell Laboratories during World War II for use of the U. S. Army Signal Corps and proved to be of great value to the armed forces. Its full possibilities for commercial service are being explored. Army-type pulse modulated microwave systems are now in commercial service between Los Angeles and Catalina Island as well as from the mainland to Nantucket Island. As developed for war purposes, multiplex operation employed a highly directive and sharply focused microwave beam of about 5000 Mc which carried eight separate messages. The intelligence of each channel is conveyed by varying the time position of the 1-microsecond channel pulses, eight of which (one for each channel) are transmitted in sequence, 8000 times a second. Thus, if a 1000-cycle tone is being beamed over one channel, one cycle of this tone requires $^1/_{1000}$ of a second, during which time eight pulses, spaced at approximately equal intervals throughout the one cycle, would be transmitted. At the receiving terminal these pulses are received in sequence by their respective channel and, being representative of the electrical intelligence at the originating terminal, are reconverted into sound intelligence. Two-way operation is obtained by using a separate radio channel in each direction of transmission. Because of the method of transmitting, this system has been designated as *pulse-position modulation* (*PPM*).

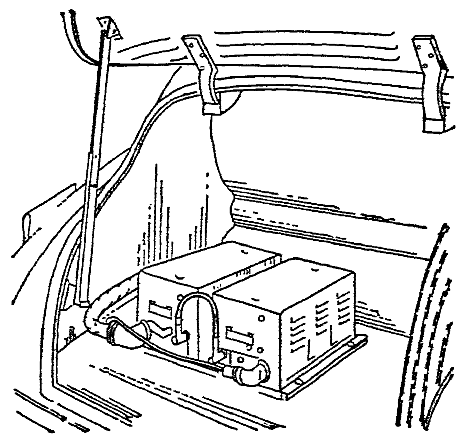

FIG. 3. Mobile Radio Transmitter and Receiver in Auto Trunk (Courtesy Bell System)

Coastal harbor and inland waterways radio telephone systems are extensive, one consisting of 14 basic shore stations, strategically located to cover the entire coast from Maine to Florida, to Texas, and up the Pacific coast to Seattle. Figure 2 shows a circuit of one of the *shore* stations. Note that by use of the monitor jacks the shore operator can select the receiver giving the best reception.

Highway mobile radio telephone systems give the operator the same facility. These systems consist principally of (1) f-m (frequency modulation) radio transmitters (about 50 to 100 miles apart) and associated receivers at fixed locations along the intercity highway which the system is to cover, (2) f-m radio transmitters and receivers for the mobile units, and (3) a control terminal associated with each fixed transmitter.

Wire lines connect the fixed receivers to the control terminal, which provides for linking the transmitter and as many as eight receivers to a two-way, two-wire line to the central office handling the system.

In operation, a customer desiring connection with one of his mobile units moving along a highway between his city and a distant point which is covered by a radio system asks for the mobile service operator in his city. This operator has access over a wire circuit to the various radio transmitters along the highway and, on the basis of the probable location of the desired mobile unit as furnished by the customer, a code assigned to the particular vehicle is dialed and is transmitted by wire and by the selected radio transmitter to the called vehicle. This code activates a selector set in the vehicle, which gives a visual and audible alarm. In calling from the vehicle, the occupant removes his handset from its holder and presses his push-to-talk handset button, which causes his transmitter to send out a signal. This signal is received by the nearest fixed receiver along the route being traveled by the vehicle, which converts the radio- to a voice-frequency signal. This signal then passes along the receiving wire circuit to the terminal equipment at or near the telephone office and signals the mobile service operator.

FIG. 4. Control Unit and Hand Set of a Mobile Radio Unit Mounted under Auto Instrument Panel (Courtesy Bell System)

Figure 3 shows a mobile installation of a transmitter and receiver in the trunk compartment of an automobile; Fig. 4, a control unit and handset under the dashboard of an automobile; and Fig. 5, a schematic of a two-tone selective signaling mobile unit.

Urban mobile radio telephone systems employ equipments like those in the highway mobile service for transmitting and receiving telephone messages or signals. However, since such systems are intended to cover only an individual city and its adjacent territory (up to about 20 to 25 miles from the transmitter), usually only one transmitting station is provided at a central location in the city and a number of receiving stations are strategically placed within the area to be served, so that the mobile transmitter signals will be received and carried to the central office in the city, wherever the vehicle may be in the area. One additional feature not provided in highway service is a one-way signaling service: when certain signals are received by the occupant of the vehicle, certain action is to be taken. Voice communication is not given in signaling service.

The fixed f-m transmitter will generally have a power output of 250 watts using an assigned frequency in the 152–162 Mc band. The mobile f-m transmitter will usually have a 15-watt output at a different frequency in this band. Initially, mobile units will be limited to one channel for a given city, and a number of such units will be assigned to the same channel.

Selective signaling units, actuated by coded dial pulses transmitted from the fixed transmitter and installed in the vehicles, will insure signaling only the vehicle being called. A two-letter, five-digit code will be used, such as WU 2-5556, which will not be duplicated

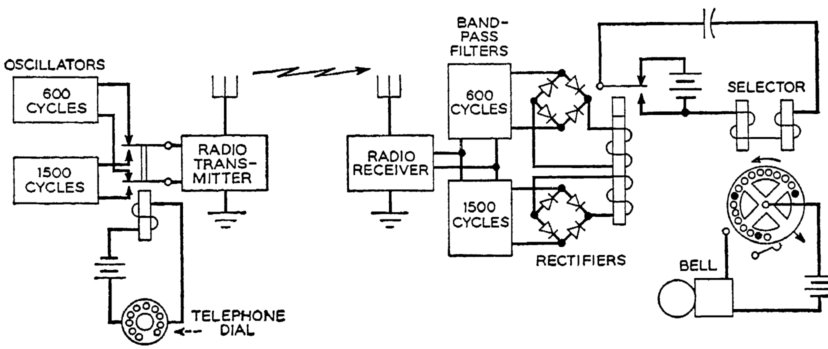

FIG. 5. Two-tone Selective Signaling System for Mobile Radio Service (Courtesy Bell System)

on the same frequencies, where interference might result. Since the mobile selector set operates the calling signal on the twenty-third pulse, the sum of the digits (not including letters) will always add up to 23, unless the plan of selection is later changed. Differentiation between vehicles operating only in one local area and those that may operate in more than one such area will be effected by assigning different code letters to the two classes of vehicles.

Railway mobile radio telephone systems are now (1949) under trial tests by several railroad companies (1) between trains and railway control points, (2) within the train itself, and (3) for use of the passengers in talking to fixed telephones.

The last-mentioned service makes use of highway mobile installations, which in most cases parallel the right-of-way. Service between passengers on moving trains and land telephone systems may be rendered by carrier-induction methods, rather than by radio, or by both types of transmission, as may seem best in the future.

Rural subscriber radio telephone systems are now in the trial stage, employing assigned frequencies within the 152 to 162 Mc band and low-power transmitters.

At Cheyenne Wells, Colo., a system has been installed (operating on a trial basis in the frequency range of 44 to 50 Mc) which provides for rural radio service to eight ranches located from 11 to 21 miles from the town. None of these ranches are reached by either power or wire telephone lines, the operating power for the ranch radio sets being obtained from home electric plants. Four of the ranches are served by direct radio links to the Cheyenne Wells central office; the other four are reached by relatively short wire extensions from a nearby radio-equipped ranch. At the central office the eight stations are grouped, through terminal equipment, to form an eight-party rural line.

Radio equipment at each of the first four ranches includes a transmitter, receiver, a telephone set, and two antennas. The 10-watt transmitter and associated receiver are housed in a steel cabinet, which can be located out of sight, with only the telephone instrument in view. The antennas are mounted on a pole or atop one of the ranch buildings.

At Cheyenne Wells, the equipment includes a 50-watt transmitter, receiver, and terminal equipment for associating the various radio links with the central-office switchboard.

Further studies will be made, based on the results of the trial tests, to determine the most practicable types of radio equipment to employ for rural service.

Special emergency radio telephone systems have been in operation for many years to serve fire, police, forestry, highway, utility companies, and a number of other services. Operation is of low power output at frequencies generally within the 1.6–3.3 and the 30–40 Mc bands.

The equipment employed for the mobile services is, in general, similar to the types discussed under coastal harbor, highway, and urban mobile service with variations required for the particular type of service involved.

The telephone and other wire-using companies have been using for several years portable emergency radio telephone equipment to bridge gaps in open-wire lines resulting from sleet, flood, or wind damage.

One type of portable radio telephone system for emergency use employs a 50-watt transmitter arranged to operate at one of ten selected frequencies within the 2.0–3.1 Mc band, and a receiver adjustable for any frequency within the 2.0–3.1 Mc band. One antenna at each terminal is switched between the transmitter and receiver, depending on the direction of transmission, by a voice-operated control unit. A volume limiter in the transmitter, and automatic volume control and a codan (carrier-operated device, antinoise) in the receiver, regulate the transmitter modulation and the receiver output and operation to provide uniform transmission. Its operating range varies with the type of terrain, noise, and atmospheric conditions from about 25 to 50 miles. Power for the terminal units is obtained from 110–120 volt, 60-cycle supply. A sensitivity control circuit actuates the transmitter at a minimum level of −47 dbm (47 db below 1 milliwatt) and likewise prevents line noise or room noise from causing false operation of the equipment.

9. TRANSMISSION AND OPERATIONAL METHODS

Quiescent transmitter operation is employed either to save power or to permit the installation of a single transmitter and receiver at the same location under conditions which otherwise would prevent satisfactory communication. The transmitter is provided with manual or voice-operated control means which render it sufficiently inactive during idle intervals so that emission from it does not interfere with reception. If saving power is an objective, the switching is directed toward securing minimum power input during quiescent periods.

Two sidebands and carrier transmission is the most commonly used method, owing to the simplicity of signal generation and detection. It requires a radio transmission band equal to twice the highest audio frequency to be transmitted. The carrier contains no intelligence-bearing signal component but simplifies detection and is useful for such control purposes as automatic tuning and volume control at the receiving end and for the operation of auxiliary relays. The power required to transmit the carrier is large compared with that required for the sidebands, and if the carrier is transmitted continuously it represents a considerable loss. In the case of 100 per cent modulation by a single-frequency tone, the carrier power is twice the sum of the power in the two sidebands.

Spread sidebands and carrier transmission uses sidebands displaced from their normal positions in relation to the carrier by an amount approximately equal to the audio band transmitted. It is sometimes used when inverter-type privacy is employed, because the spreading then can be accomplished without additional modulating equipment and merely requires that the inverter be designed for different input and output frequency bands. Advantage: less stringent distortion requirements are imposed on radio equipment because predominant intermodulation products fall outside the used band. Disadvantage: communication band, much wider than otherwise necessary, is occupied inefficiently.

Two sidebands, suppressed carrier, transmission has not been used, because the difficulties of correctly maintaining the phase of the reintroduced carrier at the receiving end generally offset the advantage of saving in power capacity at the transmitter. Furthermore, *suppression of one sideband as well as the carrier* usually offers additional advantages with less stringent synchronization requirements, since in this case the frequency of the reintroduced carrier can depart from the correct value by a few cycles without appreciable mutilation of speech quality, and it can be off as much as 20 cycles without noticeably reducing articulation.

Single sideband, suppressed carrier, transmission has certain important advantages which are especially valuable in long-wave systems where transmitter power capacity, communication band width, and static interference are controlling factors. These advantages, referred to double sideband and normal carrier modulated 100 per cent, are: 6-db increase in intelligence-bearing signal for same transmitter amplitude capacity, 3-db reduction in random received noise, no emission from transmitter during idle periods, and radio transmission band no greater than audio band width. Disadvantages: more complicated modulating process; precision frequency control is required in order to reintroduce at the receiver the carrier suppressed at the transmitter; transmitter power supply is subjected to large load variations at syllabic frequencies. This method is employed in the long-wave and short-wave systems between New York and London and on some radiotelephone systems. In the short-wave system, synchronization of the reintroduced carrier at the receiving end is accomplished satisfactorily by transmission of the carrier or an equivalent pilot signal reduced 10 to 20 db below normal carrier.

Privacy is usually achieved by modifying the signals in one or more ways which render the message substantially unintelligible unless received with special equipment. Devices called speech inverters have been developed which reverse the sequence of the audio frequencies before modulation in the radio transmitter; reinversion is then necessary after detection at the receiver. Additional privacy is obtained by varying the radio carrier in a cyclic manner. A more complicated method, known as split-band privacy, involves dividing the total audio band into several narrow bands. These can be inverted and/or transposed in various arrangements, and the combination can be changed frequently. All these methods have been applied successfully to radio circuits.

10. PRINCIPLES OF TWO-WAY OPERATION

SYSTEMS WITH FOUR-WIRE TERMINALS. Since the emission of radio waves and their subsequent detection at a distant point constitute inherently a unilateral process, duplex operation requires two one-way radio systems acting in opposite directions. Such an arrangement for telephony is shown in Fig. 6. At each end of the system a

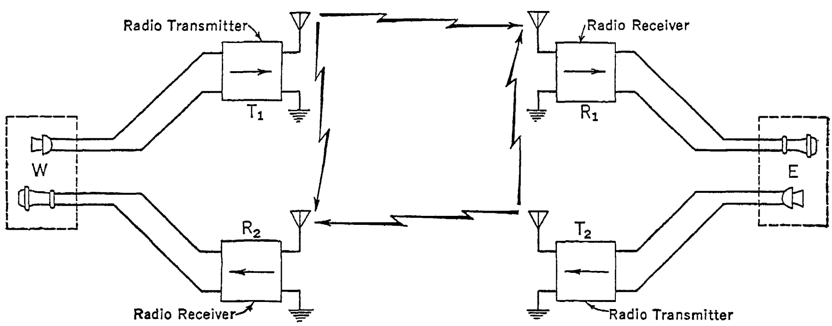

Fig. 6. Simple Radio System—Four-wire Terminals

microphone is connected to a radio transmitter and a telephone receiver is connected to a radio receiver. Thus, two persons can converse provided the radio transmission eastward does not interfere with the transmission westward; i.e., radiation from T_2 reaching R_1 must not prevent R_1 from functioning satisfactorily in receiving signals from T_1. Likewise radiation from T_1 at R_2 must not interfere with reception of signals from T_2. For the condition where the person at W is talking and the person at E is listening, the effect of T_2 at R_1 may be (*a*) increased noise, (*b*) distortion of signals from T_1, (*c*) detection of unwanted signals. Furthermore, the effect of T_1 at R_2 may result in a return signal to W which is quite disconcerting. If the person at W hears himself talking in reasonable volume, it will not disturb him unless there is sufficient delay to give an echo effect. However, if he hears unintelligible sounds in like volume, they will seriously disturb him. Such sounds appear if R_2 is overloaded by high field intensities from T_1 or if T_1 produces extra-band radiation within the selectivity band of R_2 and of sufficient intensity to be detected.

The forms of interference outlined above are prevented by adapting one or a combination of the following expedients: (*a*) use of different frequency bands for the two directions of transmission, (*b*) geographical separation of the radio transmitter and receiver, (*c*) use of directional antennas, (*d*) suppressing all emission from transmitters except during transmission of wanted signal and disabling and protecting local receivers during active intervals of adjacent transmitter. Accomplishing (*d*) involves switching operations. Manual control of the switching is satisfactory for experienced talkers, but voice-current control is favored for more general use. Single sideband, suppressed carrier systems are less susceptible to interference than other systems and may be used more readily without switching arrangements, if the transmitter and receiver are separated sufficiently.

In planning a specific system, there is a wide variety of circumstances, including economic factors and the characteristics of the particular apparatus to be used, which determine the selection of the method or combination adopted. There are no clearly defined dividing lines, but it may be stated rather generally that the use of (*a*) or (*d*) alone is satisfactory for short-distance working. All long-distance systems employ at least (*a*) and (*b*) or (*b*) and (*d*). Geographical separations range from a few hundred feet to several hundred miles. Use of (*c*) reduces the distance necessary. With (*a*) the necessary geographical separation is determined by the attenuation required to bring the ratio of field intensities of the wanted and unwanted signals within the limits of the receiver selectivity and overload characteristics. With (*d*), geographical separation is necessary for high-power transmitters, to avoid exposing the receiving system to noise due to spurious emanations from parts of the transmitting apparatus or the associated power-supply system.

SYSTEMS INTERCONNECTING WITH TWO-WIRE EXTENSIONS. Since standard telephone subscriber loops are two-wire circuits in which messages in opposite directions traverse the same wire path, the two oppositely directed radio paths in Fig. 6 must be arranged to terminate two-wire. The ordinary hybrid coil arrangement common in telephone repeaters and four-wire cable circuits fails to solve this problem except where the radio circuit meets all the requirements imposed by wire practice on corresponding wire circuits. This is seldom possible or economical on account of difficulties peculiar to the radio paths. In wire systems, transmission levels remain fixed within closely established limits, and signal volumes vary over a considerable range. In radio circuits, comparatively large variations in attenuation sometimes occur in relatively short intervals of time, except over extremely short-distance paths, and these tend to cause retransmission of received signals at such amplitudes that severe echoes and even singing around the two ends of the circuit will occur unless means are provided to prevent it. Furthermore, for all long-distance working, it is uneconomical to provide transmitter capacity which will permit appreciable variations in signal volume. To obtain maximum signal-noise ratios at the radio receivers, it is essential that the speech currents fully load the transmitters. This requires gain adjustments between the hybrid coils and the transmitters to suit the particular talkers and the condition in the connecting wire circuits.

To overcome these fundamental transmission difficulties, automatic switching systems operated by the voice currents of the speakers have been developed. These devices block the radio path in one direction while speech is traveling in the reverse direction and also keep one direction blocked when no speech is being transmitted. The operation is so rapid that it is unnoticed by the telephone users. Since these systems prevent the existence of singing and echo paths, their use permits the amplification to be varied at several points almost without regard to changes in other parts of the system, and it is possible by manual or automatic adjustment to maintain the volumes passing into the radio link at relatively constant values irrespective of the lengths of the connected wire circuits and the talking habits of the subscribers.

Figure 7 is a schematic diagram of one end of a circuit showing the essential features of a voice-operated device. This kind of apparatus is capable of taking many forms and is, of course, subject to change as improvements are developed. The diagram illustrates how one of these forms might be set up. This form employs electromechanical relays. The functioning of the apparatus illustrated is briefly as follows: the relay *TES* contact is normally open so that received signals pass through to the subscriber. The relay *SS* contact is normally closed to short-circuit the transmitting line. When the subscriber at *W* speaks, his voice currents go into both the transmitting detector and the transmitting delay circuits. The transmitting detector is a device that amplifies and rectifies the voice currents to produce currents suitable for operating the relays *TES* and *SS*, which thereupon short-circuit the receiving line and clear the short circuit from the transmitting line, respectively. The delay circuit is an artificial line through which the voice currents require a few hundredths of a second to pass so that when they emerge the path ahead of them has been cleared by the relay *SS*. When the subscriber at *W* has ceased speaking, the relays drop back to normal. The function of the receiving delay circuit, the receiving detector, and the relay *RES* is to protect the transmitting detector and relays against operation by echoes of received speech currents. Such echoes arise at irregularities in the two-wire portion of the connection and are reflected back to the input of the transmitting detector, where they are blocked by the relay *RES* which has closed and which hangs on for a brief interval to allow for echoes that may be considerably delayed. The gain control potentiometers, shown just preceding the transmitting and receiving amplifiers, are provided for the purpose of adjusting the amplification applied to outgoing and incoming signals.

The relief from severe requirements on stability of radio transmission and from varying speech load on the radio transmitters, which such a system provides, permits much greater freedom in the design of the two radio circuits than would otherwise be possible. In the system shown in Fig. 7 interference between local transmitter and receiver, as outlined previously in discussing Fig. 6, is prevented by such geographical separation as may be necessary in combination with either the use of two communication bands or single sideband, suppressed carrier, transmission. When one communication band is used for both directions with carrier and double sideband transmission, the switching systems of the type shown in Fig. 7 are extended to operate additional devices which suppress the carrier at the transmitter and disable the receiver. This switching is necessary to protect

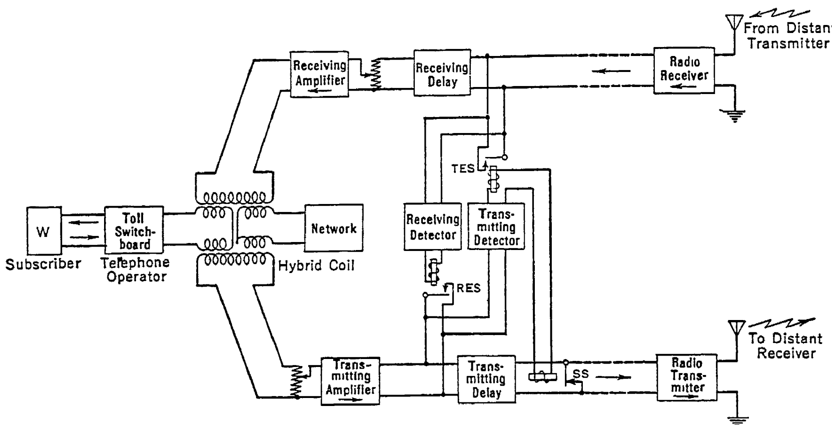

FIG. 7. Two-wire Radio Terminal Showing Arrangement of Voice-operated Switching Devices

the receiver where it is exposed to intense fields from the transmitter. When privacy apparatus is included in an installation, the voice-frequency switching is frequently arranged to transfer the same privacy unit from the transmitting to the receiving leg of the four-wire terminal (or vice versa), thus saving cost of a second privacy unit.

11. SYSTEM DESIGN

The designer of a radio circuit is limited to the establishment of certain facilities at the transmitting and receiving station which are expected to yield the desired results on the basis of available data, computations, and previous similar experience. Beyond this point, the performance is inherently a matter of probability, since transmission is subject to the vagaries of natural influences entirely beyond the control of man. Sometimes, very short-distance circuits can be provided which are substantially immune from these influences. However, the designers of long-distance circuits frequently encounter technical limitations which determine the maximum degree of reliability attainable, quite apart from considerations of cost.

The design proceeds from a statement, which includes (*a*) type and nature of service expected, (*b*) daily hours of operation, (*c*) general location of terminals, (*d*) distance covered and character of intervening region, (*e*) overall transmission requirements, (*f*) future plans. From these flow the requirements and compromises which ultimately determine the selection of transmission frequencies and methods; the location and general arrangement of transmitting, receiving, and voice terminal stations; and the choice of equipment.

Systems requiring separate transmitting and receiving stations usually involve expenditures which warrant a fairly comprehensive preliminary survey. The survey includes a search for suitable station sites and measurements of received field intensities, noise levels, and angles of wave arrival over the approximate path at substantially the proposed frequencies. This survey frequently can be effected by observing the signals from existing telephone or telegraph stations. It serves to substantiate conclusions derived from computations and from available transmission data; it gives important specific information concerning noise at receiving sites; and it should serve to disclose any conditions peculiar to particular locations which may have a profound effect upon performance.

TRANSMISSION REQUIREMENTS are related intimately with the needs and objectives of individual applications to such an extent that the statements herein should not be taken as concrete recommendations but should be regarded principally as guides to the items that need consideration when formulating the specific requirements for a particular system.

Circuits terminating four-wire and used only for direct conversations between terminals can be operated over a wide scale of conditions all of which may be acceptable for the purpose in hand. Circuits interconnecting with telephone plants should conform as far as possible to the standards of the wire systems in respect to transmission, stability, distortion, and interference effects. Allowance must be made for similar imperfect conditions in wire transmission. Otherwise the complete connection may be unsatisfactory, even though it is possible to converse over the radio circuit alone. With the possible exception of very short-distance radio circuits, it is generally true that radio transmission conditions vary through an extremely wide range, and it becomes necessary during some operating intervals to endure a comparatively poor circuit or temporarily do without one. It is desirable, therefore, to make the limiting requirements as liberal as possible.

Transmission Times. The requirements are no different from those for corresponding wire systems. The transmission time, from radio transmitter input terminals to receiver output terminals, is seldom appreciably greater than the time required for radio waves to traverse from transmitter to receiver. The propagation rate is approximately 186,000 miles per second. To this must be added time for wire circuits to the control centers, time for delay networks used with voice-operated switching devices, and time for any delays incurred in other apparatus, such as privacy systems.

Stability. It is desirable that all equipment adjustments that affect the overall circuit performance, and more particularly those that cannot be made without removing the circuit from service, retain the established conditions for long periods.

Receiving-set selectivity, in addition to discriminating sharply against unwanted signals, should provide ample margins for the total effect of frequency drifts to be tolerated over a period of several hours at all points in the system where base frequencies are generated. For example: a system employing a quartz-plate oscillator at the transmitter and a well-designed beating oscillator of the tuned circuit type at the receiver, when operating at 15 Mc and transmitting audio frequencies up to 3000 cycles, requires an intermediate-frequency band width of the order of 8000 cycles (-3 db at 4000 cycles from midband).

When the system is operated on the basis of constant net loss, it is desirable that the loss in the radio circuits be held to ± 1 db. When the system is operated on the basis of constant input volume to the radio transmitter and voice-operated devices are used, variations of ± 5 db are sometimes tolerated at the receiving end. When radio transmission is subject to rapid variations the receivers are provided with automatic volume controls which hold the output volume within a few decibels for wide fluctuations in the signal-field intensity.

Audio distortion is usually specified in terms of transmission band characteristics, amplitude or load characteristics, and departure from proportionality of phase shift with frequency. Difficulties from the last are seldom encountered in ordinary radio circuits used for voice communication.

Transmission Band Characteristics. The requirements in each instance are closely related to the needs of the particular application. Except when using radio frequencies less than 100 kc, it is seldom a difficult matter to provide reasonable bands for conversational purposes. The minimum requirements for international radio telephone circuits, as recommended by the International Consultative Committee on Telephony, are the same as for long-distance wire circuits: i.e., 300–2600 cycles as the limiting frequencies effectively transmitted. The committee also recommends that future circuits be designed to transmit at least 200–3000 cycles. Widening the band improves quality and to a lesser extent improves articulation, provided that other conditions do not become controlling. For instance, exposure to random noise at the radio receivers is substantially proportional to the band width, so that widening the band may not result in improved performance under adverse receiving conditions. In the United States, it is customary to specify the transmission-frequency characteristic in terms of departure in decibels from the transmission level at 1000 cycles.

Amplitude or Load Characteristics. Except when radio circuits are subject to rapidly varying transmission conditions, such as those frequently encountered in the short-wave range, load tests are made in the same manner as for wire circuits, and the requirements are the same for equivalent results.

The linearity requirements for the transmitting system and the receiving system are usually specified in terms of distortion products resulting from the application of pure tones. The tests are made separately for the two systems. Carrier and double sideband systems may be tested with a single tone at varying amplitudes. Single sideband systems require two-tone tests. If privacy apparatus is to be used with double sideband systems, it is usually required that the total distortion products introduced by the transmitter alone or the receiver alone and falling within the audio band shall be about 25 or 30 db below the single tone output for any tone input up to 90 per cent modulation. If two equal tones are used on any system, it is generally specified that any distortion product falling within the transmission band shall be 20 to 25 db below one tone. (For testing methods, see Section 11 and *I.R.E. Report of Standardization Committee.*)

Radio-frequency or phase modulation at the transmitters results in troublesome distortion effects at the receiving station if radio transmission occurs simultaneously over two or more paths differing in length by appreciable portions of the wavelength used. This situation is encountered in the short-wave systems, and it is sometimes specified that, during the modulation cycle, the phase shift associated with frequency modulation or phase modulation should not exceed $\pm 15°$. (For method of test, see *I.R.E. Report of Standardization Committee.*)

When no appreciable differences in simultaneous transmission path lengths are encountered, frequency modulation can be tolerated if all the radio equipment has substantially a flat frequency-transmission characteristic throughout a band sufficiently wide to pass all the essential frequencies generated and if extra-band radiation does not interfere with other services.

Interference is caused by signals from other radio circuits and by disturbances generally classified as noise.

Unwanted signals may enter the radio circuit through cross-modulation effects at the transmitting station if there are two or more transmitters, or they may enter at the receiver. Cross-modulation is likely to occur with open-wire transmission lines. It is not difficult to overcome if active lines are well separated and long parallel runs are avoided. It results from the impression on the tube circuits of one transmitter of modulated radio-frequency voltages generated by a second transmitter coupled to the first usually via the transmission lines or the antennas. In special cases, trap circuits or other simple filtering devices are introduced when found necessary, but they are objectionable if the same lines are to be used for several frequency assignments.

At the receiving station it is not enough to provide apparatus having comparatively high selective properties. It is necessary to know in what manner this selectivity is achieved, and what values of unwanted signal voltage may be impressed upon the receiver input-terminals simultaneously with the wanted signal. A receiving site and an antenna system must then be selected which will not violate these receiver requirements.

Noise at the receiving terminal is derived from the connecting wire system, the radio transmitting and receiving apparatus, and the radio noise field. If noise from the wire system meets the accepted standards for good toll circuits, as it should, it is not likely to have a noticeable effect on the performance of the radio circuit. Noise generated within the radio transmitter is measured in terms of audio signal by means of a linear monitoring rectifier exposed to the transmitter radio output. The audio signal-noise ratio thus obtained should be somewhat better than the maximum audio signal-noise ratio which it is desired to obtain at the receiving end under conditions of high signal-field and low noise-field intensities. Noise due to the receiving equipment should never be a controlling factor except when approaching the limit of sensitivity.

Since the effect of noise depends greatly on its frequencies in relation to the audio transmission band, precautions are necessary in systems employing frequency inversions to prevent the conversion of relatively harmless noise into very objectionable noise. This conversion may occur if the noise enters any part of the system between points where the inversions and reinversions are made.

The interfering effect of noise is very difficult to express accurately.

12. INSTALLATIONS

The successful establishment and maintenance of dependable, long-distance circuits with two-wire terminations require careful installation planning, the provision of adequate testing facilities, and the consideration of many problems only indirectly related to the technical operation of the system. There is a wide gap between this extreme and the simple facilities required for short-distance radio circuits without two-wire extensions (Section 7).

TRANSMITTERS AND RECEIVERS AT SAME LOCATION. Small transmitting systems for short-distance service are placed at the same location as the receiving systems. The transmitter and receiver are usually self-contained units requiring a single connection to the general power supply. If the same frequency assignment is used for both directions of transmission a single antenna is sufficient. Manual or voice-controlled switching is necessary to change from receive to transmit conditions. If two frequency assignments are used without quiescent transmitter operation, it is frequently found more satisfactory to employ two antennas slightly separated than to make provision for transmission and reception on the same antenna. The latter is possible by means of various special circuit arrangements but is almost certain to incur a penalty in respect to minimum receivable field intensities. Since the field intensity gradient around the transmitting antenna is extremely steep, it is seldom necessary to remove the receiving antenna more than 50 to 500 ft in order to secure satisfactory conditions. The distance depends on transmitter power, type of antenna, frequency difference, receiver selectivity, and load characteristics. If the antennas have directional properties, the relative positions should be selected, when possible, so that each antenna presents a null in the direction of the other. Usually the transmitting antenna is erected near the apparatus, and the receiving antenna is placed at a distance from the receiver, connections being provided by suitable transmission lines.

If it is essential that the transmitting and receiving apparatus be installed in close proximity, attention needs to be given to shielding to prevent direct interference between transmitter and receiver. Receivers designed for this type of installation seldom require further shielding when used with transmitters up to about 25-watt capacity, provided that the transmitters are also reasonably well shielded. It is a good plan to place receivers somewhat away from transmitters for ratings up to about 500 watts. The alternative is to provide a special shielded compartment for the receiver. This has been done on shipboard, where space limitation and operating convenience demand a compact installation.

As the transmitter power is increased, the possibilities increase rapidly that noise will enter the receiver directly or through the receiving antenna from various sources within the transmitter or its power circuits. If this occurs, it limits the permissible receiver sensitivity and may completely nullify the value of higher power for the purpose of working greater distances. Recourse to voice-controlled quiescent transmitter operation greatly alleviates this type of interference for installations where two or more transmitters are not to be used simultaneously. It is frequently applied to ship systems and materially increases the working distances. It is effective only in eliminating noises related to the suppressed radio signal components. Around large transmitters the residual noise after the carrier or other radio signal components are suppressed still prevents the use of extremely sensitive receivers. This is one of the compelling reasons for establishing separate transmitting and receiving stations for long-distance circuits, where extremes of power and sensitivity are essential.

SELECTION OF TRANSMITTING STATION SITE. Items requiring consideration are: ground conductivity and dielectric constant; general character of surrounding terrain; position relative to receiving stations; possibilities of interfering with broadcast reception or that of other services; transportation, power, and telephone facilities; living arrangements for station personnel; prevalence of sleet storms; unusual conditions of temperature, humidity, presence of salt spray; etc. Ground conditions affect antenna design. Desirable characteristics depend upon the type of radiating system to be employed, the frequencies and the wave angles of transmission (Sections 6 and 10). The terrain in the direction of transmission affects the vertical wave angle. Mountains and hills subtending large angles are undesirable. Steel towers, buildings, transmission lines, etc., constituting sizable obstructions directly in front of short-wave directional antennas, are objectionable since they modify the directive pattern.

THE TRANSMITTING STATION LAYOUT is based primarily on the requirements of the antennas and their relation to the transmitter. Usually the antenna or antennas are located a short distance away from the building housing the transmitter, and connection is made through open-wire or concentric transmission lines. The practice of bringing the antenna downlead directly to the transmitter is seldom followed in modern installations. Use of uniform transmission lines, all having the same impedance, greatly simplifies switching problems. Good values are: open-wire 600 ohms, concentric lines 70 to 80 ohms. Placing the antennas clear of the transmitter building avoids difficulties in erection and maintenance. Short-wave directional antennas are placed so that the building is not within the horizontal angle of the principal lobe.

RECEIVING STATION EQUIPMENT depends somewhat on the number of radio circuits involved but is also influenced considerably by the standards established in respect to service interruptions other than those attributable to the transmitting medium. The essential components are: radio receiver and its power-supply units, antennas and transmission lines, wire-terminal apparatus and voice-frequency testing equipment with associated power-supply units, general power supply, including emergency power sources. Large stations usually have facilities for observing the field intensities of received signals and noise and for the precise measurement of received frequencies. These are used to check the transmitters which are a part of the system, and those of other systems, which create interference.

SELECTION OF RECEIVING STATION SITE is a matter demanding careful consideration, especially if long-distance services are contemplated, and it is seldom safe to make a final decision without actual observations of signal-field and noise-field intensities over a period sufficient to obtain representative data. Items that should receive attention are: location relative to transmitting stations of same system and all other nearby transmitters and sources of man-made noise; local ground conditions and general character of surrounding terrain in the direction of wave arrival; transportation, power, and telephone facilities; living arrangements for station personnel; prevalence of electrical storms; unusual conditions of temperature, humidity, presence of salt spray, etc.

It is desirable to have the antennas present nulls toward all transmitters in the area which are likely to produce any form of interference.

Likely sources of man-made interference are: high-tension transmission lines, electrical machinery in factories, electrical trains, automobiles, airplanes, motorboats, etc. The last three mentioned are particularly important in long-distance short-wave reception at times when signal-field intensities are low as the result of magnetic disturbances. With an extremely sensitive receiver and a directional antenna designed for low-angle reception, no serious interference would be expected from automobiles 1 $^1/_2$ miles in front of antenna and $^1/_2$ to $^1/_4$ mile at the sides and rear.

Reception of short waves arriving at low angles can frequently be improved from 5 to 10 db by placing properly designed antennas on ground sloping uniformly downward in the direction of the transmitting station at an angle of 5° to 15°.

RECEIVING STATION LAYOUT. Primary objectives are to place the antennas in an advantageous position for the collection of energy from the incoming waves and to obtain an efficient arrangement in respect to transmission lines. In choosing directional antenna locations, close attention should be given to the position of objects capable of reflecting or otherwise redirecting unwanted waves into the sensitive angles of the antenna characteristic.

It is well to adopt a uniform impedance for all transmission lines. Convenient values are: open wire 600 ohms, concentric lines 70 to 80 ohms. In order to avoid disturbing the incoming radio waves, and also to avoid undesirable currents, transmission lines should be placed as near the ground as practicable. However, it is inadvisable to place two-wire lines less than 6 ft from the ground. Four-wire balanced lines are disturbed less by the proximity of the ground and have been used successfully at 4-ft elevations. Concentric lines may be installed underground. They should always be sealed and, in some situations, are further protected from moisture by maintenance of pressure with inert gas. Aside from somewhat higher first cost, much can be said in favor of concentric conductors, since they substantially eliminate the difficulties encountered with converging lines at receiving set locations. At short-wave stations, it is desirable to have all directional antennas present a null to the building and the road approaching it.

SHIP STATIONS are usually installed in extremely limited quarters. They require compact units, designed to allow inspection and repairs without having access to all sides and preferably without disconnection and removal of parts. Rapid frequency-changing features are especially important if it is desired to maintain close contact with more than one shore station.

Transmitting and receiving antennas are usually separated as much as possible. Simple types are generally used because they are suitable for several frequencies. Horizontal directional properties are not desirable. Electrical noise conditions vary widely with positions aboard ship.

A four-wire termination is usually employed to avoid rather expensive control-office equipment. Ship's passengers talk from a conveniently located booth. Circuits are also provided from the captain's quarters or a similar point convenient to the bridge. With a four-wire terminal, no voice-operated switching apparatus is needed other than the simple devices necessary for quiescent transmitter operation. Voice-frequency apparatus is mounted adjacent to the receiver. One attendant supervises all operations and performs the duties of a technical operator. If the ship is equipped with radio telegraph as well as telephone apparatus, and the two must operate simultaneously, precautions are necessary to avoid mutual interference.

SHORE STATIONS are usually equipped to offset, as far as practicable, unfavorable conditions aboard ship. This is done by providing transmitter power capacity from 10 to 40 times that of the ship station, by employing directional antennas, and by selecting a quiet receiving location a few miles away from the transmitting station. Antennas having moderately directional patterns (6 to 12 db maximum net gain) are used to cover the principal ship lanes effectively. Less directional antennas are needed for general coverage. When a ship is close in, at which time the required direction of transmission is likely to move rapidly through a wide horizontal angle, antenna gain is less important, and a directional antenna, unless it has pronounced nulls, is frequently found satisfactory because the unfavorable ship position is offset by the short distance. Otherwise, a simple antenna is provided for this purpose.

TELEPHONE LINES—TRANSMISSION CONSIDERATIONS

13. TYPES OF PLANT

SUBSCRIBER LINES (LOOPS) include all types of outside plant facilities needed to connect the subscriber station telephones with their local central office. Such facilities may consist of cable, either aerial or underground, open (bare) wire, carrier or radio channels, or a combination thereof. Generally, cable is used in urban areas as a means of serving local subscriber stations; where small urban open-wire plants are still in operation they are rapidly being replaced. In rural areas, open-wire lines are still in general use except in congested sections, since the fewer lines and longer distances characteristic of rural areas make the open wire more economical. As stated above, however, it is anticipated that radio facilities can be made available, commercially, to serve distant or relatively inaccessible farms *where the costs of providing the usual telephone wire facilities would be excessive.*

TOLL LINES, as generally defined, consist of various types of outside plant facilities employed to provide toll circuits between *toll centers* (*TC*). Those line facilities connecting TC and *tributary offices* are considered part of the TC plant. These latter offices, in the general meaning of the word "tributary," are small offices (in territory adjacent to the TC) connected to the TC by one or more tributary circuits and are fully or partly dependent upon the TC for the handling of their toll traffic. Toll facilities may consist of cable, aerial or underground, open wire, carrier or radio channels, or a combination of these.

Subscriber line facilities, known generally as *exchange* plant, and toll line facilities should be designed and constructed to meet, cooperatively, the overall service objectives which are known collectively as *service standards.* These standards are not fixed for all time but change with service needs and advancements in the art of communications.

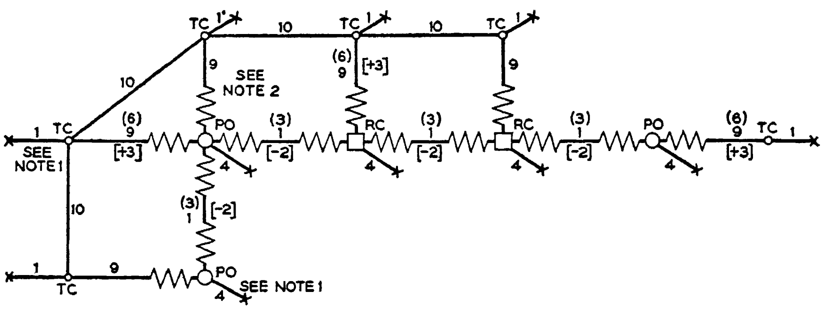
TRANSMISSION AND SIGNALING are two fundamental factors to consider in any telephone system, whether the connecting facilities between subscribers are wire, carrier, radio, or a combination of two or more of these types. If either transmission or signaling, or both, are not satisfactory for a given telephone system, the system is not workable under modern standards of service.

14. SERVICE REQUIREMENTS—TOLL

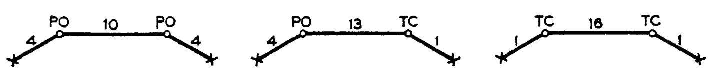
UNIVERSAL SERVICE is the goal toward which the telephone industry has been striving for many years and which, it now appears, will be attained. This goal simply means that anyone, anywhere, can talk, telephonically, with anyone else, anywhere else, whether the connection be established locally, within the nation, or between any two countries in the world. For a number of years it has been possible to talk by telephone from any point in the United States to any other point connected to the nationwide toll system and to many foreign countries. Worldwide service is being rapidly expanded to include those countries not at present reached.

TRANSMISSION OF SPEECH between two points requires that speech (sound) power from the talker actuate his transmitter diaphragm and that the transmitter convert this power into electrical power, which travels to the distant listener's receiver, where it is reconverted by the receiver diaphragm into speech (sound) power of approximately the same characteristics as the original speech power. It is obvious that the electrical power will diminish as it travels over the circuit between the talker and listener stations as the result of series and shunt impedances encountered in the lines and equipment which constitute the circuit. If the electrical power reaching the receiver is diminished to the point where it no longer drives the receiver diaphragm sufficiently to permit the listener's ear to interpret the intelligence carried by the resulting sound waves, then the electrical transmission loss in the circuit is too high to permit carrying on a satisfactory telephone conversation. It, therefore, becomes necessary to limit overall transmission losses and consequently the losses in component parts of circuits, which usually consist of two or more sections or links.

THE GENERAL TOLL SWITCHING PLAN (Fig. 1) as developed for establishing toll connections on a manual basis provides a practicable plan for accomplishing universal



FOR CIRCUITS DESIGNED TO HANDLE ONLY TERMINAL BUSINESS THE WORKING NET LOSS DEPENDS UPON TOLL TERMINAL LOSSES INVOLVED AND UPON OVERALL DIRECT STANDARDS. AS A TYPICAL EXAMPLE, WITH A DIRECT STANDARD OF 18 DECIBELS, THE LIMITING VALUES OF TERMINAL CIRCUIT NET LOSSES WOULD BE AS SHOWN BELOW FOR THE ASSUMED VALUES OF TOLL TERMINAL LOSS.



NOTES:

1. THE TOLL TERMINAL LOSS WOULD BE DETERMINED IN EACH CASE ON THE BASIS OF MEETING THE TRANSMISSION REQUIREMENTS IN THE MOST ECONOMICAL AND SATISFACTORY MANNER, FOR EXAMPLE, IN MEETING THE 10 DECIBEL LIMIT FOR OUTLET TERMINAL LOSS. THE VALUES SHOWN ABOVE ARE TYPICAL BUT THE ECONOMICAL TOLL TERMINAL LOSS IS EXPECTED TO VARY CONSIDERABLY IN INDIVIDUAL CASES.
2. PAD VALUES DEPEND ON NOISE AND CROSSTALK CONDITIONS, ON LIMITING TOLL TERMINAL LOSSES AND ALSO, IN THE CASE OF INTERMEDIATE LINKS, ON ECHO MARGIN REQUIREMENTS.

STANDARDS	DECIBELS
DIRECT	17-20
2-LINK THRU PO	20
2-LINK THRU TC	22
3-LINK	21
4-LINK	22
5-LINK	23
OUTLET TERMINAL LOSS	10

CODE

TC	TERMINATING TOLL CENTER
PO	PRIMARY OUTLET
RC	REGIONAL CENTER
-ꟿ-	SWITCHING PAD
x—1—	INDICATES TYPICAL TOLL TERMINAL LOSS
(6)	MINIMUM WORKING ECHO NET LOSS (ASSUMES NO TRANSMISSION IMPAIRMENTS)
9	EFFECTIVE WORKING NET LOSS-VIA CONDITION
[+3]	ECHO MARGIN

FIG. 1. Typical Example of the General Toll Switching Plan, Showing Limiting Toll Circuit Losses (Courtesy Bell System)

service in the United States and throughout the world, with the development and expansion of telephone systems in other countries.

From Table 1 it will be noted that any two subscriber telephones which have access to the nationwide toll network can be connected together, using not more than five toll circuit links and four switches. It is assumed that the telephones are located at their respective toll center (TC) points, i.e., not at tributary points, which would necessitate using a tributary trunk to reach the respective TC office.

The plan provides for *eight regional centers* (*RC*), Atlanta, Chicago, Dallas, Denver, Los Angeles, New York, San Francisco, and St. Louis, each being strategically located within the United States, to serve as toll switching centers of the first order. Each of these centers is connected by direct, high-grade toll circuits to each of the other centers. Within each RC area are a number of important toll centers known as *primary outlets* (*PO*), each being connected by direct, high-grade toll circuits to its own RC, other RCs and other POs, as required to best handle the traffic. Finally, each PO serves directly all the *toll centers* (*TC*) within its area, and the TCs serve the subscribers within their local areas, either directly or through their tributary offices. Thus, the plan provides for a concentration of the toll traffic at the various toll centers which have access to or are accessible from any part of the nationwide system (including Bell and Independent) through direct or switched connections.

Table 1 shows overall standards and number of links and switches, and Table 2 shows assigned losses for the different toll links, under the present general toll switching plan.

Table 1. Overall Standards

Toll Connection * (for switched traffic)	Overall Standard, decibels	Number of Circuit Links	Number of of Switches
Direct	17–20	1	0
TC-TC-TC	22	2	1
TC-PO-PO-TC	21	3	2
TC-PO-RC-TC	21	3	2
TC-PO-RC-RC-TC	22	4	3
TC-PO-RC-RC-PO-TC	23	5	4

* The letter codes are defined in Fig. 1.

In general, four-wire circuits (a separate path for each direction of transmission) or carrier channels are employed for the long-haul, intermediate toll links because of their better performance at low losses than that of two-wire circuits. Two-wire circuits are generally used for the shorter end links and toll trunks.

Table 2. Allowable Toll Link (Circuit) Losses

Toll Link (for switched traffic)	Effective Working Net Loss, decibels	Minimum Working Echo Net Loss, decibels (assumes no transmission impairments)	Echo Margin, decibels
TC-PO (end link)	10-(TTL) *	7-(TTL)	+3
PO-PO (intermediate link)	1	3	−2
PO-RC (intermediate link)	1	3	−2
RC-RC (intermediate link)	1	3	−2
PO terminal loss	10 †		

* This value depends upon the most economical and practicable toll terminal loss for each individual toll center which will meet the required *primary outlet* (*PO*) *terminal loss* of 10 db.

† This value results from taking one-half of the loss (20 db) for a two-link connection through a gain center (PO or RC).

The PO terminal loss of 10 db is fixed, unless changed under the plan. This loss may be allocated to the TC-PO circuit and the toll terminal loss as required. Toll terminal losses (TTL) vary from about 0 to 5 db.

TOLL CIRCUIT OPERATING REQUIREMENTS. The *minimum working net loss* (*MWNL*) of a toll circuit is the lowest net loss that may be assigned that will satisfy the design objectives imposed by singing, echo, crosstalk, and noise, when subject to maximum negative transmission variations.

The minimum working echo net loss (MWENL) is the lowest 1000-cycle net loss which can be assigned so that a circuit will satisfy the echo objectives, including the assigned echo margin. If the loss at which a circuit is operated is greater than the loss required to offset the echoes arising from the circulating current paths within the circuit, a *positive echo margin* is said to result. If the reverse is the case, a *negative margin* will be introduced. In order to operate the plant at lowest over-all losses on built-up or switched connections consisting of two or more links, positive echo margins have been assigned to some classes of circuits and negative margins have been assigned to others. Switching arrangements are so designed that negative margins will be offset in any connection.

Echoes are the result of imperfect balances in toll circuits equipped with telephone repeaters and four-wire terminating sets. The two-wire circuits are necessarily converted to four-wire circuits at each repeater, and the four-wire circuits require four-wire terminating sets at their terminals to convert the four-wire circuit to two-wire before extending it to the toll switchboard. At certain important switching offices, four-wire switching on a mechanical basis may be applied. At the points of conversion, a balancing network terminates one branch of the hybrid coil, and the opposite branch of this coil is connected to the outgoing or incoming toll circuit or the extension to the switchboard. It is not practicable to match the impedance of the toll circuit exactly or the extension with the impedance of the network. Thus, part of the voice currents are transferred across the hybrid bridge into the repeater inputs in varying degrees at each repeater or terminating set on the circuit instead of dividing equally between the outgoing line and its balancing network. These currents which enter the repeater inputs will be amplified and travel back to the talker with some delay, so that he hears his own words (in reduced volume) coming back to him an instant after he has spoken them. The listener may also be affected. As the delay and return volume increase, the annoyance becomes greater and may reach the point at which the conversation is not satisfactory. Figure 2 shows minimum working net losses for terminal grade circuits as limited by echoes, versus typical lengths of toll cable without echo suppressors and with anti-sidetone sets.

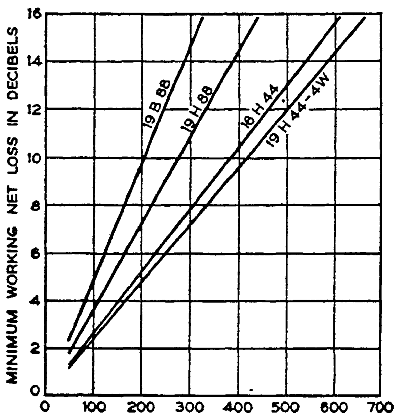


FIG. 2. Minimum Working Net Loss of Terminal Grade Circuits as Limited by Echoes, versus Typical Toll Cable Circuit Lengths without Echo Suppressors and with Anti-sidetone Sets (Courtesy Bell System)

To overcome echo difficulties, repeater gains must be properly assigned and regulated. Also, an echo suppressor has been developed which, by voice current action, causes a high loss to be introduced in one side of the four-wire circuit while speech is being transmitted on the other side. A simple schematic of this device is shown in Fig. 3. Generally, two-wire circuits are relatively short and do not require echo suppression.

The minimum working singing net loss (MWSNL) is the lowest net loss assignable to a circuit which will meet singing requirements. As indicated above under "echoes," the unbalances existing in practice at the hybrid coils of telephone repeaters and four-wire terminating sets cause part of the outgoing energy from one branch of the four-wire circuit to pass through the hybrid coil bridge points to the opposite transmitting branch of the four-wire circuit. At each hybrid coil this action occurs, so that, whether the circuit consists of only a two-wire repeater with terminating lines or a long four-wire circuit with several intermediate repeaters and a four-wire terminating set at each end of the circuit, a circulating current is established, provided that the net circuit gains exceed the net circuit losses in the circulating current circuit and the phase change in the circulating current is a multiple of 360°.

It is thus necessary in designing circuits, particularly two-wire, to limit these circulating currents by assigning repeater gains, so that, for an average circuit net loss, the most critical two-wire repeater for 95 per cent of the connections will have losses which total at least 10 db more than the gains in the two directions of transmission. For the short terminal circuits with one or two repeaters, an 8-db *singing margin* will usually be satisfactory.

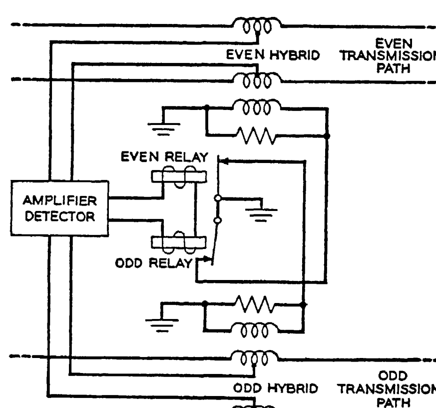

FIG. 3. Schematic of Echo Suppressor Circuit (Courtesy Bell System)

Figure 4 shows minimum working net losses, as limited by singing, versus typical toll cable circuit lengths for specified conditions of repeater spacing and singing points.

The minimum working crosstalk net loss (MWXNL) is the lowest net loss assignable to a circuit which will satisfy crosstalk requirements under all operating conditions. *Crosstalk* is the electric and magnetic transfer of speech or similar currents from one telephone message circuit to another. It may or may not be intelligible, but when it is composed of confused noise from several sources it is known as *babble*.

Crosstalk usually results from cumulative, slight unbalances between circuits or high energy level differences acting through close couplings in cable or open wire. The transferred energy is amplified wherever telephone repeaters are present.

Two types of crosstalk, *near end* and *far end*, develop between circuits. The first type travels to a listener on one circuit in a *direction opposite* to the transmission from a talker on another circuit; the latter type travels to the listener on one circuit in the *same direction* as the transmission from a talker on another circuit. Near-end crosstalk occurs in wire but not in properly arranged carrier circuits (except W.E. Co. G-type); far-end crosstalk appears in both wire and carrier circuits.

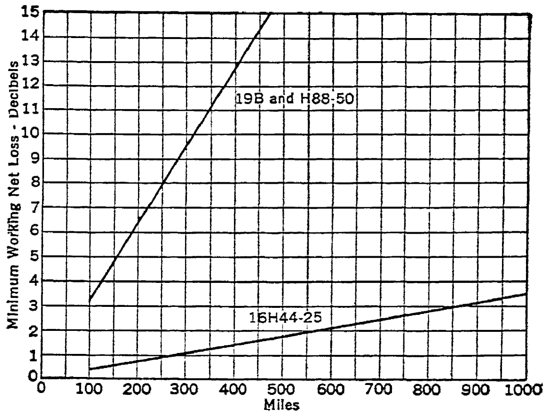

FIG. 4. Minimum Working Net Loss as Limited by Singing, versus Typical Toll Cable Circuit Lengths (Courtesy Bell System)

The effect of crosstalk on subscriber conversations depends not only on the actual volume of crosstalk heard but also on circuit and room noise present, circuit losses, and personal reactions.

Crosstalk is controlled primarily by avoiding excessive energy level differences and couplings[1] between adjacent parallel circuits. Techniques have been developed to limit both level differences (by proper regulation of repeaters and other amplifiers) and high couplings and to employ different frequency bands in controlling crosstalk.

Figure 5 shows minimum working net losses, as limited by crosstalk, versus typical *toll* cable circuit lengths.

Crosstalk values have generally been expressed in terms of *crosstalk units*, which are defined as one million (10^6) times the ratio of the crosstalk current or voltage at the observing point on the *disturbed circuit* to the current or voltage at the sending point on the *disturbing circuit* (assuming equal impedances at these two points). If the impedances are not equal, the square root of the power ratio may be used in place of the current or voltage ratio. With the development of visual indicating apparatus for measuring crosstalk and noise, crosstalk measurements have more generally been made in terms of *crosstalk coupling loss-db*, which means the net transmission loss between the sending point on the disturbing circuit and the receiving point on the disturbed circuit, it being understood that the higher the measuring set reading (loss), the less the actual coupling. More recently, the term *db above reference coupling-dbx* has come into use. This term means the coupling in decibels above reference coupling, and reference coupling means the coupling which would be required to give a reading of 0 dba on a W.E. Co. 2B noise-measuring set connected to the disturbed circuit when a test tone of 90 dba (using the same weighting as on the disturbed circuit) is impressed on the disturbing circuit.

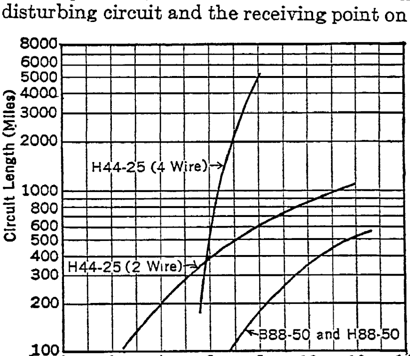

FIG. 5. Minimum Working Net Loss as Limited by Crosstalk, versus Typical Toll Cable Circuit Lengths (Courtesy Bell System)

The 2B set is designed to measure crosstalk and noise volumes or couplings (as well as other quantities) in decibel values. These values can be adjusted to a common basis for different types of lines and telephone receivers so that a given adjusted value, designated *dba*, will mean the same interfering effect to the ear, regardless of the type of line or subscriber set, affected by the crosstalk or noise being measured.

Figure 6 shows the relation between the terms crosstalk units (cu), crosstalk coupling loss, db, and crosstalk coupling, dbx.

The present design requirements for crosstalk limitations in circuits are taking into account the wide reactions of different people to different amounts of crosstalk, the variation in crosstalk volumes due to the variation in speech power of different talkers, the action of room and line noise on crosstalk effects, the intelligibility of crosstalk, costs involved in its control, and attainment of a good balance in judging the importance of the various factors entering into circuit design. Present practices indicate that it is inadvisable to permit crosstalk couplings in excess of 30 dbx (equivalent to 60 db crosstalk coupling loss or to 1000 crosstalk units), as measured from the transmitting to the receiving switchboard for a single disturber circuit.

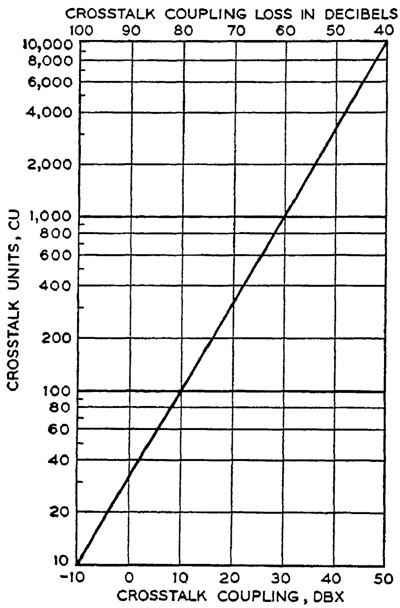

Fig. 6. Chart showing Relation between Crosstalk Units, cu; Crosstalk Coupling Loss in Decibels; and Decibels above Reference Coupling, dbx (Courtesy Bell System)

Noise transmission impairments which may exist in toll circuits due to power line induction, noise generated within telephone systems, or circuit irregularities must be limited to avoid transmission penalties in circuit operation. Noise reaching the subscriber's ear through his telephone receiver is, in fact, equivalent to adding loss to the circuit. Table 3 shows how these penalties are evaluated in terms of *noise levels-dba.*

Reference noise (RN) is used as a base in the calculation of circuit noise in terms of decibel penalties, as given in Table 3. Reference noise is registered as 0 dba on a 2B noise-measuring set when the input into this set is 10^{-12} watt of 1000-cycle power (line weighting). RN is equivalent, when measured at the terminals of a 600-ohm line (with line weighting), to 7 noise units; if measured across the terminals of a W.E. Co. No. 144 receiver, it is equivalent to 14 noise units.

Circuit noise of 29 db above RN (200 noise units) or less in a 600-ohm line is not considered to offer any appreciable noise impairment to a conversation, but for about each 3-db increase in noise level above 29 db the impairment increases 1 db, which must be included in the overall circuit loss.

Remedial measures have been perfected for controlling most types of noise to avoid penalties.

Distortion transmission impairment (DTI) to conversations results from a restricted or modified transmission of the full voice-frequency band necessary for clear, understandable speech. Such restriction or modification may be due to a low cutoff frequency of certain types of loaded line facilities and line apparatus. The older H172-63 loaded cable facilities and certain early types of telephone repeaters, carrier systems, and filters give distortion impairments. The latest types of loaded cable facilities, such as H44-25 and H and B88-50, and the latest-type standard repeater and carrier systems are considered to offer no appreciable distortion for the usual lengths employed. Figure 7 and Table 4 show distortion impairments for different facilities with FIA-AST subscriber sets and H88 switching trunks, as used in the Bell System.

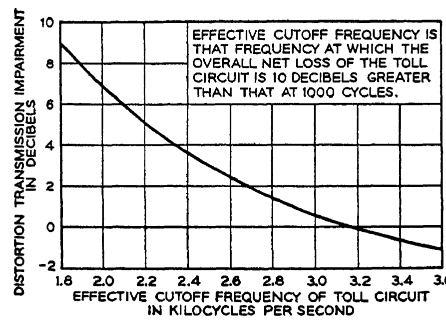

Fig. 7. Diagram Showing Distortion Transmission Impairment for Different Facilities with FIA-AST Subscriber Set and H-88 Switching Trunk, versus Effective Cutoff Frequency of Toll Circuit (Courtesy Bell System)

Volume transmission losses in toll circuits will vary with changes in temperature and, in addition, for open-wire facilities with such conditions as rain, sleet, and snow. These transmission variations are different for aerial and underground cable and open wire and also change with frequency.

Table 3. Noise Transmission Impairments Corresponding to Noise Magnitudes Measured or Computed at Various Points in the Transmission Circuit

Type of circuit		Toll circuits	Toll connecting, tandem and interoffice trunks	Local loops	
Point of measurement or estimate		Receiving toll switchboards	Local office	Subset terminals of loop	Across receiver terminals
Impedance of Measuring device		600 ohms, terminating, 6000 ohms bridging *	600 ohms, terminating, 6000 ohms bridging *	600 ohms terminating	Approximately 2000 ohms
Noise Rating	Noise Transmission Impairment, decibels	Noise Magnitudes in dba			
		Line Weighting	Line Weighting	Line Weighting	Receiver Weighting
N0	0	0 –29	0 –26	0 –20	0–17
N1	1	29.1–32	26.1–29	20.1–23	17.1–20
N2	2	32.1–35	29.1–32	23.1–26	20.1–23
N3	3	35.1–38	32.1–35	26.1–29	23.1–26
N4	4	38.1–40	35.1–37	29.1–31	26.1–28
N5	5	40.1–42	37.1–39	31.1–33	28.1–30
N6	6	42.1–43	39.1–40	33.1–34	30.1–31
N7	7	Over 43	Over 40	Over 34	Over 31

* When bridging measurements are made on a line, 600-ohm impedance is assumed each way from the bridging point. Under these conditions (*a*) with *144 rec.* line weighting, a correction † of +11 db is added to 2B set readings and (*b*) with FIA line weighting, a correction † of about +18 db is added to 2B set readings, in order to express readings in dba. If impedances each way from bridging point are not 600 ohms, correct 2B set readings as follows:
Each impedance 300 ohms, correction is +3 db.
Each impedance 400 ohms, correction is +1.8 db.
Each impedance 900 ohms, correction is −1.8 db.
Each impedance 1200 ohms, correction is −3.0 db.
Each impedance 2000 ohms, correction is −5.2 db.
† The corrections thus indicated should be added before entering Table 3.

Present Bell System practices provide for maintaining toll circuits of minimum to maximum lengths within the following deviations from the specified value: voice-frequency (VF) cable, ±1.0 to ±4.0 db; K-carrier, ±2.0 db; VF open wire, ±1.0 to ±3.0 db; open-wire carrier, ±2.0 db; and various combinations and lengths of facilities, ±1.0 to ±4.5 db.

Such limitation is provided for long VF cable circuits by devices known as *automatic transmission regulators* spaced at proper intervals along the circuit to automatically add or reduce gain in the circuit as required to maintain the specified volume limits. Figure 8 shows a pilot wire transmission regulator circuit, with its pilot wire cable pair in the same cable as the regulated cable circuits. Long cable circuits have a regulating repeater (in place of the regular repeater) about every 150 miles. These repeaters are controlled at each point by a master regulator, in accordance with temperature change in the pilot wire, which causes the repeater gains to vary above or below normal setting in steps varying from 1/4 to 1 db over a range varying from 2.75 to 19 db as required to maintain normal level. No system of automatic regulation has seemed necessary for use with open-wire voice-frequency facilities.

Since in cable circuits the attenuation-frequency curve is appreciably different at different temperatures, it is necessary to correct for this difference, known as *twist*, for high-frequency carrier systems, such as the K-system. The twist effect in a 100-mile aerial toll cable is shown in Fig. 9. Twist correcting circuits, as shown in Fig. 10, are located in long cable circuits about every 100 miles for aerial and 200 miles for underground cable.

For open-wire carrier systems, pilot channel regulator equipment is incorporated in the carrier terminal and repeater design to maintain transmission levels.

The effective transmission loss of a toll circuit is equal to the *1000-cycle loss* plus any *noise or distortion transmission impairments*, all expressed in decibels.

The overall effective equivalent of a complete toll connection from subscriber to subscriber is the sum of the *effective transmission loss* of the toll circuit or circuits and the *toll terminal losses* at the terminating toll centers.

Table 4. Distortion Impairments

Voice Frequency Facility	2-Wire or 4-Wire	Filter (Note 4)	Length in Miles for Various Impairments							
			−1 db	0 db	+1 db	+2 db	+3 db	+4 db	+5 db	+6 db

EB										Any
G1			2							
H1—No repeaters			1	3						
J			Any							
K			Any							
L			Any							

Notes:

1. Impairments are referred to a distortionless toll circuit containing a 250–3000 cycle band-pass filter having square cutoffs.
2. Impairments are substantially independent of gage.
3. Impairments are substantially independent of type of line repeater, provided standard equalization is employed.
4. A refers to 13A or 32A filters; B, to 13B, 32B or 128B filters; C, to 13C, 32C or 128C filters; D, to D93985, 32C modified per KS-4165 (D160523), or 128A filters. 1059B filter is associated with the high level 22-type repeater (104-D tubes).

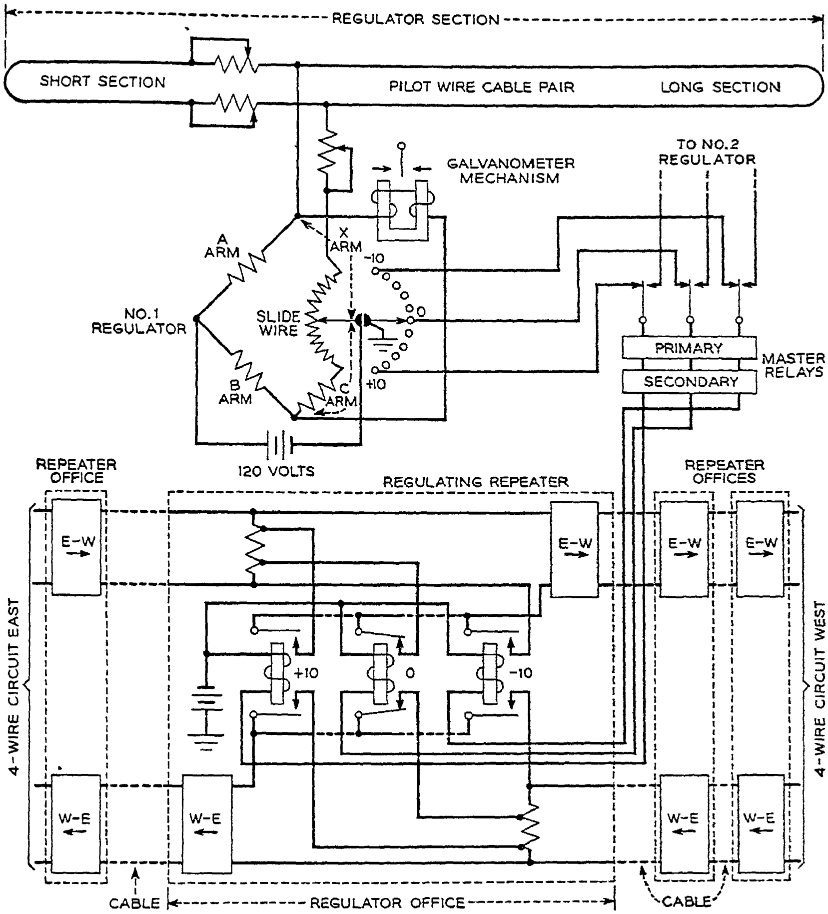

FIG. 8. Pilot Wire Transmission Regulator Circuit (Courtesy Bell System)

The desired overall transmission loss having been apportioned to the various component parts of toll connections, as shown under the plan, the pattern for the engineering of toll facilities is thus fixed. The *toll terminal loss* as determined for each toll center is defined as the average (one-half of the sum) of the effective transmitting and receiving losses (see article 15) from the toll circuit termination to (and including the efficiency of) the subscriber station apparatus. With this loss determined for a given toll center, the toll switching trunks and subscriber loops (exchange plant) must be engineered to meet this requirement, although exchange plant engineering also is subject to *exchange standards*.

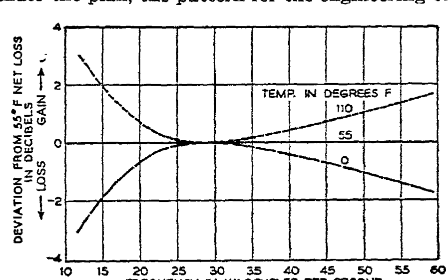

FIG. 9. Twist Effect in 100-mile Aerial Cable Circuit (Courtesy Bell System)

TOLL CIRCUIT LINE-UP PROCEDURE consists of adjusting the operating gains of voice frequency and carrier repeaters, carrier system terminals, and other associated apparatus, such as switching pads, equalizers, attenuators, and other devices necessary for proper operation of the toll circuits.

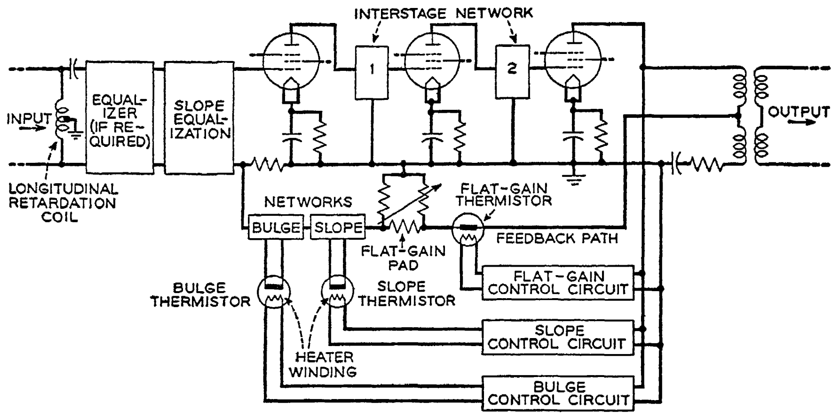

FIG. 10. Twist Correcting Circuit for Type K Carrier System (Courtesy Bell System)

From the general toll switching plan (Fig. 1) it is evident that intermediate toll circuits cannot be used for terminal traffic with the very low losses assigned without having excessive echo, singing, crosstalk, and other troubles. It is thus necessary to provide *switching loss pads* in each of these circuits at each end and in the end link circuits (PO-TC) at the primary outlet end, which pads remain in these circuits for terminal traffic and are automatically switched out of the circuits for via (through) traffic. The total pad loss usually employed is thus equal to the difference between the operating net loss of a given circuit in its terminal and via conditions.

In general, when a circuit meets the design objectives in the via condition and the loss of the switching pad or pads satisfies the crosstalk objectives in the terminal condition, singing will also be satisfactory; also, echo will be within limits if the pad loss is at least equal to the assigned negative echo margin.

Transmission levels on toll circuits require careful coordination with other adjacent or nearby circuits to prevent excessive crosstalk. Also levels should be relatively high (within the capabilities of the associated equipment) to provide suitable signal-to-noise ratios. Levels of about +3 to +6 db generally are employed at the input to two-wire lines, and from +4 to +10 db at the input to four-wire voice-frequency lines. Open-wire carrier system units employ about +16 db (input to the line) for Bell-owned systems.

TOLL LINE SIGNALING usually employs 20-, 135-, or 1000-cycle signaling systems. For short non-composited toll facilities, 20-cycle signaling is usual; for the longer toll circuits having composite sets 135- or 1000-cycle signaling is required. Since 1000-cycle signaling will readily pass along any type of message circuit that will transmit voice frequencies as such or in modulated form, this type of signaling is general for all long toll circuits. For crossbar toll operation, as described in article 3 of this section, pairs of frequencies in the range of 700 to 1700 cycles are sent out over toll trunks for pulsing the desired signals.

15. SERVICE REQUIREMENTS—EXCHANGE

EXCHANGE PLANT STANDARDS are based largely upon giving the telephone-using public a convenient, satisfactory service at the least cost consistent with protecting the investment and employee interests.

The establishing of *exchange plant standards* involves taking into consideration the efficiency of subscriber telephone sets as well as loop, trunk and central-office equipment (COE) losses and signaling ranges. It is thus necessary to establish a means of rating subscriber loops and trunks with respect to a known transmission standard in order that the capabilities and costs of the various types of equipment and line facilities that are available for use in exchange plant may be compared and it may be judged whether or in what respect the equipment facilities meet the assigned standards for a given exchange.

Overall transmission standards are the upper limits for the overall effective station-to-station transmission and form the basis of plant design. In the practical application of such standards, allowances are usually deducted for room noise, and sometimes for other impairments, from the overall standard so that the resulting *design standard* may be used directly in the design of the exchange plant.

The determination of the most desirable transmission standards for a given exchange is a matter of engineering and business judgment, based on a comprehensive view of local conditions and on past performance.

On the basis of general usage of the W.E. Co. FIA-AST or equivalent subscriber sets, Bell System practices contemplate ultimately overall exchange transmission standards of 10 to 14 db for multioffice exchange area traffic, with the possibility of the standards being 1 or 2 db higher for tandem operation. In single-office areas the standard is generally taken as approximately equal to the loop limit, considering both transmission and signaling.

A working reference system was devised some years ago by the Bell System as a means of rating exchange loop and trunk plant. This system, shown in Fig. 11, includes two identical common-battery subscriber loops, each connected through a 24-volt battery-feed repeating coil, to a variable, distortionless (up to 3000 cycles) 600-ohm impedance

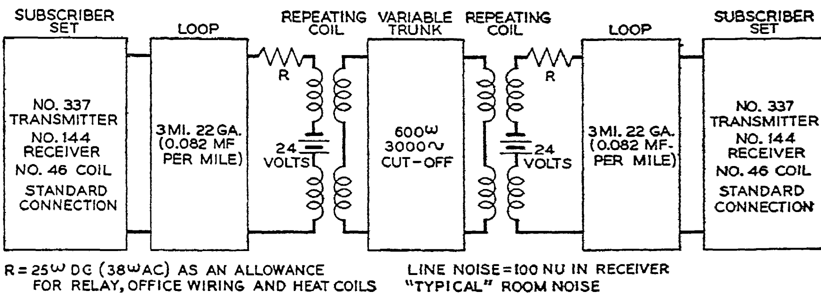

FIG. 11. Working Reference System for Specification of Effective Losses (Courtesy Bell System)

trunk. The length of loops and types of station and central-office apparatus are typical of conditions and apparatus existing at the time the system was devised and are still regarded as suitable for reference purposes.

The working reference system is so designed that it permits comparing *effective transmission losses*, which include volume and distortion losses, line and room noise, and sidetone effects. The system itself has an actual effective transmission loss or rating of 18 db, based on 7.5 db in the transmitting loop, 1.8 db in the receiving loop, and 8.7 db in the trunk. The line and room noises included in each loop are respectively 100 noise units (NU) and room noise comparable to that in quiet offices or fairly noisy residences. This room noise is equivalent to 50 db RAP (reference acoustic power, which is 10^{-16} watt of sound power per square centimeter at the listening ear).

EFFECTIVE TRANSMISSION PERFORMANCE of exchange telephone plant, as interpreted in the United States and some other countries, is evaluated by the generally accepted method of counting the number of requests to repeat words or sentences, in a short interval of time, made by talkers with average volume over the circuit to be evaluated. Other methods of evaluation, such as the "immediate appreciation" method, have been studied but have not been adopted in the United States.

For convenience, each effective loss is considered to have three components—volume, distortion, and sidetone losses. The distortion and sidetone losses in the working reference system *are considered to be zero for reference purposes*, and the effective loss of this system is thus numerically equal to the volume loss.

The individual effective losses which make up the effective loss of a complete circuit are:

1. Transmitting loop loss.
2. Receiving loop loss.
3. Trunk loss.
4. Terminal junction loss.
5. Central-office loss.
6. Intermediate junction loss.
7. Loss due to line noise.

The effective loss due to room noise is not considered a circuit loss, although it does affect conversations.

Losses 1 and 2 are determined by comparing the effect on conversation of the element or complete loop to be rated with the effect of the corresponding element or complete loop of the reference system, using the other components of the reference system to complete the talking circuit. Thus, since the effective loss of the transmitting loop of the reference system is 7.5 db, any transmitting loop which is substituted for the reference loop and which gives the same grade of service (repetition rate) also has an effective loss of 7.5 db. However, if the substituted loop gives the same grade of service after an increase of 2 db is made in the variable reference trunk loss, then the substituted loop has an effective loss 2 db lower than the reference loop, or if the reference trunk loss is adjusted to 2 db less than normal the substituted loop has an effective loss 2 db higher than the reference loop. Receiving loops are rated in the same manner, using the reference receiving loss of 1.8 db.

A given trunk may be rated by substituting it for the reference trunk and using the reference loops in the connection. The adjustment in the reference trunk loss determines the rating of the given trunk (called the *effective connecting circuit loss*) with respect to the reference trunk loss of 8.7 db, the fact that the assigned effective loss of the reference trunk is equal to its attenuation below 3000 cycles being kept in mind. The effective connecting circuit loss thus obtained is not in a useful form but may be made so by dividing it into an *effective trunk loss* and two *effective terminal junction losses* (one at each end), which latter are considered equal for this symmetrical circuit.

This division between trunk and junction losses is necessary for the practical establishment of a set of effective trunk loss curves, since for each type of trunk the terminal junction losses are different for each different combination of loops, sets, and central offices at the trunk terminals. The *effective trunk loss* consists of the volume attenuation of the trunk and that part of the distortion that is proportional to trunk length, thus permitting the establishing, for each type of trunk, of a value of effective trunk loss on a per mile basis. Each effective *terminal junction loss* includes a *volume reflection correction* plus one-half of that part of the *distortion loss* of the trunk that is not included in the effective trunk loss plus a correction for the effect on *sidetone* of the trunk impedance. The effective terminal junction losses can thus be considered as correcting factors which, when added to the sum of the other losses, will give the correct effective loss for a complete circuit.

The assumption that the effective connecting circuit loss (trunk rating) is made up of a constant plus a loss proportional to length is a good approximation for complete circuits containing a single type of trunk, except for effective trunk losses of about 5 db or less and for coil loaded trunks of any effective loss. For the low-loss trunks, accuracy in determining the trunk loss is not usually important. For loaded trunks, the curve of connecting circuit loss versus length departs from a straight line, because the end sections change with a change in the trunk length. However, if the connecting circuit loss is plotted only for lengths permitting half-section termination, a smooth curve is obtained which closely approximates a straight line above 5-db loss, and this curve may be used to determine the trunk loss per mile and the terminal junction loss for this termination. Similar curves, approximating straight lines, paralleling the one for half-section termination, may be set up for any other desired end section at each end. Such approximate straight lines determine the effective terminal junction losses for the respective end sections chosen. Thus, the *effective connecting circuit loss* of a loaded trunk, terminated at half-section at one end and at other than half-section at the other end, is considered as made up of the *effective trunk loss per mile* times the total geographical length of the trunk in miles (including the end sections) plus the *effective terminal junction loss* for each end section.

The effective loop losses apply directly only with the 600-ohm reference trunk. The effective trunk loss applies satisfactorily for any combination of loop, set, and central office, but the effective terminal junction losses obtained with the reference loops do not apply for other combinations of loop, set, and central office. The terminal junction losses for other combinations of these elements, including other than the reference trunk, may be determined as required.

EFFECTIVE LOOP LOSSES include the loss of three different types of *simplified central-office circuits*, namely, the 24-volt repeating coil circuit used in the working reference system, a 48-volt repeating coil circuit typical of standard circuits for toll connections, and a 48-volt step-by-step circuit used in local dial offices.

In practice, actual central-office circuits have equipment and wiring, additional to the simplified circuits, the loss of which is dependent upon the actual loop and trunk conditions. However, a single value of loss for the additional equipment and wiring for each type of office and connection is usually sufficient if it is determined under typical limiting loop conditions. The *effective local offices losses* are therefore determined between the working reference loops and trunk for the more commonly used central-office connecting circuits.

For trunks composed of different types of facilities, such as 19- and 22-gage cable, *intermediate junction losses* occur at each junction of the dissimilar types of facilities because of reflections of energy at these points. Such losses have been determined for various combinations of facilities used in the Bell System and must be added as part of the overall trunk loss.

Effective losses due to line noise (Table 3 of this section) should be added to the other effective losses in a given loop when the electrical noise at the receiver terminals of the loop is greater than the reference noise (100 units) assumed in the reference loops. Less noise than reference noise in the receiver is considered equivalent to reference noise.

In addition to the above-mentioned losses, if the room noise for a given loop is more or less than the room noise (50 db RAP) assumed for the reference loop, *effective room noise losses* corresponding to the difference between the actual and assumed room noise must also be added to the overall given loop loss. Figure 12 shows the effective loss due to room noise versus room noise of different intensities for two different sidetone conditions.

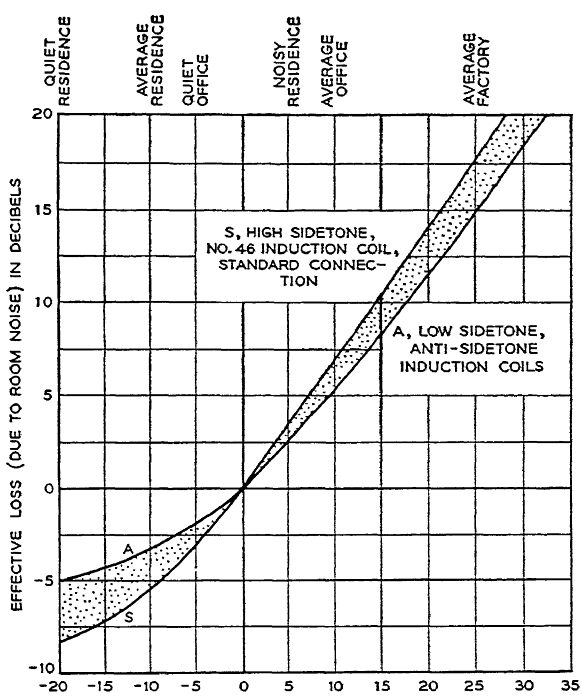

FIG. 12. Effective Receiving Loss Due to Room Noise, versus Room Noise of Different Intensities (Courtesy Bell System)

The values shown are approximate, since it is difficult to determine the actual losses due to room noise because of a number of variable factors, some of an intangible nature.

The Bell Telephone Laboratories have made field and laboratory investigations comparing the ease of carrying on a telephone conversation over different circuits in actual service, and also studying the physical characteristics of circuits and instruments, as well as their ability to transmit speech sounds, using syllabic articulation tests under a large number of variable conditions encountered in service. From these investigations a number of *effective transmission loss curves* showing effective loop losses in decibel versus loop length in thousands of feet have been prepared for the commonly used types of central offices, loop facilities (cable or open wire), and telephone sets, based on the working reference system.

Figure 13 shows separate effective transmitting and receiving loss curves (provisional) for both 24-volt exchange grade and 48-volt toll grade battery supply and also the average $(T + R)/2$ curves for both grades of battery supply. These particular curves apply for W.E. Co. type 1 or 10 Manual or Panel Dial Offices, non-loaded 22-BSA gage cable loops, and the latest-type W.E. Co. Antisidetone (AST) subscriber sets with FIA (handset) or 635-706A (deskstand) type instruments. These curves are typical of other sets of subscriber loop loss curves for different types of central offices, loop facilities, and sets, except that the loss values are different for the different conditions.

In addition to the non-loaded subscriber loop loss curves, effective loss curves are required showing, for different lengths and conditions, the losses of loaded trunks and loops, subscriber loop losses having loops composed of two or more different types of facilities, current supply losses versus transmitter current and versus loop resistance, transmitting and receiving losses due to sidetone, terminal junction losses, and many similar curves useful to the engineer.

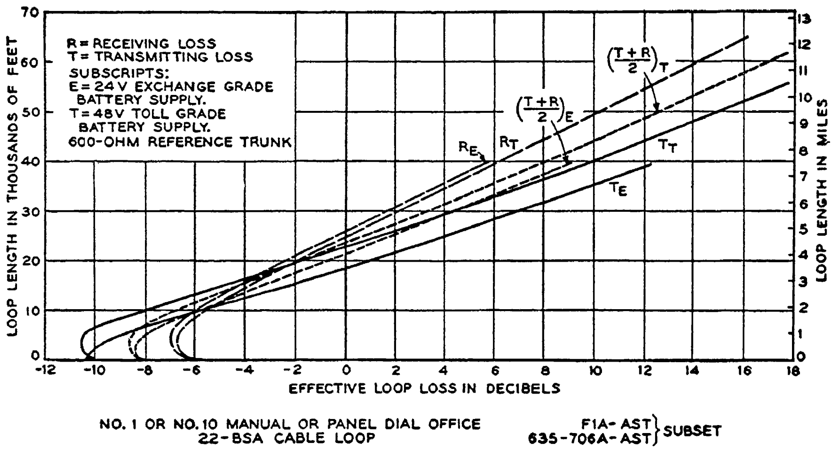

FIG. 13. Effective Transmission Losses in Common-battery Subloops (Courtesy Bell System)

SWITCHBOARD OPERATOR EFFECTIVE TRANSMISSION PERFORMANCE is also rated by means of the working reference system, except that the reference trunk impedance is 900 ohms instead of the 600 ohms employed for subscriber loop ratings. In making comparisons, the operator circuit is connected to the reference system in place of one of the subscriber loops. Since no loop is involved for this connection, single values of transmitting and receiving losses are adequate for rating each combination of operator's telephone set circuit and instruments.

The typical values of line and room noise specified for the operator terminal are 45 db RAP for line noise in the listening ear and 65 db RAP for room noise. The reference operator receiver (W.E. Co. No. 528) is more efficient than the reference subscriber receiver (W.E. Co. No. 144), and the reference room noise for operators is higher than that for subscribers. Incoming room noise from the distant operator's set also adds to the overall effective loss in the receiving operator's circuit. The latest design in operator transmitters and receivers provides improvements in operator transmission which will permit overall operator to operator standards in the approximate range of 10 to 12 db, which is comparable with present local subscriber to subscriber plant design.

16. PLANT DESIGN—TOLL

TOLL FACILITIES have been developed, since the earliest open-wire (iron) type, to include the following: (1) open wire, (2) cable, (3) carrier, and (4) radio.

TOLL OPEN-WIRE FACILITIES consist principally of hard-drawn copper, copper steel, and high-tensile-strength steel bare wire.

The three gages of *hard-drawn copper line wire* employed most commonly in Bell System plant are 165, 128, and 104 (mil diameter) wire, the electrical characteristics of which are shown for various positions and arrangements on the pole line in Fig. 14. For wet weather the value of g increases and other factors change. Several other gages of copper line wire are in use in this and other countries, such as 102 mil diameter, but the three mentioned above are representative of this type of wire usage. Also, a number of basic wire gages are in use, so that the mil diameter of a given gage of wire, such as No. 8, may be different under the different basic gages. Figures 15, 16, and 17 show, respectively, the attenuation frequency characteristics of different gages of hard-drawn copper physi-

Notes:
1. All values are for dry weather conditions.
2. All capacity values assume a line carrying 40 wires.
3. Resistance values are for temperature of 20 deg cent (68 deg fahr).
4. DP insulators assumed for all 12-in. and 18-in. spaced wires—CS insulators assumed for all 8-in. spaced wires.

FIG. 14. Characteristics of Open-wire Telephone Circuits at 1000 Cycles per Second. (Courtesy Bell System.)

cal (side in Fig. 15) circuits over the voice, type C, and type J carrier frequency ranges, for both wet and dry weather conditions. The wire spacing and types of insulators involved are 12-in. and double-petticoat (DP) for Fig. 15, and 8-in. and CS glass for Figs. 16 and 17. In the frequency range of 20 to 150 kc, the attenuation factor increases rapidly with frequency where the wires are covered with snow or ice. For example,

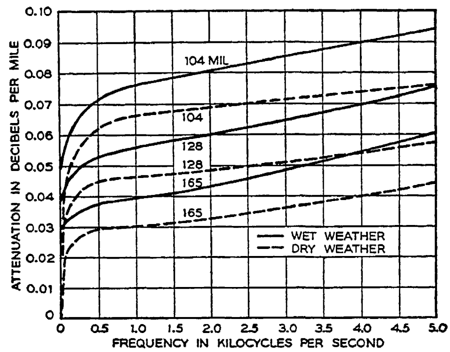

FIG. 15. Attenuation-frequency Characteristics of Open-wire Side Circuits over the Voice Range (Courtesy Bell System)

with about $1/2$ in. total diameter of melting glaze on a type J, 8 in., CS insulated, 165-gage carrier pair, the attenuation increases approximately from 0.13 db per mile at 20 kc to 0.9 db per mile at 150 kc. Variations of attenuation with temperature due to resistance change in open wire are about 1 per cent per 4 $1/2$ deg fahr change from 68 deg fahr.

In recent years, *copper steel wire* has been used extensively for telephone circuits, combining strength with relatively low transmission losses and d-c resistance values. This wire is manufactured with 30 and 40 per cent conductivity, which is the conductivity ratio (in percentage) of the wire to that of the annealed copper standard of like diameter.

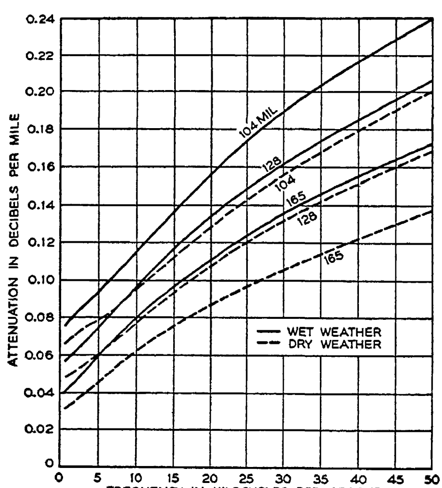

FIG. 16. Attenuation-frequency Characteristics of Open-wire Physical Circuits over the Type C Carrier Range (Courtesy Bell System)

A 40 per cent conductivity copper steel wire, which is the more commonly used type, has a steel core with a welded copper casing having a radial thickness of 20 per cent of the total radius of the wire.

The tensile strength and attenuation of copper steel pairs are about 2 to 2 $1/2$ times that of hard-drawn copper of the same size. Owing to higher attenuation, telephone repeaters

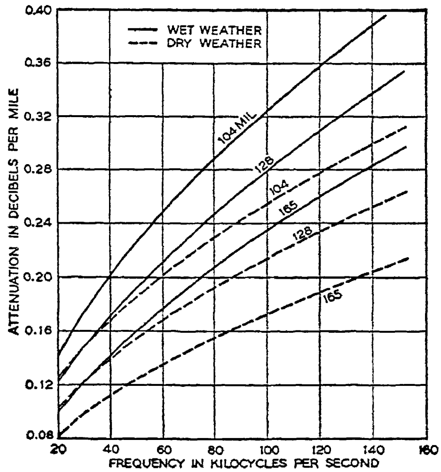

FIG. 17. Attenuation-frequency Characteristics of Open-wire Physical Circuits over the Type J Carrier Range (Courtesy Bell System)

require closer spacing with copper steel than with hard-drawn copper circuits. The characteristics of copper steel pairs are given in Table 5.

Table 5. Characteristics of Copper Steel Pairs

(Estimated for 68 deg Fahr—40 Per Cent Conductivity—53 Pairs CS Insulators per Mile)

Size of Wire, mil diameter	Frequency, kc	Resistance, ohms	Inductance, mh per pair mile		Characteristic Impedance, Dry, ohms		Attenuation, db per mile, dry		Attenuation, db per mile, wet

Notes:

1. Resistance (d-c) is 0.1 ohm less than resistance at 0.2 kc for all three gages.
2. Leakage conductance and capacities of copper steel pairs are comparable to those of same size hard-drawn copper pairs (Fig. 14).
3. For DP insulators the attenuation change from dry to wet weather conditions is about twice that for CS insulators.
4. The above estimated values will vary somewhat from actual measurements, owing to the effects of transpositions, spacing, and other small irregularities, which cannot be calculated. For 12-in. pairs, assume on the average about 10 per cent lower high-frequency impedance and about 10 per cent higher high-frequency attenuation values. The deviations should be less for the closer spaced pairs with point-type transpositions. (Courtesy Bell System.)

HIGH-STRENGTH STEEL WIRE has practically replaced the various grades of iron (E.B.B. and B.B.) and mild steel wire for telephone purposes because of its greater strength and coordination with other wire services. The high-strength steel wire now in production by several manufacturers is used for only the very short toll circuits in some parts of the country, on account of its high attenuation and inherent noise characteristics. Its principal usage is in exchange plant. Steel wire is now generally zinc coated (galvanized) electrolytically, which insures a more uniform coating than the "hot dip" process. The usual weights of zinc coating vary from 0.8 to 2.4 oz per sq ft, depending upon the customer's requirements. The characteristics are given in more detail in article 17, Plant Design—Exchange.

CABLE FACILITIES for toll purposes comprise a number of types of loaded and non-loaded cable pairs. *Toll entrance cables* are employed for extending open-wire toll lines into toll or toll terminal offices or stations for distances usually limited to a few miles. *Toll cables* are employed as permanent backbone toll plant, interconnecting principal cities and important intermediate switching and equipment centers. Toll and toll entrance cables may be of the aerial or underground type or combinations of both, but the tendency is to place them underground for greater reliability of service.

Table 6. Load-coil Spacings

Code Designation	Nominal Spacing, feet	General Application
A	700 *	Cables serving open-wire carrier.
B	3000 *	Cables serving open-wire carrier. Toll and exchange cables.
C	929 *	Cables serving open-wire carrier.
D	4500 *	Exchange cables.
E	5575 *	Toll entrance cables. Replaced by H, except when used with C spacing.
F	2787 *	Cables serving open-wire carrier (phantom circuits).
H	6000 *	Toll, toll entrance, and exchange cables.
J	600 †	Cables serving J open-wire carrier.
X	680 *	Equivalent capacity in carrier office cables.
Y	2130 *	Equivalent capacity in carrier office cables.

* For side and phantom cable capacitances of 0.062 and 0.102 μf per mile, respectively.

† For physical pair capacitance of 0.025 μf per mile.

Cable facilities, being necessarily of small-gage, soft-drawn, insulated copper conductors, in order to provide economical sizes of conductor complements, have relatively high mutual capacitances, resistances, and greatly increased attenuation per mile over the larger-gage, wider-spaced, open-wire conductors. Figure 18 shows the characteristics of standard types of paper-insulated cable telephone circuits at 1000 cycles per second, as used in the Bell System. In column 2 of Fig. 18, the abbreviations N.L.S. and N.L.P. refer to non-loaded side and non-loaded phantom respectively, while the remaining abbreviations show the load coil spacing by letter (H-6000 feet and B-3000 ft), the inductance in millihenries by the figure, and whether the circuit is a side or phantom by the letters S and P respectively. For a designation such as H-44-25, the first and second figures refer to the side and phantom coil inductances, respectively.

Table 7. Toll-entrance Cable Loading

Carrier Frequency Range, kc	Type of Loading		
0– 10	B H-15-15 (B for side, H for phantom)

0–145	J-0.72	165 open-wire, 8 in. 128 open-wire, 8 in.	Used with disk-insulated pairs in shielded, spiral-four quadded cable.
0–145	J-0.85	128 open-wire, 8 in.	
0–145	J-0.94	104 open-wire, 8 in.	
0– 30	X-2.7	Office cable loading.	
0– 10	Y-9	Office cable loading.	

The type of *loading* at present employed in *toll cables* for *four-wire* voice frequency message cable circuits is usually the 19-gage H-44-25 or H-88-50 type, since less variation in attenuation over the voice range and higher cutoff frequencies are obtained with these loadings (Fig. 18) than are possible with the older, higher-inductance-type loading. Repeaters generally are spaced at 40–50 mile intervals. For *two-wire* voice-frequency message cable circuits, 19-gage H-88-50 or B-88-50 loading is usually employed. The variation in attenuation over the voice range is small, the cutoff frequency is amply high, and telephone repeater spacings of about 40–50 miles generally are used.

For program transmission (article 18) 16-gage B-22 loaded cable pairs were specially

Note. The values for cutoff frequency and transmission loss per mile, as given in the last two columns, are calculated from the primary constants which are assumed as uniformly distributed. These values accordingly may not be identical with the measured values given in standard formal instructions. The values given in *Bell System Practices* should therefore be used for engineering work.

FIG. 18. Characteristics of Standard Types of Paper-insulated Cable Telephone Circuits at 1000 Cycles per Second (Courtesy Bell System)

developed to give a high cutoff frequency. These facilities are capable of transmitting a frequency band up to about 8000 cycles without serious distortion.

Figure 19 shows the attenuation frequency characteristics of various types of cable circuits loaded for voice frequency and program service.

Table 6 gives the code designations of load coil spacings as devised for Bell System use.

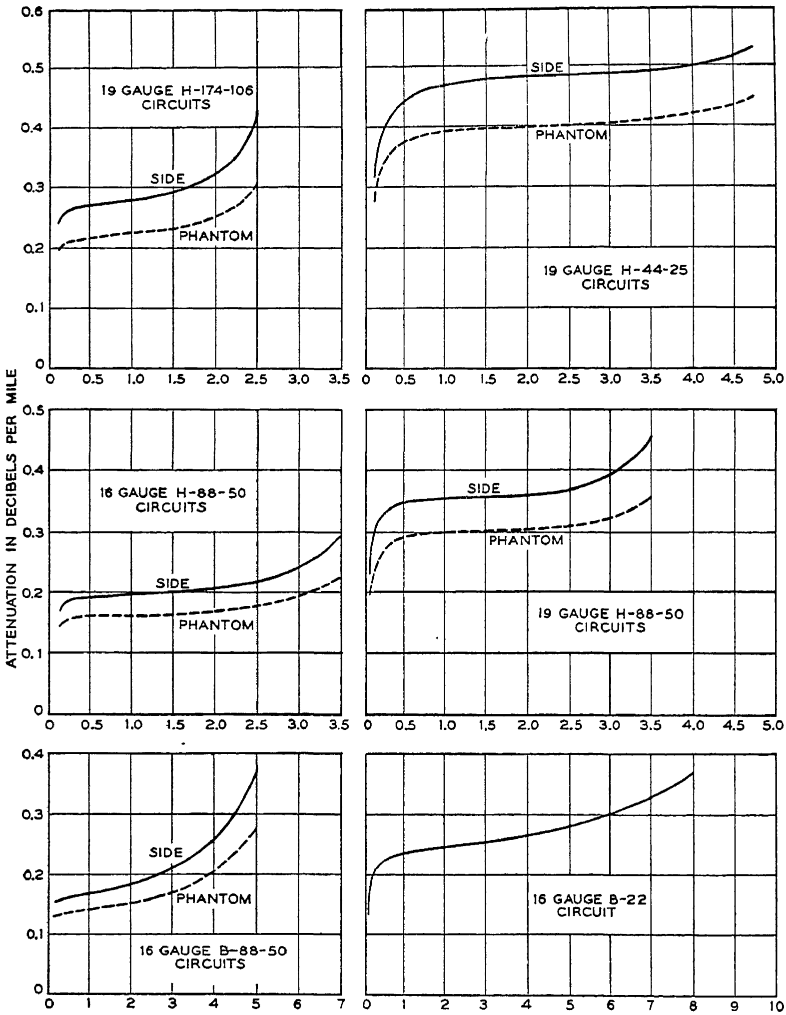

FIG. 19. Attenuation-frequency Characteristics of Various Types of Loaded Cable Circuits (Courtesy Bell System)

The type of *loading* generally used in *toll entrance cables* is of the H-31-18 type for voice-frequency circuits and of the types shown in Table 7 for carrier circuits.

Non-loaded cable facilities are employed in both toll entrance and toll cables. Such toll entrance facilities may be used without appreciable transmission penalty up to about 3000 ft in extending open-wire circuits into offices or intermediate toll equipment points. For K carrier systems, which are operated through toll cables, only non-loaded pairs may be used, since loading is not available for the K frequency range. For J carrier systems a specially designed low-capacity, 16-gage, spiral-four loaded or non-loaded cable may be used for entrances.

Cable facilities used for toll purposes have, in general, been composed of 10-, 13-, 16-, and 19-gage cable conductors, paired and quadded for physical and phantom circuit operation. Some non-quadded cables for physical circuits only have been used. At present 19 gage is largely employed, but in a few cases 16 gage may be added. The newer *toll cables* have the short pair twist, high dielectric strength, core to sheath, and nominal mutual capacities of 0.062 and 0.096 μf per mile for side and phantom respectively. The standard sizes of toll and toll entrance cable cover a wide range of standard numbers of quads and pairs, and several different gages may be placed in the same lead cable sheath, including pairs for exchange use, as required to meet service needs.

Toll entrance cables for carrier, non-phantomed, open-wire lines have the long pair twist and nominal capacities of 0.062 and 0.102 μf per mile for the side and phantom, respectively.

Variations in net losses in cable facilities due to temperature changes are shown in Fig. 20.

FIG. 20. Net Loss Variations with Temperature for Different Gages and Loadings of Cable Circuits (Courtesy Bell System)

The cables may have a plain lead sheath covering with no outer protection, or, if protection is required from gophers, digging, or other extraneous disturbances, the sheath may be covered with jute, gopher and jute protection, corrosion protection, or tape armor for either aerial or buried construction. Submarine cables have single or double armored protection, composed of heavy steel wires laid around the sheath with jute and compound in one or two layers. Metallic shields are also used, as required, around the cable core, individual groups or quads of cable conductors, to protect circuits from electrical disturbances.

CARRIER FACILITIES may be provided in either open wire or cable. For any given carrier system between two points, the facilities selected must be suitable for that system. *Low-frequency carrier systems* of the G and H types generally employ 12-in.-spaced, open-wire facilities, having voice-frequency characteristics, except that, as the number of these systems increase on a given pole line, a carrier transposition scheme may be required to limit crosstalk, since the usual voice-frequency schemes are not designed for the higher frequencies. The C carrier system generally employs 12- or 8-in.-spaced, open-wire facilities, transposed for frequencies up to 30 kc, although the physical pairs or phantom groups may be transposed one at a time, according to the selected transposition scheme, as required to provide for the carrier systems on the given pole line. The J carrier system, being in the *high-frequency group*, requires 8- or 6-in.-spaced, open-wire facilities specially transposed to limit crosstalk at frequencies up to 140 kc.

With the G, H, and C systems, DP insulators and transposition drop brackets are usually satisfactory for wet or dry weather, but for the J system it is necessary to provide CS insulators and point-type transpositions, where the pole line will initially or ultimately have a full complement of carrier systems. Wire sag must be limited to small deviations from normal and all other physical irregularities must be controlled where carrier systems are operated. These limitations assume greater importance as the system frequency increases.

The K carrier system, operating through cable only, requires suitable conductors. Non-loaded pairs of 0.062-μf capacity per mile and of 19 gage, selected as the most economical gage, must be properly balanced in the cable mutually and against other facilities and segregated (using separate cables or layer shields) for the two directions of transmission. Figure 21 shows the attenuation-frequency characteristics of 19-gage non-loaded cable circuits over the K carrier range at different temperatures.

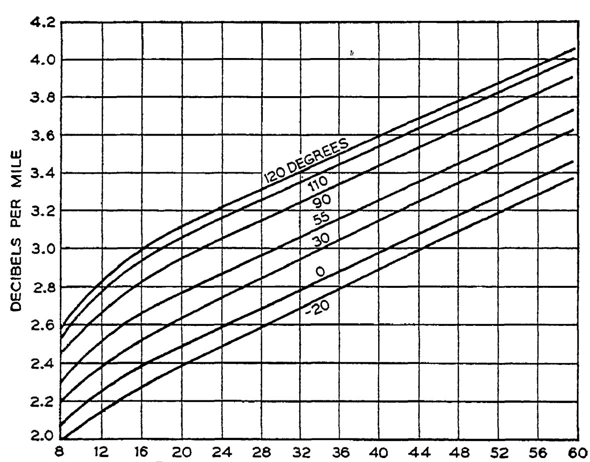

FIG. 21. Attenuation-frequency Characteristics of Non-loaded 19-gage Cable Circuits over the Type K Carrier Range at Different Temperatures (Deg Fahr) (Courtesy Bell System)

COAXIAL CABLE is required for L carrier system operation, on account of the high-frequency range of this system (up to possibly 7 Mc or more). This type of cable, first installed commercially between Minneapolis, Minn., and Stevens Point, Wis., in 1941, is built up of multiples of two coaxial tubes or units, plus ordinary paper-insulated conductors as needed to take care of requirements for short-haul message circuits and signaling and alarm trunks.

The Stevens Point-Minneapolis cable contained four coaxial units, with two 22-gage pairs in the center, a 19- and 22-gage pair in each of the four outer interstices between the units, and eighteen 19-gage quads surrounding this assembly. Since that installation many changes and improvements have been made in the design and construction of coaxial cable. One of the latest designs provides for 8 coaxial units and about 78 quads of 19-gage copper equivalent, built in with and surrounding the units to form a full-size lead-sheathed cable. The quads may be used for message and program service, order wires, alarms, and miscellaneous applications, and the coaxial units for message, television, and possibly other services.

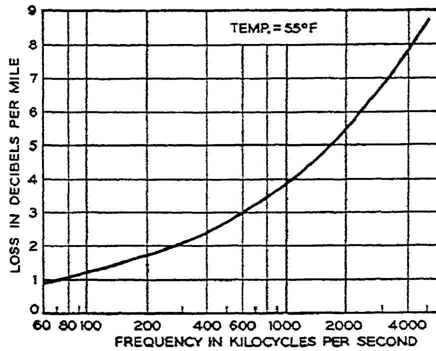

Fig. 22. Attenuation-frequency Characteristics of an 0.375-in. Longitudinal Seam Coaxial Cable Circuit (Courtesy Bell System)

The present *coaxial unit* consists of a single 12-mil copper tape (outer conductor) formed into a tubular conductor, which is, in turn, tightly wrapped with two 6-mil steel tapes, the outer of which covers the gaps between the turns of the inner steel tape. Each edge of the copper tape has small serrations which engage the opposite edge of the copper tape, and the two edges thus interlock to form a tube. This design is known as "longitudinal seam" coaxial. A 10-gage (100.4-mil) copper wire (inner conductor) is supported in the center of this tube by polyethylene disks (0.085 in. thick), spaced about 1 in. apart.

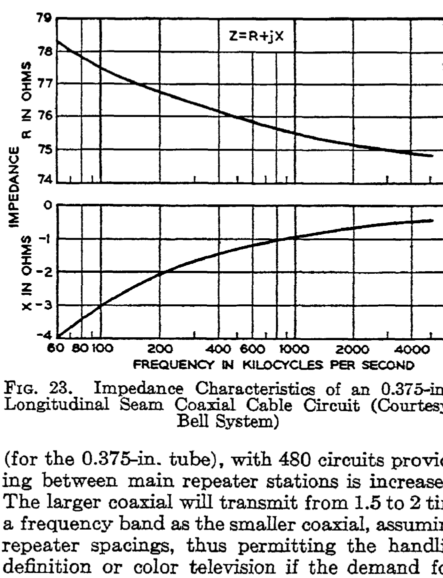

Fig. 23. Impedance Characteristics of an 0.375-in. Longitudinal Seam Coaxial Cable Circuit (Courtesy Bell System)

The inside diameter of the present standard coaxial tube is 0.375 in. (an original design employed a 13-gage central conductor and an outer conductor having an inside diameter of 0.27-in.). Attenuation and impedance characteristics are shown in Figs. 22 and 23. The new type permits lengthening auxiliary repeater spacings from about 5.4 miles (for the 0.27-in. tube) to about 7.9 miles (for the 0.375-in. tube), with 480 circuits provided in each case. Also the maximum spacing between main repeater stations is increased from about 90 to more than 150 miles. The larger coaxial will transmit from 1.5 to 2 times as wide a frequency band as the smaller coaxial, assuming the same repeater spacings, thus permitting the handling of high definition or color television if the demand for it arises. Figure 24 shows construction of an eight-unit coaxial with a complement of wire quads.

Lightning protection for the complete cable is provided by placing a 10-mil, corrugated, copper jacket over the lead sheath of the cable, which is first wrapped in thermoplastic material and a layer of tough cloth. The copper jacket is then covered with cloth tape.

Each regular coaxial unit is paired with an identical alternate coaxial unit, which is automatically switched into service, replacing the regular unit, in case of fault occurrence.

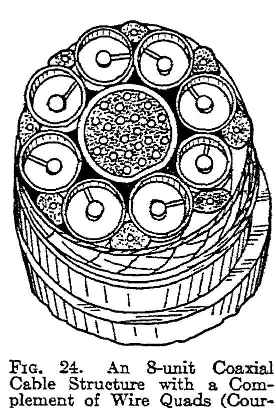

Fig. 24. An 8-unit Coaxial Cable Structure with a Complement of Wire Quads (Courtesy Bell System)

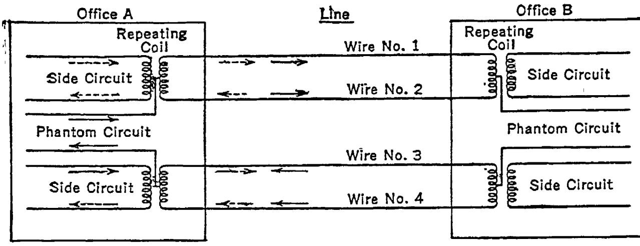
PHANTOM CIRCUIT operation is common in both open wire and cable. Two open-wire physical circuits or two cable pairs, which are twisted together to form a quad (four wires), can be equipped at their terminals to provide a third circuit, called a phantom, as shown in Fig. 25.

The side-circuit currents circulate over the side circuits as shown by the dashed arrows, and the phantom-circuit currents circulate over the phantom circuit as shown by the solid arrows. The line sides of the phantom repeating coils are closely balanced with respect to the phantom tap so that the phantom-circuit current, dividing about equally



←– – – instantaneous direction of side-circuit currents.
←——— instantaneous direction of phantom-circuit currents.

FIG. 25. Phantom Circuit Derived from Two Side Circuits

between the two wires of each pair, causes no appreciable induced current in the side-circuit terminations. Also, the side-circuit currents do not enter the phantom. This arrangement provides three circuits from four wires but requires a well-maintained balance in the line sides of the repeating coils and between the four wires, and adequate transposing, both in the open-wire group and the cable quad, to prevent excessive noise and crosstalk.

17. PLANT DESIGN—EXCHANGE

Exchange facilities, employed in connecting subscriber station equipment with central offices, for interoffice trunking in multioffice exchange areas, and for miscellaneous uses, may consist of cable or open wire or a combination of both types of facilities. The latest

FIG. 26. Attenuation Losses of Non-quadded Exchange Area Cable Facilities

developments affecting rural service include (1) trial installations of telephone carrier systems on rural power distribution lines, serving areas where telephone facilities are not available, and (2) direct radio channels between the central office and farm or ranch homes heretofore economically inaccessible for the usual pole line and open-wire construction.

EXCHANGE CABLES, in general, employ five different gages of soft-drawn copper conductors, namely, 26, 24, 22, 19, and 16 gage. A relatively small amount of 28-gage cable, developed to conserve copper during World War II, has been manufactured, but with normal copper prices its use in place of 26-gage, where applicable, does not effect appreciable cost savings. Exchange trunk cables are usually of 19 or smaller gage.

Type of Facility	Values Shown Are: Per Unit Length of	At Temp of F°	Dry or Wet	R (Loop), ohms (dc)	L, henrys	G, mhos (1000 cycles) ($\times 10^{-6}$)	C, farads ($\times 10^{-6}$)	$\frac{G}{C}$

* Mid-section iterative impedance in case of loaded facilities.

FIG. 29. Secondary Constants of Exchange Area Cable Facilities at 1000 Cycles per Second—22, 19, and 16 Gage

Exchange cables are usually of the non-quadded, paper- or pulp-insulated types, having attenuation losses at 1000 cycles, as shown in Fig. 26. These cables are not generally loaded for subscriber loop use, but are frequently loaded when employed for interoffice trunks, particularly in the larger exchange areas. The primary distributed constants of exchange area cable facilities and of miscellaneous paired conductors for exchange use are shown in Fig. 27. The resistances, inductances and capacitances are in d-c values, but for practical purposes, may be considered equivalent to the 1000-cycle values. The leakage conductances are specifically 1000-cycle values. The secondary constants of of exchange area cable facilities at 1000 cycles, are shown in Figs. 28 and 29.

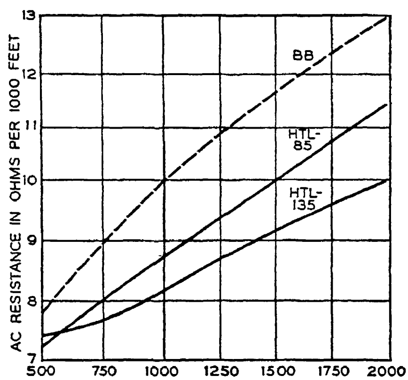

FIG. 30. Comparison of A-c Resistance of BB Grade Iron Wire and Two Types of High Tensile Telephone Line Wire—No. 12 BWG (Copyright 1945 by Indiana Steel and Wire Co.)

OPEN-WIRE FACILITIES for exchange use are principally of iron or high-tensile-strength steel, the steel being used almost exclusively in recent years, owing principally to economy and better service performance. New types of steel have been developed for telephone wire as the result of extensive studies of the materials used, and by means of heat and other treatments applied during manufacture. Some buried wire (such as W.E. Co. U or UA types, loaded or non-loaded) is used in rural areas for short distances, the characteristics of which are given in Fig. 27.

The a-c resistance of BB grade iron wire and of Crapo HTL-85 and HTL-135 high-tensile telephone line wire, over a frequency range of 500 to 2000 cycles, using current of telephonic magnitude, is shown in Fig. 30. The smaller variation in a-c resistance of the Crapo wire (manufactured by Indiana Steel and Wire Co.), as compared to the BB wire, tends to reduce modulation effects on voice currents traveling over the wire, and thus to improve the quality of the transmitted speech. Figure 31 shows comparative breaking strengths between the above three wires, as presented by Indiana Steel and Wire Co. Figure 32 shows the characteristics at 68 deg fahr of 109 (No. 12 BWG) high-strength steel and 134 (No. 10 BWG) steel wire with 0.8-oz zinc coating, 12-in. spacing, and DP insulators.

Copper steel wire (104 mil diameter), the characteristics of which are shown in Table 5, has roughly one-half the attenuation per mile at 1000 cycles of 109 high-strength steel wire (Fig. 32). Thus, this wire may be used advantageously in place of high-strength steel wire where the lower loss is required to meet exchange transmission standards. Copper steel wire (0.081 mil diameter and 40 per cent conductivity) having per pair mile an attenuation loss of 0.22 db (wet) and resistance of 42.8 ohms at 68 deg fahr may also be used where applicable.

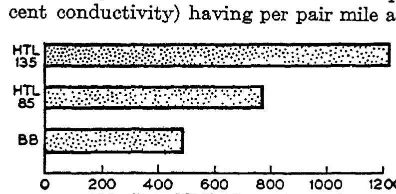

FIG. 31. Comparative Breaking Strength of BB Grade Iron Wire and Two Types of High Tensile Telephone Line Wire—No. 12 BWG (Copyright by Indiana Steel and Wire Co.)

Buried wire (paired, insulated, such as W.E. Co. U or UA type) is sometimes used, loaded or non-loaded, in place of or as an extension of open-wire rural plant, depending on economies.

CARRIER CHANNELS superimposed on rural power lines are now under trial operation to determine the practicability and requirements for thus serving rural subscribers in locations not at present served by telephone lines. The equipment, developed by the Bell System and designated as the M-1 carrier telephone system, is being made in quantities by the Western Electric Co., the privilege of producing it being extended to other manufacturers.

The first two systems, installed in 1945 for trial at Jonesboro, Ark., and Selma, Ala., provide rural service to four subscribers over an 11-mile section of 7200-volt, multigrounded neutral, single-phase power line out of Jonesboro, and to four subscribers over a 14-mile section of 6900-volt, multigrounded neutral, single-phase power line out of Selma.

The principal elements of the rural power line carrier system, as now developed, are shown in Fig. 33. Single channel operation is employed, using for the trials frequencies

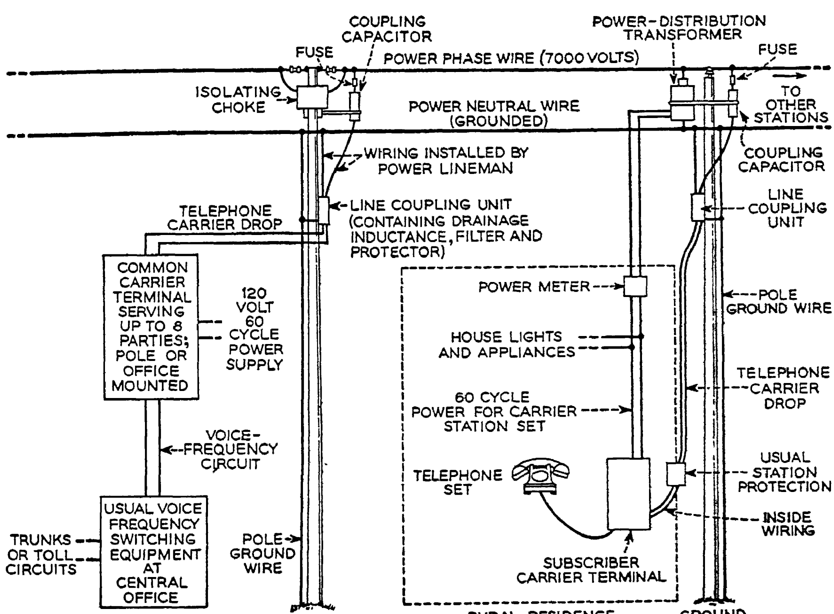

FIG. 33. Principal Elements of Rural Power Line Carrier Telephone System (Courtesy Bell System)

of 165 kc central office calling subscriber and subscriber receiving, 195 kc subscriber calling central office and subscriber talking out through central office, and 185 kc one subscriber calling another subscriber on the same line but through the central-office carrier terminal equipment. The M-1 system is designed, however, for double sideband carrier transmitted amplitude modulation, with as many as six channels, each serving eight subscribers and each using three frequencies. These frequencies are different within each channel and for each channel, being selected for transmission from the common terminal to the stations within the range 155 to 230 kc and for transmission from the stations to the common terminal within the range 290 to 450 kc.

Figures 34 and 35 show block diagrams of the common carrier terminal at the central-office end of the system and of the subscriber carrier terminal (station set), respectively, of the types used in the trial tests.

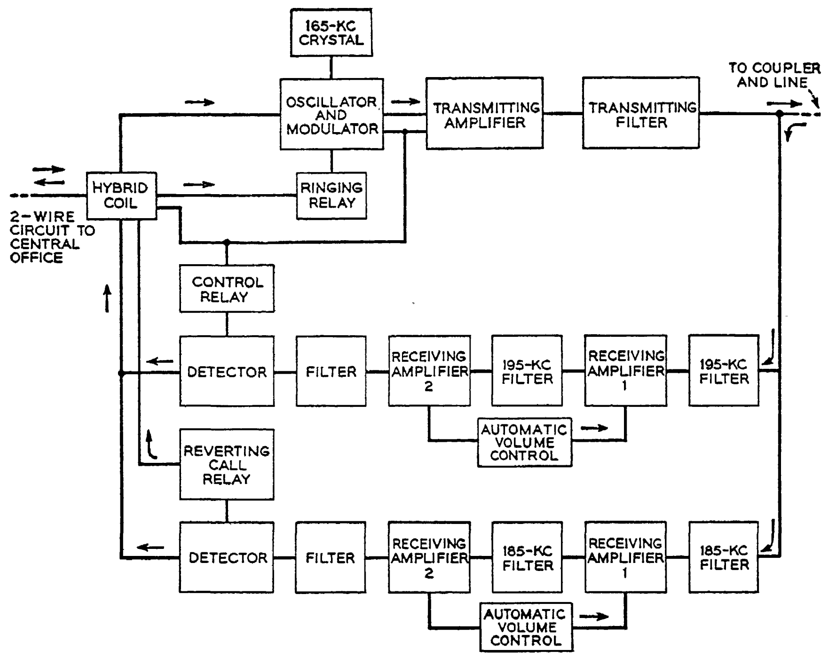

FIG. 34. Block Diagram of Common Carrier Terminal at the Central-office End of a Rural Power Line Carrier Telephone System (Courtesy Bell System)

The carrier terminals are connected to the power line through a 0.002-μf capacitor (8700-volt rating for the trials), and a line coupling unit. This unit has a drainage inductance coil, filter, and protector. All branches of the power network not used for carrier transmission have inserted in the primary phase conductor an isolating choke for the main power circuit and a tap choke for branches from the main circuit. Transmission chokes are used in branches from the main power circuit, where the branch is being used for carrier, in order to reduce the bridging loss of the branch to through transmission over the main line. The common carrier terminal is designed to terminate the power line in about 500 ohms impedance for the carrier frequencies used, as are the coupling capacitors and line coupling units at subscriber stations or at the end of a power line tap where no subscriber station exists.

Each carrier terminal requires continuous 110–120 volt, 60-cycle a-c power supply, and the unmodulated carrier power delivered to the line coupling unit from each terminal is about 1 watt. The subscriber terminal requires about 8 watts of standby and 30 watts of operating power.

The common carrier terminal connects to the manual switchboard or dial unit over a regular two-wire voice frequency circuit. Divided code ringing is provided using interrupted carrier current in proper time sequence, or bridged code ringing can be used if required.

Where the power circuit is not of the single-phase, multigrounded neutral type or it is desired to operate more than one system on the same power line but in different sections, special consideration of the factors involved will be required.

Preliminary data indicate that the average transmission loss between the common terminal and the most distant station at the operating carrier frequencies of the M-1 system, including subscriber coupling unit bridging and transmission choke losses, will be about 2.0 to 2.5 db per mile. The overall loss between the common terminal and any station should not exceed 35 to 40 db (15 to 18 miles of line). Under low atmospheric static conditions, the carrier system can be adjusted to provide about the same effective transmission $(T + R)/2$ from any station to the central office as would be provided from a regular voice-frequency station having the latest-type antisidetone, local battery talking set (W.E. Co. FIA-AST-LBT-2 cells).

The M-1 carrier system may also be adapted to telephone wire lines, where additional telephone circuits may thus be provided more economically than by other methods. This usage requires further study.

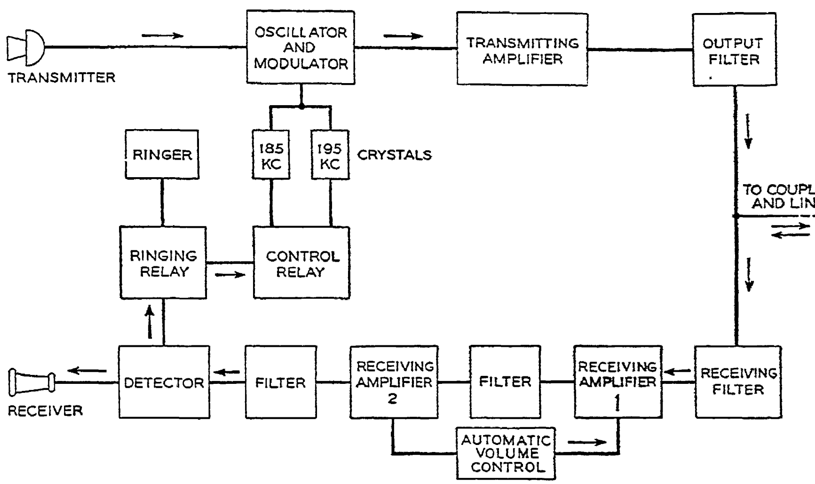

Fig. 35. Block Diagram of Subscriber Station Set of a Rural Power Line Carrier Telephone System (Courtesy Bell System)

In operation, the system responds as though the connecting circuit between the central office and subscriber were the usual wire line. On revertive calls (one subscriber calling another on the same circuit or channel), the calling subscriber places the call to the called subscriber in the usual manner (through the operator or equipment) and then puts his handset on the cradle. When the ringing signal, which the calling subscriber hears, is stopped, indicating that the called subscriber has answered, the calling subscriber removes his handset from the cradle and talks. The conversation is carried on through the common terminal, and operator supervision is provided if the office is of the manual type.

Radio channels for rural telephone service are under trial test, as discussed in article 8 of this section. It is expected that suitable equipment will be developed, based on these tests, which will permit utilizing radio channels for this service on a commercial basis.

SUBSCRIBER LOOP DESIGN. The design procedure and considerations in engineering subscriber loop plant are briefly summarized (for a single cable route) as follows:

(*a*) Determine the most economical gage requirements for the ultimate area to be served by the various complements of cable, considering both transmission and signaling design limits, using the effective subscriber loop loss curves, if available.

(*b*) Examine the possibilities of obtaining further cable economies by reducing bridged tap or distribution cable losses which were assumed in determining the design limits.

(*c*) Examine the possibilities of utilizing any existing plant with the new plant being designed, without exceeding the design limits.

(*d*) If the loop loss or signaling limits are exceeded in existing plant, determine the most economical plan of meeting the limits, such as using special sets, reducing bridged cable losses, loading the longer cable pairs, or choosing larger-gage cable or long line circuits.

(e) If some margin of loop loss and loop resistance results from the use of existing plant in connection with the plant being designed, study the advisability of smaller-gage pairs than indicated under (a) above, taking into consideration the permanence of the existing facilities and the relation of the proposed plant to the ultimate plan.

(f) Combinations of gages are frequently practicable, particularly since the trend is toward the finer-gage cable adjacent to the central office.

(g) Composite (more than one gage) cables are installed extensively, the larger gages serving the outlying areas.

(h) Loading on long loops is sometimes employed to meet loop loss limits. H-44 or H-88 loading on 19-, 22-, or 24-gage cable results in substantial loss reductions over non-loaded loops, which might permit smaller-gage conductors for long loops. Bridged taps on loaded pairs must be limited to avoid serious impairments.

(i) Signaling limits may economically be extended, in some cases by modifications or readjustments of central-office equipment, larger-gage conductors or long line units for the longer loops, or occasionally the use of two pairs in parallel may be justified to reduce loop resistance.

(j) Loop and trunk plant design is based on the most efficient types of subscriber sets available or, in some cases, anticipated within a relatively short period of time.

(k) Special exchange lines, such as private or PBX tie and foreign exchange lines, conference and bridging arrangements, and one-way speech networks, require special design work to meet their particular needs.

The *zoning* of subscriber sets is a procedure that provides for the introduction of station apparatus in such a way as to obtain the desired grade of transmission at the lowest practicable overall cost. Owing to the different efficiencies of the various types of station apparatus in service and under continuous development, it is necessary to insure that this apparatus will be installed as required, so that (1) the cost of the outside plant will be the minimum, (2) transmission will be satisfactory for the outside plant design, and (3) station apparatus costs will be minimized by obtaining a reasonable service life for the older apparatus, avoiding as far as possible premature replacements of existing apparatus and providing an orderly program for the introduction of new station apparatus. Thus, exchange areas, as required, are divided into zones within which only certain types of station apparatus may be used.

TRUNK PLANT DESIGN is based on the transmission loss limit assigned to each group of trunks, as determined from the loop and trunk study. The *design limit* is obtained by deducting from the overall permissible trunk loss (1) terminal junction losses, due to characteristics of the proposed trunks, which differ from the reference trunk; (2) intermediate junction losses, due to a trunk being composed of different types of facilities; (3) losses due to loading irregularities; and (4) equipment and office losses at intermediate points between the trunk terminals. Data have been prepared for the Bell System showing both terminal and intermediate junction losses under the usual conditions encountered in practice. In some cases, under certain conditions, these losses are actually negative (transmission gains).

The design limits for the trunks, having been determined for the various conditions under which the given group of trunks will operate, represent the *permissible effective trunk losses*. The type of trunk is then selected which meets the design limits and has least outside plant costs, taking into consideration existing trunk plant, future trunk facility needs over the route involved, and any other factors that may have a bearing on the selection of the type of trunk. Figure 36 shows *effective losses* for non-quadded exchange area cable trunks.

The signaling limits for trunks are based on signaling, pulsing, and supervision requirements, which vary materially for different types of offices and associated terminal equipment. These limits, as well as leakage requirements, are usually indicated on the standard drawings for each type of central-office circuit, which may be different for the two ends of the given trunk. The lower value, if there is a difference, will be controlling in determining the signaling limit.

Overall trunk resistance for signaling purposes is usually computed from unit values for temperatures of 68 deg fahr. For underground trunk plant the resistance change with temperature will be about 3 per cent maximum, which may usually be disregarded. For aerial cable, the change may be as much as 10 to 12 per cent, and this variation of resistance with temperature change should be considered in the signaling design limits.

With the larger-gage trunk facilities generally used in the past, the transmission design limit usually controlled the selection of the type of trunk facilities, but with the higher permissible interlocal trunk losses in recent years (resulting from allocation to trunks of part of the new instrument gains) and the trend toward higher supervision limits with current types of dial equipment, the field of use of the finer-gage cables has been extended, so that signaling limits may be controlling in some cases.

FIG. 36. Effective Trunk Losses—Exchange Area Cable Trunks

PROGRAM SERVICE

18. PROGRAM SERVICE

In general, program service, as furnished by the telephone companies, consists mainly of providing suitable wire or carrier facilities to the broadcasting companies for the transmission of program material, which usually originates in broadcasting studios or other locations and which is broadcast from radio transmitters to the public.

Programs, being of a varied nature, from the finest orchestral music to ordinary speech, require different grades of telephone facilities to meet the broadcaster's requirements. For this reason the telephone companies have developed and have made available for broadcasting purposes several rather broad classifications of facilities, as shown in Table 1.

SERVICE REQUIREMENTS, being more exacting for high-quality than the lower-quality program circuits, involve the control of (1) transmission levels and losses, (2) frequency, delay, and phase distortion, and (3) noise and crosstalk. See Section 12 for critical cutoff points in the frequency ranges of various musical instruments and speech.

Transmission levels and losses in open wire and cable are maintained as specified, by special program amplifiers, the latest types having a flat gain characteristic with a maximum gain of about 30 to 40 db and outputs of about 10 to 20 db above reference volume,

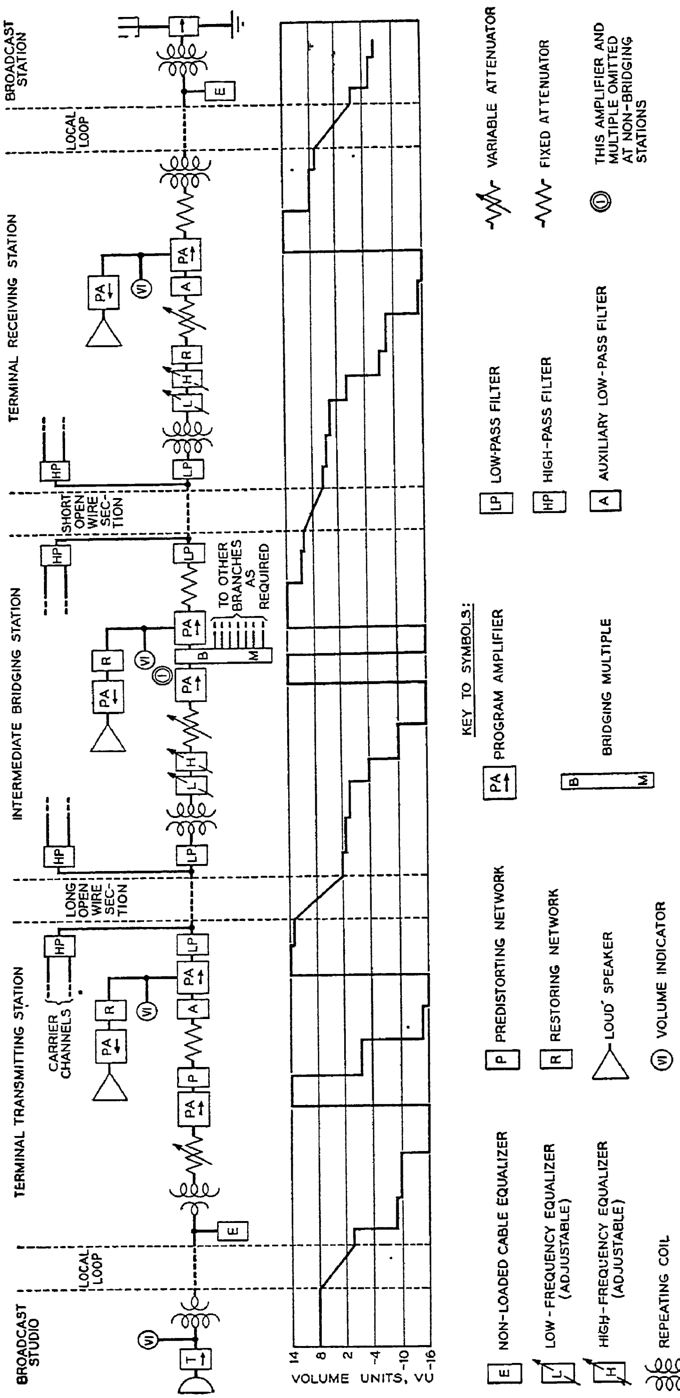

Fig. 1. Typical Layout and Level Diagram for a Wide-band Open-wire Program Circuit (Courtesy Bell System)

depending on the type of amplifier. The levels must be high enough to provide a satisfactory signal-to-noise ratio and must also be coordinated with the levels of adjacent circuits or systems, to avoid causing interference in them. A variable attenuator, having a range of 0 to 32 db, controls the amplifier gain. Figure 1 shows a typical layout and level diagram for a wide-band (8000 cycles) open-wire program system.

Attenuation variations in the line over the frequency band (frequency distortion) are compensated for by low- and high-frequency equalizers of the constant-resistance type, which correct for variations in the preceding line section, to meet requirements.

A repeating coil (impedance ratio, line to drop, of 1 : 1.15) is provided at each repeater point between the incoming line and line equalizing apparatus, which latter is on the line side of the line amplifier. This coil gives the proper termination to the line and insulates the line from the terminal equipment against noise and for protection. Suitable repeating coils are also provided at both ends of the local loops for similar reasons. A non-loaded cable equalizer is provided for the local cable loops.

Special filters are required for facilities which transmit both program and carrier frequencies, in order to separate the two frequency bands at the line terminations and direct them into their proper equipments. Line filters, designed for 5000-cycle program systems, introduce slight delay distortion in the program frequency bands. If the number of line sections in tandem equipped with these filters is about eight or more, a *delay equalizer* for each two filters is necessary to maintain the time of propagation of all frequencies in the program band within satisfactory limits (not to exceed about 0.3 millisecond difference between maximum and minimum delays for a range of 500 to 5000 cycles). An auxiliary low-pass filter may be provided, if required, for 5000-cycle systems, to effect further discrimination against high-frequency interference from the line.

Table 1

Classification of Facility	Approximate Frequency Band in Cycles
Intercity Circuits	
1. High quality	100– 5,000 50– 8,000
2. Medium quality	200– 3,500
3. Speech only	300– 2,500
Metropolitan Area Circuits	
1. Studio-transmitter circuits for AM stations	50– 8,000 *
2. Studio-transmitter circuits for FM stations	50–15,000
3. Network loops—between studio and point of connection (toll office) with intercity network channels	†
4. Pick-up circuits—between points of program origin and studio or point of connection with intercity channels	†

* Band may be extended to higher frequencies if specifically requested by the customer.

† Equalized at request of the customer for band width desired (usually 50–8,000 cycles).

An auxiliary low-pass filter may be used on 8000-cycle program circuits to supplement the low-pass filter of the carrier line filter set where further discrimination is needed.

Noise must be limited in all program circuits, so that it will not interfere appreciably with the quality of the broadcast.

Predistorting and restoring networks are employed in open-wire program systems, particularly the 8000-cycle system, to minimize high-frequency noise from nearby carrier systems. Predistortion is accomplished by introducing, at the sending end of the circuit, a network which effectively raises in volume the currents above 1000 cycles to a higher level than normal for line transmission, thus increasing the signal-to-noise ratio at these frequencies. Since the power at the higher frequencies is relatively small, the amplifiers are not overloaded by this procedure. The restoring network at the receiving end of the circuit restores the predistorted currents to their original amplitude and phase relation. The net reduction in high-frequency interference is equal to the relative losses introduced by the restoring network at the frequencies restored. Figure 2 shows the characteristics of these networks, which are of the lattice type and are composed of combinations of inductance, capacitance, and resistance elements.

Crosstalk also must be controlled. Methods of limiting crosstalk include such items as proper selection of facilities, maintenance of proper levels, and avoidance of the adverse effects of circuit irregularities which may develop from time to time.

PROGRAM FACILITIES may be of open wire or cable, assigned for program use in the program frequency band, or such facilities may consist of single-sideband transmission over cable carrier systems, using three channels of a twelve-channel unit, or over other carrier system channels.

Open-wire facilities for *long-haul* broadcasting usually consist of 165-mil hard-drawn copper-wire circuits, although 128- or 104-mil wire is frequently used, where available and appropriate, but generally for the shorter-haul circuits. Preference is given to 8-in. non-phantomed pairs.

Amplifiers are spaced about twice as frequently (50 to 150 miles) for 104 circuits as for 165 circuits. Open wire, being more subject to noise and crosstalk than cable or carrier, must be carefully selected and maintained in order to provide facilities of suitable quality.

Cable pairs (non-quadded) may be employed for *long-haul* program service. The latest type of cable system for this purpose is the 16-gage B-22 loaded system, which is satisfactory for a band of 35 to 8000 cycles.

The 16-gage B-22 system operates over one-way transmission paths. The non-quadded cable pairs are loaded at a 3000-ft nominal spacing with 22-millihenry coils. The attenuation-frequency characteristics of this facility are shown in Fig. 19, article 16, and the impedance, cutoff, and velocity values are shown in Fig. 18, article 16. Amplifiers and

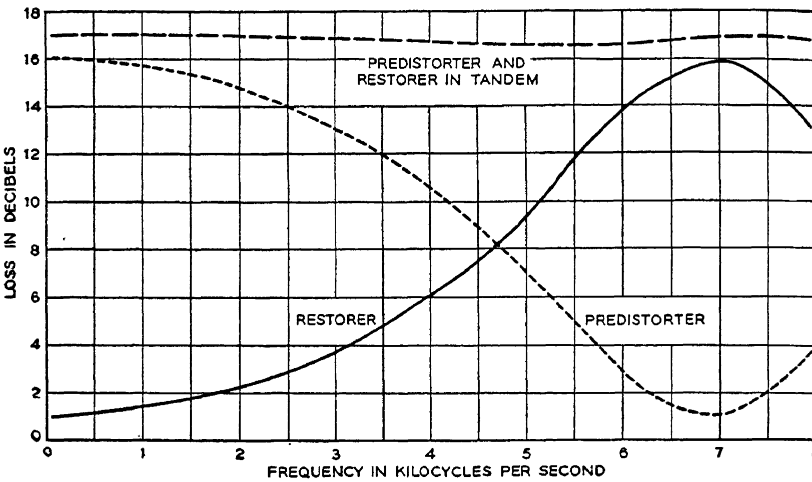

FIG. 2. Loss-frequency Characteristics of Predistorting and Restoring Networks—Open-wire Program System (Courtesy Bell System)

associated apparatus are located at about 50-mile intervals. Attenuation and delay equalizers, as required, are associated with each line amplifier input circuit. A supplementary adjustable equalizer is usually required in each repeater regulator section, because of the variations in capacitance and conductance of the different cable sections through which the program circuit passes. The application of this system for new installations may be limited somewhat in the future by the newer developments in *single-sideband carrier program transmission.*

High-quality program circuits may be operated over cable carrier systems, using single-sideband transmission and three channels of the system. The single-sideband system is designed to operate over as many as ten carrier links in tandem. Figure 3 shows a schematic of a single-sideband program terminal arranged for transmitting over cable carrier.

Medium-quality program circuits may be assigned to 19- or 16-gage H-44 or B-88 cable side circuits, but non-linear and delay distortion in the repeaters and loaded pairs and transmission variations, particularly at high and low frequencies, limit the length of these facilities to about 300 miles for H-44 and B-88 loaded facilities. Channels of the cable carrier system may be used for medium-quality service if not more than one link of these carrier systems is used. Non-loaded cable is limited to relatively short lengths.

METROPOLITAN-AREA PROGRAM FACILITIES, as indicated in Table 1, are designed to provide (1) studio to transmitter circuits for both a-m (amplitude-modulation) and f-m (frequency-modulation) broadcasting stations, (2) network loops between the studio and the point of connection (usually the telephone company toll office) with intercity network channels, and (3) pick-up circuits between the point of program origin and the studio or the point of connection with intercity network channels.

The types of line facilities used may consist of non-loaded exchange or toll cable pairs of various available gages, loaded exchange or toll cable pairs (where loading is required for transmission reasons), or open-wire pairs. Metropolitan-area program circuits, to a large extent, employ non-loaded exchange cable pairs, and in some cases open-wire pairs, with or without intermediate amplifiers.

Equalization may or may not be required, depending on the band width to be transmitted, length and gage of facilities involved, and the transmission deviation permissible over the frequency band.

For studio to transmitter circuits, serving a-m stations, a relatively flat transmission-frequency characteristic may be obtained between 50 and 8000 cycles, using standard equalizer equipment, for sections of non-loaded cable not exceeding about 21.5 miles of 16-, 10.0 miles of 19-, 6.5 miles of 22-, 5.0 miles of 24-, or 4.2 miles of 26-gage cable conductors. Longer lengths of cable may be divided into sections not exceeding the above lengths, which are then treated individually. It is desirable, from a transmission stand-point, to employ a uniform type of facility for program circuits when available.

For studio to transmitter circuits, serving f-m stations, standard equalizer arrangements provide a satisfactory transmission characteristic over metropolitan-area circuit lengths usually encountered. In one instance, such a circuit, consisting of 24 miles of 19- and 22-gage cable pair (non-loaded), with three intermediate amplifiers, was equalized to limit the overall transmission variation to 1.9 db for a frequency band of 30 to 15,000 cycles. Wider bands, extending to 18 or 20 kc, have been provided in special cases when requested by the customer, using special equalizing methods.

Carrier loaded (C 4.1 or C 4.8 loading) cable facilities when available may be equalized for metropolitan-area circuits, serving either a-m or f-m stations. The B 22 facilities are suitable for frequencies up to 8000 cycles for any length of circuit likely to be encountered, using amplifiers and equalization as required.

SPECIAL FEATURES developed for program systems include:

(*a*) Bridging arrangements, in which provision is made for connecting one or more branch program circuits to the main program circuit at a given point.

(*b*) Monitoring, in which attendants may listen in and supervise programs (to insure satisfactory operation) at designated points on the broadcast network.

(*c*) Reversals, in which provision is made for two-way transmission over the same network facilities, by reversing the direction of transmission of all connected one-way apparatus at will, either manually or automatically, and under control of the telephone company or the customer.

(*d*) Order wire and talking arrangements, which permit the various control points and attendants to converse readily regarding network operations without interfering with the broadcast facilities.

SUBSCRIBER STATIONS

19. SUBSTATION EQUIPMENT

SUBSCRIBER STATION EQUIPMENT consists of a large number of types and designs of subscriber telephone sets and auxiliary apparatus, essential to the furnishing of a complete telephone service in the most economical and satisfactory manner.

The basic subscriber telephone set is assembled in a number of designs to meet the needs of different services and the subscriber's convenience, but the operating principle is primarily the same for all these sets. The basic set consists principally of a transmitter, receiver, induction coil, condensers, ringer, and spring assembly (switchhook), suitably mounted in a metal or plastic housing. The set will also have a dial if it is connected to a dial exchange or unit, and for magneto telephones a dry-cell battery for transmitter current and a magneto generator for signaling must be provided.

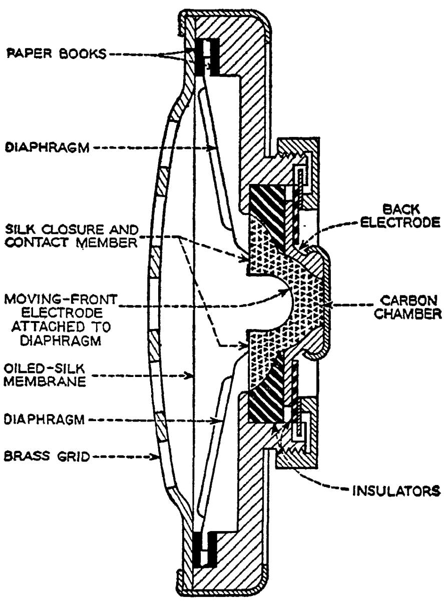

FIG. 1. Cross-sectional View of Modern Non-positional Transmitter Unit (Courtesy Bell System)

THE TELEPHONE TRANSMITTER is designed to receive airborne sound waves of various frequencies and convert them into electrical waves of similar frequencies for transmittal over a telephone circuit. It is essentially a device which makes it possible for relatively weak sound energy to control electrical energy of greater average strength.

The modern transmitter unit employs an insulated, spherical-shaped carbon chamber holding the carbon granules, and a very light metal conical diaphragm, with a dome-shaped center, which is positioned in the carbon chamber in such a way as to hold the granules in the chamber. The dome and chamber are the front and back electrodes, respectively, of the unit. Figure 1 shows a cross-sectional view of the Western Electric Co. No. F1 unit. The electrode surface area in contact with the carbon granules is the same, regardless of the position in which the transmitter is used. The No. F1 unit has a resistance (new) of about 30 to 40 ohms and is applicable to any type of subscriber telephone set of Western Electric Co. make. Transmitter current should not exceed about 100 milliamperes for normal usage and life. A small condenser is usually connected directly across

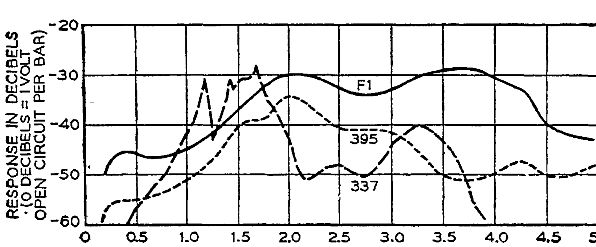

FIG. 2. Transmitter Response Characteristics (Courtesy Bell System)

the transmitter electrodes of the F1 unit, when used in handsets, to minimize packing (welding together) of carbon granules as the result of arcing in the carbon chamber when the transmitter current is rapidly interrupted by switchhook flashing or other operations.

The response of all makes of the modern non-positional transmitter is greatly improved over the older types, as shown for Western Electric Co. instruments in Fig. 2.

THE TELEPHONE RECEIVER is designed to receive electrical waves of various frequencies and convert them into sound waves of similar frequencies for the listener's ear. It is essentially a reconverter from electric to sound energy (within its frequency range) and is a necessary complement of the transmitter in the transmission of speech.

The modern receiver is generally of the unit or capsule design, which is applicable to various types of telephone receivers and assembled sets as made by the respective manufacturers. One make (W.E. Co. HA1) consists principally of a bipolar permanent magnet, with the parts assembled in a zinc alloy frame. The diaphragm of Permendur is seated on a ring projection of the frame, just above the magnet, with an air chamber of definite volume behind it. This chamber has a small outlet hole covered with a silk disk of specified acoustic impedance. The diaphragm also has an air chamber of definite volume between it and the receiver cap, which latter has six holes of definite length and area. The unclamped diaphragm thus rests between two air chambers of specified volumes and outlet impedances, and variations in receiver efficiency with temperature changes as well as diaphragm freezing to the pole pieces are practically eliminated.

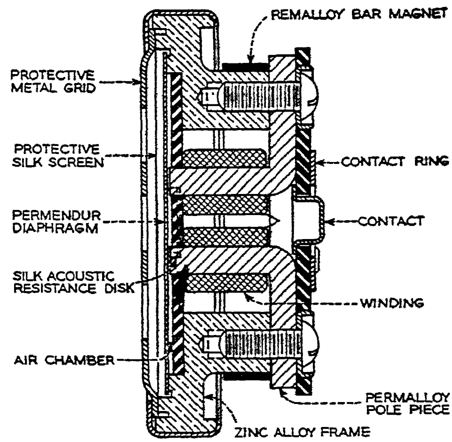

Fig. 3. Cross-sectional View of Modern Receiver Unit (Courtesy Bell System)

The HA1 receiver unit has a working impedance at 1000 cycles of about 140 ohms with a positive angle of 60°. Figure 3 shows a cross-sectional view of this type of receiver unit, and Fig. 4 shows its response characteristic as well as that of the older type W.E. Co. No. 557 receiver.

The HA1 receiver is affected adversely by d-c flow of either polarity, which for 100 milliamperes amounts to about 4.5 and 6.0 db loss in volume efficiency for the opposing and aiding directions, respectively, of current flow.

The anti-sidetone type induction coil is now generally employed, in place of the older sidetone type. Figure 5 shows schematic diagrams of both sidetone and anti-sidetone station circuits and the direction of instantaneous current flow for both the transmitting and receiving conditions.

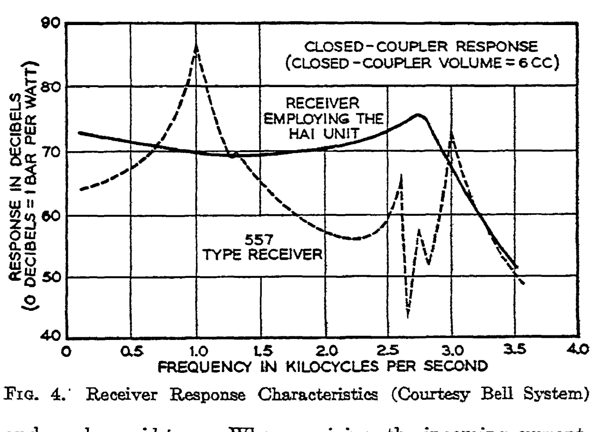

Fig. 4. Receiver Response Characteristics (Courtesy Bell System)

In the *sidetone connection* (Fig. 5, circuit 1), the speech currents produced in the transmitter divide between the A and B windings (solid arrows). The current in each of these windings induces a voltage in the other winding (dashed arrows). The two currents in A combine to flow out over the line, and the two currents in B combine to flow through the receiver and produce *sidetone*. When receiving, the incoming current divides between the transmitter (T) and the receiver (R) branches (solid arrows). The current in A induces a voltage in B, which establishes an opposing current in B (dashed arrow), but the incoming line current in B is larger, so that the resultant current through R is sufficient to actuate the receiver diaphragm.

The *sidetone reduction connection* of the sidetone coil employed on short loops having the sidetone type of subscriber set is shown in Fig. 5, circuit 2. With this connection the transmitter current cannot flow directly through the receiver (R) branch, but some induced current does flow through R because of the inductive coupling between windings A and B. Since transmitter current does not flow directly through B, this winding does not induce a voltage in A, such as occurred in the sidetone connection, and the transmitter line current is not thus aided, resulting in lower transmitting efficiency. In receiving, the incoming line current does not enter the B winding directly but flows through winding A, establishing an induced voltage from A to B, which causes received current to flow through R. Thus, the induced R current is not opposed by line current flowing directly, as was the case in the sidetone connection, resulting in slightly higher receiving efficiency.

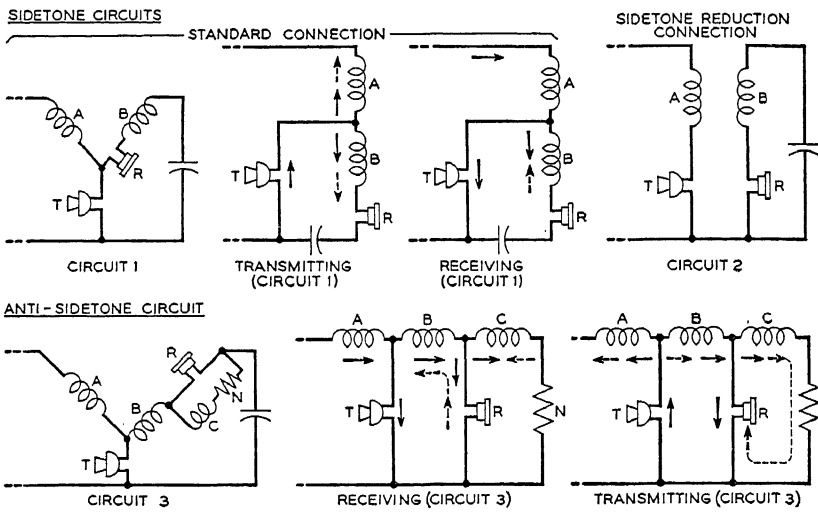

FIG. 5. Sidetone and Anti-sidetone Station Circuits (Courtesy Bell System)

In the *anti-sidetone connection* (Fig. 5, circuit 3), a third winding of relatively high resistance, so that the winding has both an inductance (C) and resistance (N) component, has been added to the sidetone circuit.

In receiving, the incoming current divides between the transmitter (T) branch and winding B (solid arrows). The current in B divides between the receiver (R) branch and the winding C (solid arrows). The currents in A and B induce voltages in C, and, by properly proportioning the coil winding relations, the current in C (dashed arrow) resulting from these combined induced voltages is opposite and about equal to the current flowing directly in C. The C winding thus has no appreciable effect on *receiving volume*, and the *receiving efficiency* of both the sidetone and anti-sidetone circuits is about the same. However, owing to sidetone suppression, the *effective receiving losses* for the anti-sidetone circuit are substantially less.

In transmitting, the transmitter (T) output current divides between the windings A and B, and the current entering B divides between the receiver (R) branch and the C winding (solid arrows). These currents in A and B induce voltages in B and A, respectively, resulting in an induced current flowing in an aiding direction in the line and in B (dashed arrows). The induced current in B divides between R and winding C (short dashed arrow). Also, there is induced in C a voltage (resulting from the currents flowing in A and B directly from the transmitter) which establishes a current in C (long dashed arrow). The combined currents in C flow through R in a direction opposite to the current (solid arrow) which comes directly from the transmitter. Since these opposing currents are, by design, about equal, the receiver is not appreciably affected during transmitting, and sidetone is practically eliminated. The *transmitting volume efficiency* of both the anti-sidetone and sidetone circuits is about the same, but the *effective transmitting losses* for the anti-sidetone set are substantially less, principally because, when less sidetone is heard by the talker, he unconsciously raises his voice level until the sidetone heard is about equal to what he is accustomed to in ordinary conversation. Increased voice level results in transmission gain.

The range of line impedance conditions is usually much greater for the local battery anti-sidetone set which is used on the longer loops into outlying and rural areas. In order to provide an approximate balance for these line conditions, the local battery anti-sidetone circuit is designed with a balancing network that can be connected for a line impedance of 600, 900, or 1500 ohms (angle 50°).

Under average conditions, and depending upon the amount of sidetone reduction which may be effected in any particular case and upon the circuit design, a transmission improvement of about 5 db may be expected from use of the anti-sidetone in place of the sidetone circuit.

THE RINGING CIRCUIT of a common-battery subscriber set includes a ringer and condenser, but a condenser may or may not be required in this circuit for a magneto set. The common-battery sidetone circuit has a single condenser for use in both the receiver and ringer circuit, but with development of the anti-sidetone circuit a separate condenser is used in the receiver and ringer circuits. With the two- (split-) condenser arrangement and high-impedance ringers, the susceptiveness of the subscriber set to incoming line noise is materially reduced over the single-condenser set, especially on balanced party-lines (same number and type of ringers connected to ground on each side of the line). *Ringers* are manufactured in a large number of types (usually with permanent magnet yokes and biasing springs) and impedances for use with the several signaling systems and to meet signaling requirements. The types of *signaling systems* used include straight line (20 or 16 $^{2}/_{3}$ cycle), harmonic, superimposed, and pulsating ringing, of which *straight line ringing* is commonly used for individual line, two-party selective, four-party semi-selective, divided code, or non-selective bridged stations.

Harmonic ringers are designed for frequencies of 16.6, 20, 25, 30, 33.3, 42, 50, 54, 60, 66, and 66.6 cycles. These ringers have reeds of different weights which respond only to the frequency for which they are designed. The harmonic system provides selective signaling for up to five bridged or ten grounded ringing stations (five connected to ground on each side of the line).

Superimposed ringing requires the superimposing of d-c potentials (positive and negative) on the regular a-c ringing current in order to raise the peak positive and negative voltages sufficiently to break down a three-element, cold-cathode, vacuum-tube gap, which is connected from line to ground at each station. The tube may be so connected that its gap will break down when either the positive or negative combined potential is applied, but not both. The ringer is connected between one element of the tube and ground so that, when the tube functions, the a-c ringing current will operate the ringer. This type of ringing is used in four-party selective and eight-party semi-selective service. The control gap of one type of tube has a nominal breakdown of 70 volts, and the nominal main (ringing) gap sustaining voltage is 75 volts.

A-c relays, first used in this type of service, generally have been replaced by the tube.

Pulsating ringing employs positive and negative pulsations sent out over the line from the office. The station ringers are biased with a spring so that they operate when either the positive or negative pulsations are applied, but not both. This type of ringing may be used for four-party selective or eight-party semi-selective service.

Ringer impedances are designed to meet various service conditions. The low-impedance group will have d-c resistances of from 1000 to about 2500 ohms, and the high-impedance group of from 3500 to about 5700 ohms or more.

Usually each ringer has a biasing spring, one end of which is attached to the armature and the other end, by means of a winding cord, to an adjusting stud on the ringer frame. Thus, the armature can be tensioned or biased to the degree necessary for the type of service involved, and to avoid cross rings and also bell taps during switchhook and dial operation. Ringers may be of the polarized or non-polarized type, depending upon the type of ringing system employed.

The number of ringing bridges across a line or from either side of a line to ground is limited to a total capacitance of the ringer condensers not to exceed 2 μf where not more than eight such bridges are involved on non-polarized lines.

Condensers are usually of 2-μf capacitance when used in single-condenser sets and in the transmission circuit of two-condenser sets. The ringer circuit of these latter sets may have a condenser of 0.5- to 1.0-μf capacitance, depending upon the ringer impedance, or for some types of magneto stations the condenser may be omitted.

Hand generators of the three- or five-bar type, depending upon the length of line and number of bridged stations, are generally necessary in magneto subscriber sets for signaling the office or another subscriber on the same line. These generators carry a spring assembly which functions to open and close the generator circuit across the line when the generator is idle and operating, respectively. Figure 6 shows a view of a five-bar generator (Stromberg-Carlson make).

The switchhook spring assembly in subscriber sets generally consists of two pairs of make-break springs which automatically close and open the transmitter and receiver circuits when the handset is lifted from and restored to its cradle. These springs are designed to retain their adjustments over long periods of time. One manufacturer is using heavy-gage, phosphor-bronze with precious-metal contacts, which provide positive, nonmicrophonic contact.

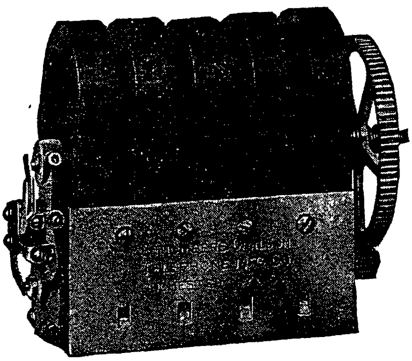

Fig. 6. Five-bar Hand Generator for Use in Magneto Subscriber Telephone Sets (Courtesy Stromberg-Carlson Co.)

Dials are required at all dial stations served by mechanical offices or private automatic exchanges of any type. The dial is the subscriber's only means at dial stations of securing connection with other dial subscribers or with toll or assistance operators in his exchange area. Figure 7 shows front and rear views of one type of dial assembly. The front view shows the finger wheel and stop and the number plate with its letter and number designations appearing through the finger wheel holes. The rear view shows the spring assembly, consisting of shunt (off normal) springs which short-circuit the transmitter and open the receiver circuits during dialing, and the impulse springs which open and close the subscriber line circuit, thus causing pulses of current to flow in this circuit at an average rate of about 10 pulses per second. The finger wheel, having been turned to the finger stop for any selected letter or number, is released, and as it returns to normal under spring action it is geared to operate the pulse pawl at a speed controlled by the governor. The pulse pawl alternately opens and permits the impulse springs to close as many times as there are units in the digit pulled.

Small filters consisting of inductance, capacitance, and resistance are generally bridged across the impulse spring contacts in order to reduce dialing interference to nearby radio receivers.

Housings of various types are provided, in which the required subscriber telephone set units described above are assembled. These housings are made of zinc alloy, plastics, steel for baseplates, and other materials, including rubber for cushioning. The various units are usually assembled on a universal baseplate, suitable for wall or desk-type sets.

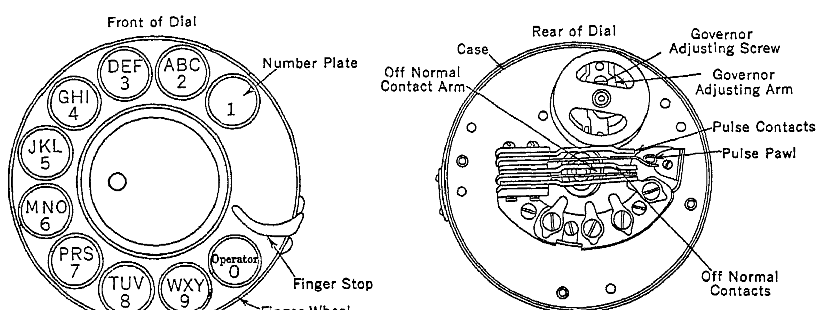

Fig. 7. Front and Rear View of Dial as Used with Dial Type Subscriber Telephone Set (Courtesy Bell System)

In one type of set, made by the Kellogg Switchboard and Supply Co., plug-in type induction coil (AST) and condenser units permit ready replacements to be made by pulling out the unit to be replaced and plugging in the new unit. The design of this company's set includes a universal permanently wired circuit, consisting of a stamped metal grid nested in the underside of an interconnecting block which mounts on a baseplate. This grid is connected through the block to screw terminals and pin jacks mounted on the upper side of this block. The induction coil has a three-way and the condenser a two-way switching unit to permit convenient circuit adjustments.

Some companies are now providing non-interfering or press-to-talk features in telephone sets intended primarily for use on multiparty rural lines, to permit listening on the line without the transmitter being cut into the circuit and without interfering with the ringing and dialing or with conversations in progress.

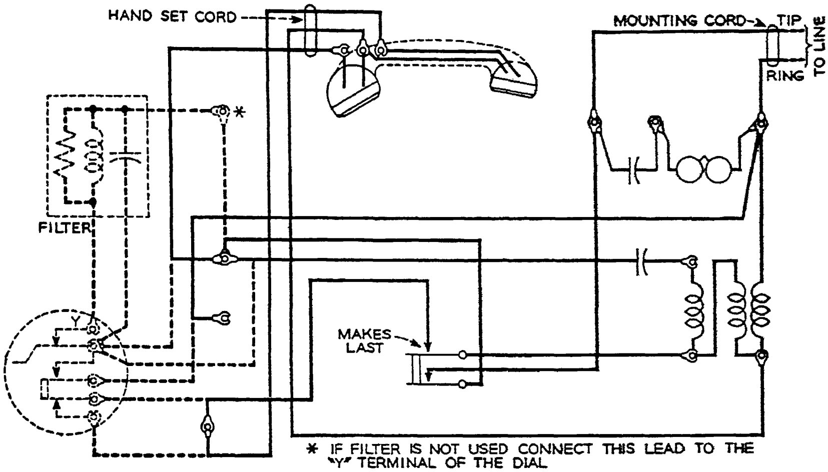

FIG. 8. Schematic of Wiring of Subscriber Hand Telephone Set—Common Battery Talking—Common Battery Signaling (Courtesy Bell System)

Figures 8 and 9 show, respectively, schematics of the wiring of a typical common battery talking-common battery signaling (CBT-CBS) and a typical local battery talking-common battery signaling (LBT-CBS) subscriber hand telephone set for individual, two-party selective, or four-party semi-selective service. The dial and filter circuits are required for dial service only.

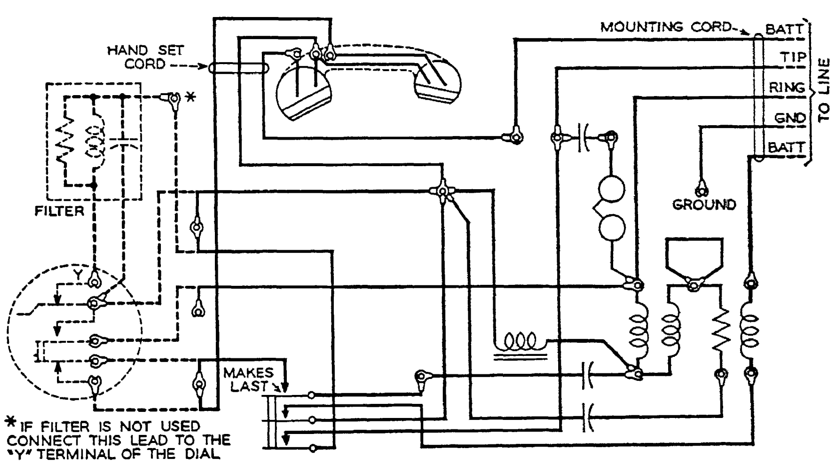

FIG. 9. Schematic of Wiring of Subscriber Hand Telephone Set—Local Battery Talking—Common Battery Signaling (Courtesy Bell System)

SUBSCRIBER SERVICES involving other than the regular subscriber telephone set just described require a wide variety of substation apparatus. Owing to limited space in this handbook, only brief mention can be made of some of the principal services currently rendered, which are:

1. *Station wiring plans*, whereby individual central office, PBX, or private lines may be connected at one or more telephone stations of which one or more or none may have a

regular attendant. In these cases, each station telephone may be equipped in its base with several pushbutton type keys, or separate key boxes may be provided which can be used for originating, answering, intercepting, holding, or transferring central-office calls on one or more lines, or connections can be established between stations without using either a central-office or PBX line. Various arrangements for controlling, locking out, grouping, or extending station calls are also available. Signaling between stations is usually by a pushbutton and buzzer circuit with battery or low voltage alternating current derived from the commercial power supply. Operating power may be supplied locally or from the central office.

2. *Loudspeaking and distant talking systems* may be employed between a master and one or more regular stations, facilitating communication, and such systems may be associated with regular telephone facilities and equipments. These systems require amplifiers, which are associated with each loudspeaking and distant talking telephone set, to provide adequate volume from the loudspeaker. Commercial power is usually employed for this equipment.

3. An *operator-type transmitter and receiver set*, with an associated key and jacks, may be provided at subscriber stations to facilitate handling messages over the telephone.

4. *Loudspeaker conference service* may be provided, where groups of people desire to listen to a local or distant talk and are assembled at one or more points. An amplifier and loudspeaker with a suitable subscriber set and switching keys are required for this service. Commercial power is used for this equipment.

5. *Coin collectors* of various types are located in public places where customers may place local or long-distances calls, either by prepayment or postpayment of the charges. Some of these collectors are placed in booths; others, in the open at locations convenient for public use.

6. *Subscriber amplifier deaf set equipment* provides for amplification of the incoming voice currents before reaching the subscriber's receiver. The incoming volume level is raised sufficiently, in many cases of deafness, for the subscriber to carry on a telephone conversation which would otherwise not be possible.

7. *Code calling systems* sound code signals at various points throughout a subscriber's establishment to notify certain employees or officials that they are wanted at the telephone or for some other reason. The controlling station on this system is usually located at the subscriber's PBX switchboard and is operated by the PBX attendant as a separate system, or the system may be actuated directly from a dial PBX or PAX system without an attendant.

This system requires code sending and station signal equipment, properly located and interconnected by wiring. Commercial a-c power supply is employed for operating it.

8. *Loudspeaker paging systems* are designed to provide a means of simultaneously transmitting messages or announcements verbally from a central location to a number of points within an establishment. These systems have a variety of uses from summoning a person to a telephone or directing employee activities, to providing information to a limited area.

9. *Subscriber telephone sets for explosive atmospheres* are available for use in mines, oil refineries, or munition plants. The equipment is designed to prevent sparking of the various parts under operation, causing explosions.

10. *Outdoor-type telephone sets* are provided for mounting in outdoor places for fire, police, taxicab, and other services. These sets are enclosed in cast-iron or wooden housings, which protect the equipment from weather conditions.

11. *Sound powered telephones* are provided in locations where it is desired to avoid possible central energy failures and where the distances between stations are relatively short, such as in an establishment, on a ship, or as portable field telephone equipment where batteries are not desirable. These telephones operate through action of sound waves striking the transmitter diaphragm and causing a variation in a magnetic field which produces electric currents in the telephone circuit of frequencies similar to those in the sound waves. The receiving apparatus functions quite like the regular telephone receiver.

12. *Program distributing systems* are designed to furnish program material, either from broadcasting stations or central program points, to hospitals, schools, hotels, business establishments, factories, homes, and many other locations. Program material may consist of music, speeches, announcements, and various other features of interest. This material is usually transmitted over wire lines from its source to one or more common amplifiers and thence distributed to subscribers over wire lines to loudspeakers at the various locations.

20. SUBSCRIBER STATION PROTECTION

Substation protection is required to protect subscribers and substation equipment from dangerous voltages and currents. The telephone plant is designed to withstand, with some margin, its normal operating currents and voltages. But there are other sources of electrical power, chiefly lightning and commercial power lines, which may under certain conditions impress large and destructive voltages, with resulting excessive currents, on the telephone plant, either by direct contact or by induction.

Danger from lightning in cities is less than in sparsely settled areas because of the shielding effect of buildings, trees, and various overhead structures. The danger from power-line contacts with aerial telephone plant is always present where the two types of plant are in close proximity, although material progress has been made in lessening this hazard over the years by improved methods of construction and protection. Stations connected to lines which are exposed to more than 250 volts between wires usually require protection and are classed as exposed stations.

The *maximum voltages* most commonly impressed on subscriber lines for telephone purposes range from 24 to 50 volts direct current and from 75 to 175 volts alternating current. Direct-current flow over the subscriber loop (individual line service) does not usually exceed 150 to 200 milliamperes and in most cases is less than about 100 milliamperes.

One type of *substation protector* widely used consists principally of two pairs of carbon protector blocks (open space cutouts) and two line fuses (one pair of blocks and one fuse for each side of the line), with associated spring and terminal holders, mounted on a porcelain base. Another design employs two metal plates, each of which connects with one side of the line and has a sawtooth inner edge positioned 0.004 in. from a grounded carbon block. The discharges take place across this gap. The ground electrode of the protector must be well grounded in every case.

CARBON PROTECTOR BLOCKS (sometimes designated as lightning arresters or dischargers) are manufactured in several designs, with the gap between the line and ground block varying from about 0.003 to 0.075 in. or more. The dielectric between the blocks may be air, or mica or acetate separators may be used. One design common throughout the United States consists of a grooved porcelain block with carbon insert for the line contact, and a solid flat (plain) carbon block for the ground contact. The line spring bears against the carbon insert set in the porcelain frame, and the porcelain frame bears against the ground block. The carbon insert is held in place by a glass cement of low melting point, and is forced against the ground block when arcing across the gap is sufficient to soften the cement.

The carbon insert is accurately positioned in its porcelain frame to provide a 0.003-in. gap for substation protection, or, when used at the junction of cable and open wire lines, this gap is 0.006 in. The peak breakdown voltages for these gaps are about 350 average and 550 maximum for the 0.003-in. gap and about 710 average and 1080 maximum for the 0.006-in. gap.

The fuses, being connected in series with the line and on the line side of the protector blocks, are designed to open each side of the line when the protector blocks discharge heavily or break down completely and when the resulting current through the fuses exceeds their ratings, which are usually 5 or 7 amperes, although fuses of other amperage may be used, depending upon operating company requirements.

Grounding of the protector requires a reasonably low-resistance ground (less than about 25 ohms), which may be obtained at the subscriber's premises by connecting to (1) the public water pipe system, (2) a private water pipe or well casing system, or (3) a driven ground (ground rod or pipe), preference being given in the order named.

A common ground with the secondary neutral of power distribution wiring is usually employed at the subscriber premises unless adequate separation between the telephone and power wiring on the premises can be maintained. This is to avoid excessive potentials being impressed on the telephone wiring, where separate grounds are employed, should there develop abnormal currents in the secondary neutral due to its becoming crossed with the primary power circuit.

Where extensive public water pipe or other systems having a low resistance to ground are available, common grounding should be used. Where such systems are not available, consideration must be given, in deciding on a separate or common ground, to the probability of high potentials being impressed on the telephone wiring in case of high currents in the secondary neutral.

Figure 10 shows one type of substation protector, widely used, with a fuse mounted along each side and the protector blocks held in a spring assembly set in a well in the center of the porcelain mounting block. The metal cap shown screws down over the blocks, excluding dirt and moisture.

Substations located at power stations generally require special protection. Whenever an abnormal condition on a power system results in ground current between the power station and an outside point on the system, the ground-potential rise at the power station above that of distant grounds will depend on the IZ drop in the power-station ground.

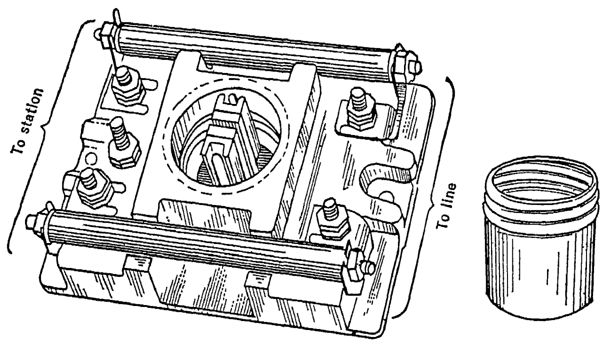

FIG. 10. Substation Protector (Courtesy Bell System)

Such a potential rise might exceed the breakdown potential of the usual telephone protector and render the telephone circuit inoperative at a time when it is most needed. Special protective devices, consisting of a neutralizing transformer or remote grounding of the telephone protector, may be considered in determining the type of special protection to use.

21. PRIVATE BRANCH EXCHANGE EQUIPMENT

Private branch exchange (PBX) equipment, as discussed here, includes manual and dial, cordless and cord, attended and unattended switchboards, whatever particular designations (such as PAX or PABX) are given to them by various companies. These boards range in size from the small ten-line system to the largest multiple type having a capacity of about 3000 lines or more.

MANUALLY OPERATED PBX BOARDS may be of the cordless type serving a few stations or of the cord type for the larger installations. These boards may also be operated in conjunction with PBX dial equipment.

A typical type of *manual cordless common-battery PBX board* has a capacity of twelve extensions (stations), five central-office trunks, and five connecting circuits. Each extension and each trunk terminates in a vertically mounted key unit which has three keys with levers in a vertical row. Each key lever can be operated either up or down or remain in its normal middle position. The upper and middle horizontal rows of keys, when operated up or down, connect their respective trunks or extensions to a common strapping between the keys in the board, and the lower horizontal row of keys does likewise when operated to the up position. In the down position, these latter keys bridge a holding coil across the trunk for the trunk keys and apply ringing current to the extensions for the extension keys, and the ringing keys are non-locking.

Each trunk has a visual drop and condenser bridged across it, and each extension has a visual signal in series, so that the central office and the extensions can each signal the attendant. A supervisory relay is provided in each connecting circuit, which circuit also provides talking battery for extension to extension connections, through a retard coil. For trunk to extension connections, talking battery is furnished over the trunk from the central office. The attendant's telephone set is connected to the first vertical key unit on the right side of the board.

Nominal power of 24 volts direct current is required for talking battery between extensions or between the attendant and the extensions and is usually furnished over cable pairs from the office, as is the required 20-cycle ringing current for the board. A hand generator is provided for the board for emergency use or where office ringing power is not available.

Incoming rings over a trunk operate the trunk drop, and the attendant answers by operating an idle connecting circuit key associated with the trunk, and also the attendant's corresponding key, both in the same horizontal row and to the same position, up or down. This connects the attendant's telephone to the trunk line.

If an extension is being called over a trunk, both trunk and extension keys are operated to corresponding positions and the extension ringing key is operated. When or before the extension answers, the attendant restores the attendant's telephone set key to normal, and when the supervisory signal indicates that the conversation is finished both the trunk and extension keys are operated to normal.

Extension to extension calls are established similarly by properly operating the calling and called extension keys.

Trunk calls can be held by the attendant operating the trunk holding key. The attendant or any extension may dial through the board to a dial office, if the telephone set is equipped with a dial. Outgoing trunk calls signal in to a manual common-battery office automatically.

Another type of *manual cord common battery PBX board* has a capacity of 320 extensions, 15 central office trunks, and 15 cord circuits. This board is of the two-panel, single-position, non-multiple type suitable for medium-size installations ranging from 80 to 320 extensions. Two boards may be operated side by side to increase the capacity. The trunks, central office or tie (to another PBX), and the extensions terminate on jacks between which the connections are established by means of the cord circuits. The trunks are ringdown incoming to and automatic signaling outgoing from the PBX. Each pair of cords has a talking and listening key and a ringing key for ringing on either the front or back cord, and double lamp supervision, except that supervision is provided on the extension cord only, for trunk calls. Each trunk and extension circuit is equipped with lamp signals for signaling the attendant, and up to 20 line relays may be provided for extensions to increase their signaling limit.

The attendant's telephone circuit contains a dial for dialing on dial trunks or extensions. The board may be operated in conjunction with dial PBX boards for intercepting calls or other services.

Talking battery is supplied for extension to extension connections through the single bridged retard coil in each cord circuit, but for trunk to extension connections talking battery is furnished from the central office. Nominal 24-volt battery required at the PBX for talking and circuit operations, and 20-cycle ringing power for ringing extensions, are usually provided over cable pairs from the central office. A hand generator is usually furnished for emergency use.

This board is designed to establish connections between local extensions and between these extensions and a manual or dial central office or other PBX.

Incoming calls from either a trunk or extension to an extension light an associated lamp signal at the board, and the attendant answers by operating the talking and listening key of the answering cord, which has been inserted in the calling jack. The connection is then completed by inserting the calling cord in the called extension jack and ringing this extension. Outgoing calls to the central office are handled over a trunk similarly, except that signaling the central office is usually automatic.

A type of *large manual cord common-battery multiple PBX board* has a capacity of 1520 extensions (without designation strips), 240 trunks, and 15 cord circuits (per position). The number of extensions may be increased by using a 34 $^1/_2$-in. in place of the usual 24 $^1/_8$ in. jack panel opening. There are two panels per position and four panels per multiple jack appearance for both extensions and trunks and one position per switchboard section.

The trunks and extensions terminate on series cutoff type jacks in the face of the board, and each jack has a multiple line lamp (for manual operation) associated with it. Since each extension or trunk appears in the jack multiple at every fourth panel throughout the board, the multiple lamps can be arranged to light, for an incoming call, at each appearance up to a total of four, thus attracting the attention of a greater number of attendants and improving answering performance. Line relays may be provided for the extensions to increase their signaling range. The manual trunks are usually ringdown incoming and automatic outgoing, and for a dial office they are of the dialing type.

The cord circuits are of the bridged-impedance series-condenser type, which provide battery feed to each cord of the pair separately through bridged retard coils. The tip and ring of the cord pair each has a condenser in series which prevents d-c flow in one half of the cord circuit affecting d-c flow in the other half. Talking battery is thus supplied each extension from the PBX cord circuit for extension to extension calls and to the extension for tie trunk to extension calls. For central-office trunk to extension calls the cord circuit is so arranged that extension talking battery is furnished from the central office, except where PBX long line circuits are provided at the PBX.

Each cord pair has a talking and dial key and a ringing key for ringing on either the front or back cord. Double lamp supervision is provided for each cord circuit on extension to extension calls, and single supervision for trunk to extension calls. A position dial may be cut in on any cord for dialing by operating the talk and dial key.

The distributing frames are enclosed in sections at the head of the switchboard. Facsimile sections may also be located in the switchboard line-up. The board may be operated in conjunction with dial PBX boards for intercepting or other services.

The power required for operation of this board is a nominal 48-volt d-c source for talking and circuit operations, and 20-cycle ringing current. Owing to the usually relatively heavy battery drains, storage batteries are provided at the PBX and charged by a separate power unit at the PBX or, where economical and practicable, over cable pairs from the central office. Ringing current is also generally supplied to the PBX over cable pairs from the office, and each position is equipped with a hand generator for emergency use.

This board is designed for establishments, such as large department stores, institutions, and organizations, where PBXs of the smaller types are not adequate. It may be operated in manual or dial office areas and in conjunction with other manual or dial PBXs.

Operation is similar to a regular exchange manual switchboard except for the several special features that may be provided to meet the individual subscriber's needs.

A typical *medium-size dial PBX unit* of the step-by-step (SXS) type has a capacity of up to 79 extensions, 10 central office and 10 attendant's trunks, for two-digit dialing. The SXS equipment consists principally of 20 line finders, 100 line and cutoff relays, and miscellaneous equipment mounted on the side of the switch frame, and 20 selector-connectors and 19 trunk equipments mounted on the reverse of the frame.

This PBX unit functions with a suitable companion manual PBX containing a jack appearance for each trunk and extension for the purpose of receiving, originating, and intercepting calls that cannot be handled by the SXS unit. Incoming calls reach the manual attendant, who dials the called extension over an attendant's trunk. Outgoing calls may be handled and calls requiring special treatment are usually handled at the manual board. The SXS unit handles direct calls between extensions and from extensions to the central office, associated manual PBX board, and other PBX boards equipped to receive dialing pulses.

Power requirements for the SXS unit consist of nominal 48 volts direct current for talking and circuit operations, and machine ringing current. D-c power is usually supplied by a small power unit located at the PBX, or over central-office cable pairs if the load permits and pairs are available. Ringing current is generally furnished over central-office cable pairs.

Dialed calls are completed by the usual step-by-step processes (described elsewhere in this section). Calls handled at the manual PBX may either be dialed in dial office areas or completed over automatic signaling trunks in manual office areas.

Dial PBX units of the step-by-step type having capacities up to 3200 extensions, depending upon the number of extensions required, are available. Two-digit dialing (under 100 extensions) requires line finders and selector-connectors (operating as a selector on the upper levels and a connector on the lower levels) while four-digit dialing requires first and second selectors and connectors. If incoming dial repeating trunks are provided, they terminate on incoming connectors for two-digit and on incoming selectors for three- or four-digit dialing. The line finders have a 200-point bank; the other switches have 100-point banks.

These dial PBX units are usually associated with manual PBX units, the latter receiving, originating, and intercepting calls that the SXS unit is not arranged to handle. The SXS unit handles calls between extensions and calls to the central office or to another PBX which are capable of receiving dial pulses from the extensions or over dial repeating trunks. The extensions of the SXS unit may be reached direct from other PBXs if proper dialing facilities are provided, but calls to these extensions from the central office are usually handled at the manual PBX board.

PROTECTION for PBX trunks and extensions at the PBX is the same as for regular subscriber to central-office lines of the same classification, that is, exposed or non-exposed. In addition, owing to paths to ground through the equipment in the PBX board, which may permit foreign currents large enough to cause trouble to flow through the equipment, heat coil type fuses having the same operating characteristics as central-office heat coils (except that they open rather than ground the line wires) are provided in each exposed trunk and extension at the PBX. In the case of large PBXs a section of fine-gage cable sometimes is used in place of the 7-ampere line fuses. This is similar to the fusing provided at central offices (see article 6).

ORDER TURRETS, manufactured in various types and capacities, are employed in business or service establishments, such as department stores, telegraph offices, taxicab companies, and newspaper offices, to receive orders for goods or requests for services.

One type of order turret for multidepartment businesses has a capacity of one two-way trunk and one outgoing trunk from the turret to the subscriber's PBX and one incoming trunk from the PBX to the turret. The incoming customer calls are received at the PBX board and routed over trunks to the proper department turret, where an attendant receives the customer's request. The turret serves as a small switching unit between a single telephone in the departments thus equipped and the PBX, and it avoids the installation of several telephones at each location.

An order turret system, where incoming calls are concentrated in one line-up of turret positions, is also available. Incoming customer calls from either a manual or dial central office or PBX are received in incoming trunk circuits, allotted by an allotter circuit to a sequence storing circuit, and thence released to an idle attendant in the sequence in which the calls are received. Thus the calls are distributed automatically as rapidly as turret attendants become idle and with minimum loss of time in handling. This type of system has a capacity of 120 incoming trunks (with first group of selectors), 110 attendant's trunk circuits, and 110 attendant's positions. A small order turret located in front of each attendant has four keys and two lamps, a trunk, and a calling waiting signal for receiving and originating calls. Calls can be held, released, or transferred by means of these keys. Usually a manual or combined manual and dial PBX board is associated with this turret system. Power supply is 20–28 volts direct current, for which a local automatic power plant is provided. Ringing current is usually furnished over cable pairs from the central office.

SECTION 18

TELEGRAPHY

TELEGRAPHY

THEORY

By John D. Taylor

Fundamentally, the process of *communicating* by telegraph consists of sending electrical impulses by wire or radio from a transmitting to a receiving point. These impulses are so selected, arranged, and transmitted (in sequence), that they are received, interpreted, and recorded as intelligible characters at the receiving point. Such interpretation may be made by the ear listening to the click of a telegraph sounder or the tone in a head receiver or loudspeaker, or by automatic and mechanical devices.

Basically, it was necessary to develop *codes* (intelligence-bearing arrangements of electrical impulses) and to provide transmitting and receiving devices and interconnecting channels, capable of satisfactorily passing these codes between the desired locations.

1. METHODS OF TRANSMISSION

Telegraph codes or signals are transmitted electrically (1) by open-wire land lines or cables or short submarine cables, using either direct or alternating current, (2) by long submarine cables (oceanic), using only direct current, and (3) by radio, using only alternating current.

Direct-current telegraphy employs a d-c source of power, which is either interrupted, reversed in polarity, or altered in magnitude by the transmitting mechanism. The line current frequency with present high-speed telegraph systems does not usually exceed about 200 cycles per second, and thus systems using this type of transmission are generally referred to as *low-frequency systems.*

Alternating-current telegraphy employs, for each transmitting channel, a relatively narrow band (about 170 to 300 cycles wide) of a-c frequencies, which are modulated by the telegraph signals, being transmitted, before being applied to the line. A basic block of frequencies, approximately 3000 cycles wide, is used to provide a group of carrier channels, the number of channels per block depending on the width allocated to the individual channels. Carrier telegraph systems utilize one, two, four, or more basic blocks of frequencies in each direction of transmission, the blocks being stacked one above the other in the assigned frequency range by translation or second-modulation, as discussed in article 3, Section 17.

The transmission and reception of signals may be either manual or automatic. In *manual operation,* the transmitted signals are formed by a hand-operated switch or *sending key,* and the signals are received either on an electromagnetically operated sounder, which converts the signals into audible clicks, or on a Morse recorder, which makes an ink record of the received impulses. These audible or recorded signals are interpreted by an operator, who typewrites the message manually. *Automatic operation* provides for the formation and transmission of the signals by an automatic circuit-interrupting device or *transmitter,* which may be controlled either directly or indirectly by a group of keys similar to a typewriter keyboard. The received signals are automatically interpreted and recorded in typewritten form by a *printer.* In some cases, notably in the operation of submarine cables, a combination of automatic transmission and manual reception is employed. The transmitting and receiving equipment, and the associated line terminal apparatus, are so closely related that the entire assembly is usually referred to as a *telegraph system.*

2. CODES

Characters of the alphabet, figures, and punctuation marks are transmitted as combinations of marking and spacing impulses. A *marking signal* or impulse is one which causes the receiving apparatus to be operated, and a *spacing signal,* which separates successive marking signals, places the receiving apparatus in the unoperated condition. Spacing signals may be intervals of no current, impulses of opposite polarity to the marking signals, or impulses of different current value from the marking signals. *Two-element codes,* employing only two conditions of current, positive and negative, or current and no current, are mainly used on land line circuits. *Three-element codes,* which use both positive

Fig. 1. Telegraph Codes—Morse, Continental, and Cable Morse

and negative polarities and also a zero or no-current interval to separate groups of impulses, are employed chiefly on long non-loaded submarine cables, where the comparative freedom from extraneous interference removes the chief objection to the use of a zero interval for the separation of signal groups.

The Morse Code is used almost exclusively in the United States on hand-worked land lines; the *Continental Code* has been adopted by almost all foreign telegraph administrations, and is universally employed on radio telegraph circuits. In these two codes, the dot signal is the basis of time measurement. A dash is three times the length of a dot; the spaces separating successive impulses in a combination are of dot length; the spaces between impulse groups are equal to three dots; and a space equivalent to six dots is used to separate words. The Cable Morse Code is used almost entirely in the operation of long submarine cables. All impulses and spaces are of equal length, a positive impulse representing a dot and a negative impulse representing a dash.

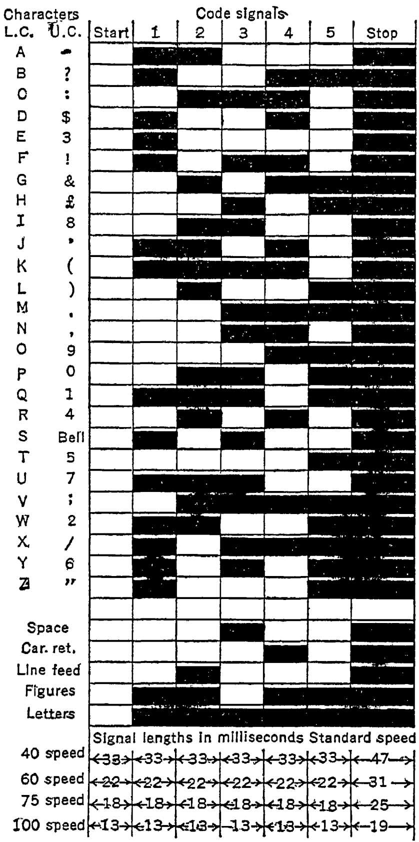

FIG. 2. Teletypewriter Code (Courtesy Bell System)

In calculating speeds, the average Morse character is equivalent in length to approximately 8.5 impulses of dot length, or about 4.25 cycles, while Continental characters average about 9 impulses or 4.5 cycles each. The Cable Code averages 3.7 impulses or 1.85 cycles per letter. These figures take into account the frequency with which the various letters of the alphabet occur in ordinary telegraph traffic.

Figure 1 shows the combinations of dot and dashes used in the Morse and Continental Codes, and the positive and negative polarity and zero current intervals used in the Cable Morse Code.

While the Morse and Continental Codes are designed for *manual* operation, the Cable Morse Code is transmitted *automatically*. The automatic transmission of telegraph signals is almost universally employed for land line, cable, and radio telegraph systems, because of its greater speed and ease of operation, resulting in large economies. Manual operation, when and where used, is, in general, confined to short-haul traffic and special services of such a nature as not to warrant or be adaptable to automatic operation.

In developing automatic telegraph systems, it was necessary to *design machines or devices*, which would automatically send and receive electrical impulses (positive or negative) and to *devise individual arrangements of these impulses*, representing intelligible characters. It was further required that these arrangements could be set up manually for transmission, and sent, received, and interpreted automatically at speeds suitable to the transmitting medium.

One type of sending and receiving device for use in automatic systems is the *teletypewriter* or *teleprinter* (described in detail in article 7 of this section), which utilizes a *5-impulse code* for each character with a single impulse for starting and also for stopping both sending and receiving units between characters. The code devised for the teletypewriter, which is practically identical with that of the teleprinter, is shown in Fig. 2, in which L.C. and U.C. are abbreviations for lower- and upper-case characters on the typing keyboard and the black and white spaces are the marking and spacing impulses, respectively. The signal impulse lengths in milliseconds (ms) are also shown for different operating speeds (words transmitted per minute).

Of the 32 separate combinations available, using 5 equal-length impulses for each character, the combination of all spacing impulses has no character assigned to it and is not transmitted.

The line frequency for the teletypewriter operation depends upon the number of words per minute being transmitted. For 60-speed transmission (about 60 words per minute) the shortest signal element is about 0.022 sec (see Fig. 2), and the line frequency is

$$1/(0.022 \times 2) = 22.7 \text{ cycles per second}$$

3. TELEGRAPH SIGNALS

Electrical impulses must be formed by the transmitting device, transmitted through a connecting medium, and finally received and interpreted by the receiving device, so that the received message is identical with the original sent message and is efficiently transmitted. However, owing to the electrical characteristics of telegraph circuits and associated apparatus, telegraph signal currents are generally more or less modified (electrically) in transmission, and, if suitable corrections were not made, these modifications or distortion would, in many cases, cause errors in the received message.

Telegraph signals, in d-c operation, are classed as (1) *neutral* (current flows over the line in either direction for the operated or *marking* position and no current flows for the non-operated or *spacing* position of the line relays) or (2) *polar* (current flows over the line in one direction for the *marking* and in the opposite direction for the *spacing* position of the line relays). For either type of signal, the change of current from mark to space or space to mark is known as a *transition.*

4. WAVE SHAPES

NEUTRAL SYSTEM. The change in line current values, with respect to time, may be plotted to show the *wave shape* of the telegraph signal for any telegraph circuit, as shown in Fig. 3 for a neutral circuit transmitting the Morse signal (dot, dash) representing the letter *A*. For such a circuit, *A* in Fig. 3 shows the wave shape of the current, if the times of building up and decaying to the steady-state values are neglected, *B* shows the effect on the wave shape of series inductance (line relay or composite set winding), and *C* shows, by the shaded area, the additional effect on the wave shape of the composite set or other condensers.

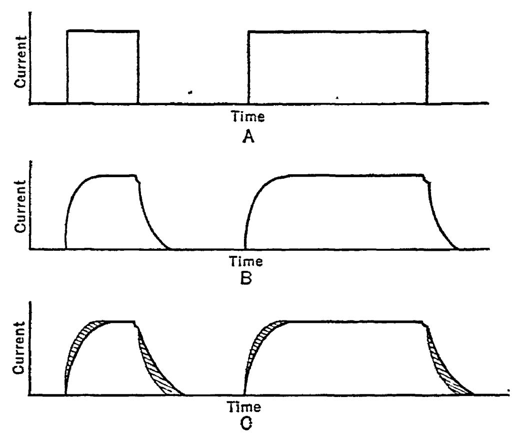

FIG. 3. Wave Shape for Letter A—Neutral Telegraph System (Courtesy Bell System)

With reference to *C*, Fig. 3, when the telegraph sending key closes, the inductance in the circuit opposes any sudden change in current value, and part of the current is diverted from the line to charge the composite set condensers to about the applied battery potential, as the line current builds up to its maximum value; when the key opens, the current immediately starts to decay and, although partly sustained by flow of current from the condensers and the opposition of the inductance to current change, shortly reaches its minimum value.

Current wave shapes are important factors, which affect telegraph relay performance and adjustments. For any given relay, there is a definite operating and release (less than the operating) current value for given operating conditions. Figure 4 shows a schematic d-c circuit, containing a neutral type of telegraph relay, milliammeter, battery, and rheostat. The retractive spring tension is controlled by adjusting screw S_1, the armature to pole piece air gap by S_2, and the armature travel distance by S_3 and S_4.

Figure 5 shows the effect of relay adjustments on operating and release current values (indicated by the black dots, O, R, O_1, and R_1 on the curves), and on the effective length (T and T_1) of the telegraph signal. In telegraph parlance, the shorter marking signals are called "light" and the longer marking signals "heavy." In practice, relay adjustments are made, as required, to provide satisfactory received signals from usually distorted wave shapes, caused by the electrical or mechanical characteristics of the line and associated equipment or changes therein.

Effective signal length might also be increased or decreased for a given neutral telegraph circuit with a fixed relay adjustment by raising or lowering, respectively, the applied circuit voltage. However, since line current values are limited, in practice, by crossfire into other telegraph circuits or by interference with telephone transmission, this method of controlling the signal length is restricted and not usually employed.

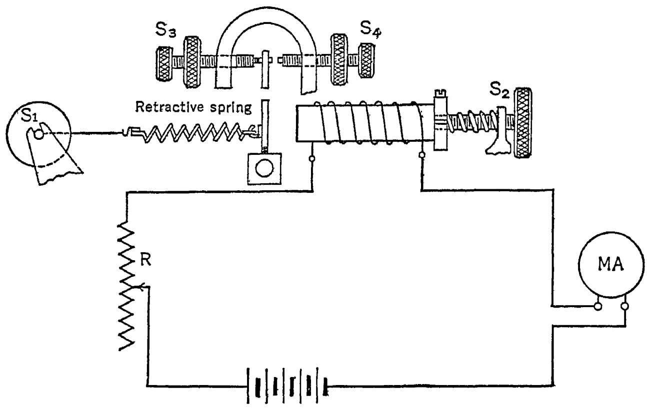

FIG. 4. Schematic of a D-c Telegraph Circuit with Neutral Relay (Courtesy Bell System)

Relay adjustments are also affected by line conditions, such as leakage of line currents to ground through tree or other contacts or the direct capacitance between the line wire and ground. In general, for open-wire telegraph circuits this leakage factor varies as among

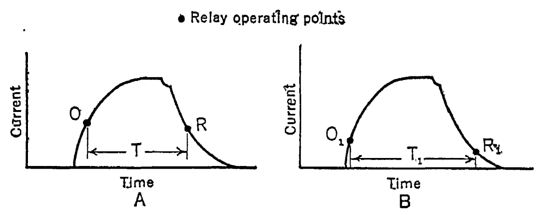

FIG. 5. Effect of Relay Adjustment on Telegraph Relay Operation (Courtesy Bell System)

wires and increases materially from the dry to wet weather condition. Figure 6*a* shows a neutral telegraph circuit with grounded battery at one station and Fig. 6*b* the same circuit with grounded battery at both stations, and for both circuits the leakage to ground,

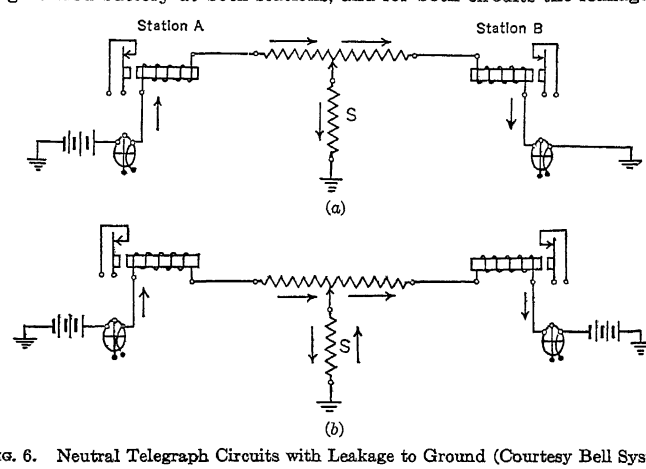

FIG. 6. Neutral Telegraph Circuits with Leakage to Ground (Courtesy Bell System)

which may be concentrated principally at one or more points or generally distributed along the line, is represented by the resistance S.

Figure 7 shows leakage effects on the current curve for the circuit (Fig. 6*a*). The curve in Fig. 7, *A*, represents the ideal condition of no leakage. The curve in *B* represents the leakage current alone through *S*. Since the inductance through *S* is less than through station B, the leakage curve in *B* is steeper than the curve in *A*, and this resultant, which affects station A relay, may be about as shown in *C*. In this curve, the effective signal length T_c is greater (heavier signal) than T_a in *A*. The leak *S* also shunts the path through station B and tends to decrease the line current to this station, as well as to flatten the current curve, as shown by *D*.

The wide variation of effective signal lengths, T_c and T_d, through station A and B relays, in series, would not occur if half of the total line battery voltage was applied at each station, oppositely poled to the line, as shown in Fig. 6*b*. Since each battery supplies current to the leakage path *S*, but in opposite directions, the resultant current through this path will generally be small and the line current through the station A and B relays will be more nearly equal and stabilized than for single end battery feed, thus improving signal transmission.

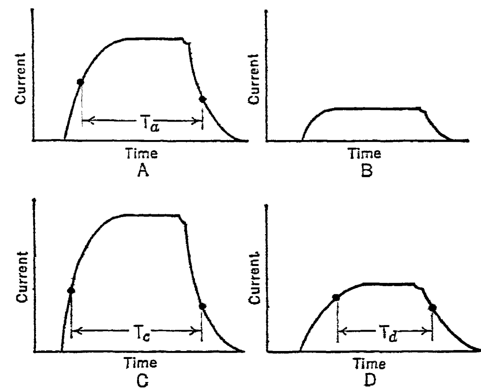

FIG. 7. Effects of Leakage on Current Curves for the Neutral Telegraph Circuit of Fig. 6*a* (Courtesy Bell System)

Telegraph current wave shapes formed by direct current are, in effect, somewhat similar to a-c wave shapes and contain various harmonics of the fundamental frequency, as will be discussed later. Owing to the normal line wire capacitance to ground (irrespective of other leakage paths), the a-c components of the telegraph currents will be shunted, in some degree. Thus, the line capacitance not only reduces the effective current at the receiving station but also tends to distort the current wave shape and to limit the length of operating line section between repeater points.

As indicated in Fig. 5, the relay operating points occur on a current curve between points of transition. The change from the spacing to the marking condition is designated *space-to-mark (S-M) transition*, and the change from the marking to the spacing condition is designated *mark-to-space (M-S) transition*. At the sending end of a telegraph circuit, the S-M transition takes place when the key is closed, and the M-S transition occurs when the key is opened.

There is a certain *time delay* from the closing of the sending key to the operation of the receiving relay and from the opening of the key to the release of the relay. In the first case, this delay is designated *space-to-mark transition delay (S-MTD)* and in the second case, this delay is designated *mark-to-space transition delay (M-STD)*, as shown in Fig. 8*b*.

In Fig. 8*a* the line capacitance is represented by the dotted condenser path to ground. When the sending key is closed, this capacitance is charged by current flowing over the line from the sending station, and the current is retarded in building up to its full value by the inductance in the circuit, as indicated by the sloping wave shape in Fig. 8*b*. The current which flows continuously in the biasing winding of the receiving relay produces a constant magnetic field tending to hold, in this particular circuit, the receiving relay armature against its spacing contact. When a marking signal current is received, the stronger opposing magnetic field set up by the larger marking current in the operating winding of the receiving relay causes the relay armature to move to its marking contact.

Although the operating points of a relay depend upon its design and adjustments, it may be assumed, for the purposes of this discussion, that the relays in Fig. 8*a* will operate on 33 and release on 27 ma of direct current, or plus and minus 3 ma from the 30 ma of biasing current, as shown in Fig. 8*b*. When the operating current increases to 30 ma, the effective operating current in the receiving relay is then zero, but when it reaches 33 ma, operation occurs and continues until the line current, decaying on open circuit, decreases to 27 ma, when the relay releases.

The S-MTD period is the time it takes for the operating current to increase from zero to 33 ma, and the M-STD period is the time it takes for the current to decay from its maximum value of 60 ma to the release value of 27 ma. These periods vary from a fraction of a millisecond (ms) to several milliseconds, being determined, for a given circuit and adjustments, solely by the circuit characteristics. For a given circuit and operating conditions, each transition delay (S-MTD) will be the same for repeated signals, and the same holds true for each delay (M-STD), but the S-MTD delays may not be equal to the M-STD delays.

Each mark, of whatever length, begins with an S-M transition and ends with an M-S transition. The S-MTD period reduces and the M-STD period increases the effective

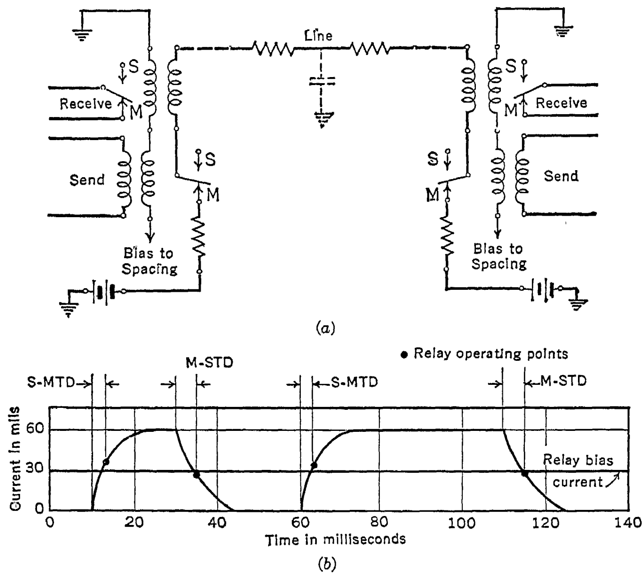

FIG. 8. (a) Neutral Telegraph Circuit and (b) Signal Wave Shape (Courtesy Bell System)

length of the mark, so that, if these two delay periods are equal, the length of the mark will not be changed by transmission over the circuit. Each space, of whatever length, begins with an M-S transition and ends with an S-M transition. The M-STD period reduces and the S-MTD period increases the length of the space, so that, if these two delay periods are equal, the length of the space will not be changed by transmission over the circuit. The transmission of signals is considered perfect if the received effective marks and spaces are exactly the same length as the sent marks and spaces.

POLAR OPERATION. Wave shapes in polar telegraph systems are affected by circuit inductance, capacitance, and leakage somewhat as in neutral telegraph systems. Figure 9

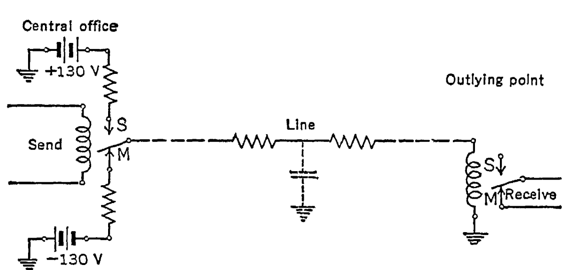

FIG. 9. Simplified One-way Polar Telegraph Circuit (Courtesy Bell System)

shows a simple one-way polar telegraph circuit, arranged to send −130 and +130 volt impulses from the central office (sending point) to an outlying receiving point, having series line resistance and capacitance between the line and ground.

Assuming that the sending-end connections are adjusted to provide normally steady-state line currents of +35 ma (marking) and −35 ma (spacing), as shown in Fig. 10, the line capacitance to ground will delay the change of line current from spacing to marking (S-M transition) and from marking to spacing (M-S transition).

The M-S and S-M wave shapes (Fig. 10) are identical in form and symmetrically located about the zero line, and the S-MTD and M-STD are equal. Thus, since the sending end potentials are equal and of opposite sign, since the circuit resistance remains constant for both positions of the sending relay armature, and since the operating points of the receiving relay are symmetrically located at about the middle of the wave shapes, the received polar signals are unbiased.

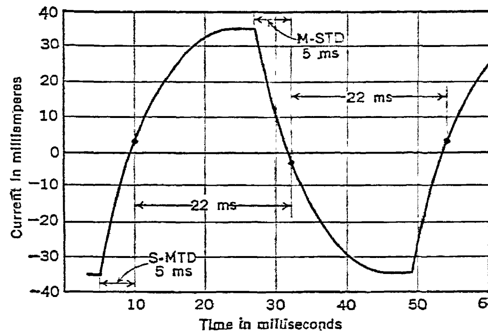

FIG. 10. Signal Wave Shape in Typical Polar Telegraph Circuit (Courtesy Bell System)

TELETYPEWRITER AND TELEPRINTER OPERATION. In teletypewriter or teleprinter operation, there are five equal length impulses, each of which may be negative (mark) or positive (space), in accordance with the code of signals (Fig. 2) for this type of operation. These five impulses represent the character to be transmitted. Two additional impulses are sent with each character, one starting and one stopping the machines.

If a series of impulses, representing, for example, the letter *D*, are plotted with time as the horizontal axis, as shown in Fig. 11, it will be noted that the wave shape, in the upper

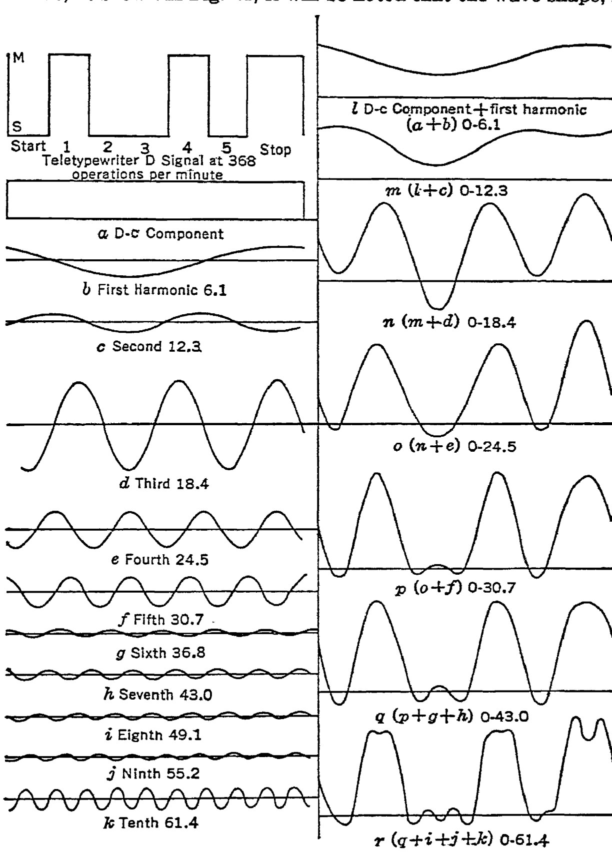

FIG. 11. Analysis of Wave-shape Components of Teletypewriter Character D (Courtesy Bell System)

left-hand corner of the figure, which is impressed on the line at the transmitting end of the circuit, has "square" corners. However, if such a wave is analyzed, it will be found to contain an infinite number of component frequencies, all of which, in practice, cannot and need not be transmitted to the receiving terminal.

Though a very simple receiving device might be used, if all the components could be faithfully transmitted over a circuit, such a circuit could not be economically provided. Also, with an ideal receiving device, it would only be necessary to transmit a maximum frequency equivalent to that which considers the duration of each unit signal element of the code as $^1/_2$ cycle (1 cycle would be the time involved from the end of element 1 to the end of element 3 of the square wave in the upper left-hand corner of Fig. 11). This condition is closely approached for long submarine cable telegraph systems, where the high conductor cost warrants expensive terminal equipment for reasons of efficiency and economy. However, for land line teletypewriter commercial use, neither expensive circuits nor elaborate terminal arrangements are justified, and the facilities and equipment that are provided represent a compromise on a cost balance basis.

For good telegraph transmission with comparatively simple equipment, it is desirable that the received signal contain a substantial part of the second and third harmonics of the frequency of the unit signal element. For 60-speed teletypewriter signals, the shortest signal element is 0.022 sec, which is equivalent to $^1/_2$ cycle. The fundamental frequency at this speed then would be $1/(0.022 \times 2) = 22.73$ cycles per second, the third harmonic of which would be about 68.2 cycles per second.

If one teletypewriter character is continuously repeated at 60-speed, the signal wave (there being one per character) repeats itself about 6.1 times per second, so that, for the purpose of discussing the signal components in teletypewriter operation, the wave may be considered as composed of a d-c component and harmonics of a fundamental frequency of 6.1 cycles, rather than harmonics of the signal element frequency. Thus, in Fig. 11, the left-hand column shows several of the more important harmonic components of the D signal, their relative magnitudes and phase relationships, the first harmonic (curve b) being shown as a sine wave of the same time period as the *overall signal;* the right-hand column shows the combined resultant of the d-c component and the overall signal harmonics, added successively, as indicated.

Since the fundamental signal element frequency for 60-speed operation was shown previously to be 22.7 cycles per second, theoretically the character D could be interpreted correctly by an ideal receiving device if components, in correct phase relation, up to and including the fourth harmonic of the overall signal (curve o in right-hand column) were received.

In practice, overall signal harmonics up to about the tenth (corresponding to about the third harmonic of the signal element frequency) are transmitted, which gives a signal wave similar to curve r and which resembles somewhat the square-corner wave in Fig. 11.

CARRIER TELEGRAPH. Carrier telegraph systems employ modulated alternating currents of different frequency bands. The voice-frequency (low-frequency) system utilizes the band of 255 to 3145 cycles for 18 channels of 170 cycles per channel. The modulated output of this system may be impressed, if desired, on broad-band telephone carrier or radio channels of higher-frequency bands, making use of such channels for telegraph rather than for telephone service. The high-frequency system for telegraph was the first one developed. It is for open-wire facilities and operates in three different frequency assignments, all of which lie within the overall range of 3.33 kc to 11.25 kc. These systems will be described later in this section.

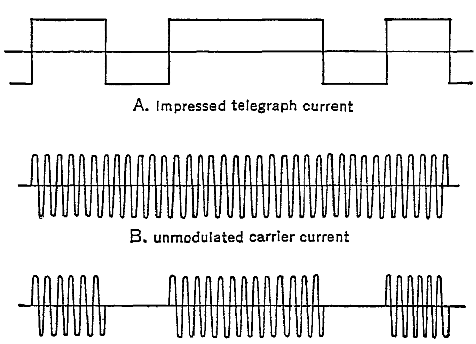

FIG. 12. D-c Modulation of Carrier Currents—Telegraph Carrier Systems (Courtesy Bell System)

As previously described, the basic signal element is a square wave produced by making and breaking a d-c sending circuit or by applying opposite potentials (one at a time) to the transmitting device. Generally, the carrier wave is supplied continuously to the transmitting device and is interrupted (modulated) in accordance with the d-c signals being produced by the local sending circuit and impressed on the carrier wave at this device. Figure 12 shows the impressed telegraph current (polar operation), the unmodulated carrier current, and the modulated carrier wave. The received segments of carrier current signal are rectified in the demodulator circuit, and the resulting unidirectional plate current pulses act on a receiving d-c relay. These received d-c current signals, being similar in pattern to the sent d-c signals, actuate the receiving relay in accordance with the sent signal.

Since the sending d-c signal contains, for practical reasons, up to about the third harmonic, which at 60-speed operation is about 70 cycles, both carrier sidebands transmitted will also contain this band width, or, for both bands at this speed, the frequency spread would be about 140 cycles. For higher or lower speeds, this spread would be greater or less.

5. DISTORTION

An ideal (perfect) telegraph circuit reproduces telegraph signals at the receiving end exactly as they are impressed at the sending end, with respect to length, but not necessarily amplitude, of the component marks and spaces. The time of travel of the signal over a circuit is usually not important, even though such time exceeds the duration of a unit signal element.

Distortion in telegraph transmission is thus determined by comparing the length and relative arrangement of the signal elements as sent with the length and relative arrangement of such elements as finally delivered by the receiving device.

The overall or total resultant distortion of signals, for a given telegraph circuit, consists of two principal types of distortion, namely systematic and fortuitous, which result from a number of different causes and require different treatments in design and maintenance work in order to meet service requirements.

Assume that a given telegraph character is sent continuously over a telegraph circuit and that each repetition of the character is considered perfect as sent. Measurements of the distortion of each of the unit marks (elements) in a large number of successive repetitions of the character at the receiving end will generally indicate that the distortion differs (1) from element to element in a given repetition of the character and (2) from character to character for a particular element in the character. The average of a large number of distortions for a particular element is designated as systematic distortion. The individual departure of the distortion from the average for a given measured distortion is designated as fortuitous distortion. The total distortion of each signal element is the algebraic sum of the systematic and fortuitous distortions and is the amount of deviation between the sent and received signals.

Figure 13 illustrates roughly for 10 repetitions (not enough for a good average in actual cases) the distortion which may affect a marking signal of unit duration as received. The average length of received signal is shown to be 90 per cent of the sent signal, resulting in a −10 per cent systematic distortion which applies to all the repetitions. The departure of the individual distortions from the average varies between repetitions, as shown in the right-hand column, and in the left-hand column the resultant distortion is indicated.

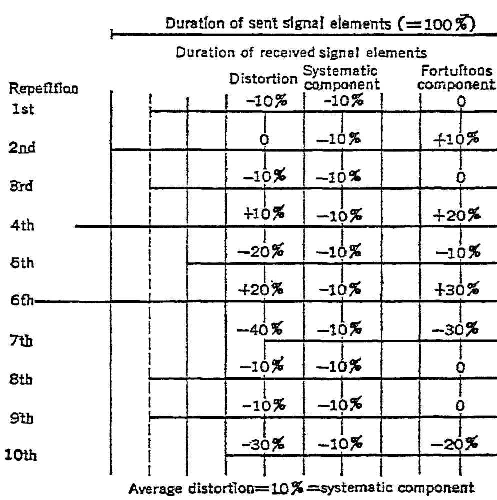

FIG. 13. Systematic and Fortuitous Distortion (Courtesy Bell System)

Systematic distortion may be divided into two component distortions, *bias* and *characteristic*, for the purpose of analyzing and treating the causes of this type of distortion. The nature of these components may be explained by assuming a telegraph system in which marks and spaces are sent by means of currents equal in magnitude but of either positive and negative or negative and positive sign, respectively, as desired.

Bias Distortion. Assume that the systematic distortion, as measured, is due to a higher positive than negative sending-end potential, and that this fact results in lengthening the marks when positive current is used for transmitting marks, and in shortening the marks when negative current is used for transmitting marks. Then, interchanging the functions of the two current conditions employed changes the sign of the systematic distortion but not its magnitude and is called bias distortion, indicating a lack of symmetry in the circuit.

A *marking bias* is called a *positive bias*, and a *spacing bias* is called a *negative bias*; and, since the lengths of the marks and spaces may be indicated in milliseconds (ms), the amount of bias may also be indicated in milliseconds by the formula (M-STD) − (S-MTD) = ms bias, the first two terms being mark-to-space transition delay and space-to-mark transition delay, respectively, and the sign of the result (using this formula) being the sign of the bias. Thus, for a given circuit, if M-STD = 6 ms and S-MTD = 3 ms, the milliseconds bias is +3, indicating that every mark, regardless of length, will be increased 3 ms, and every space, regardless of length, will be decreased 3 ms.

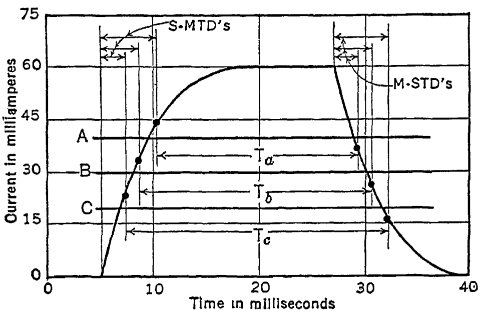

FIG. 14*a*. Effect of Relay Biasing Current on Signal Length (Courtesy Bell System)

Though a given *ms bias condition* is due to such factors as unequal marking and spacing line currents, ground potentials, and improper biased relay adjustments, this condition will remain constant for the transmission of signal reversals (but not random signals) irrespective of the speed of transmission. However, the effect of a given ms bias condition on transmission does vary with the length of the transmitted marks and spaces. For example, in a manual telegraph circuit the dashes (long marks) are about 3 times the length of the dots (short marks), and both dashes and dots decrease proportionately in length with increase in speed of transmission. Assuming first a slow speed, where the dots are 30 ms long and the dashes are 90 ms long, a ms bias of +10 will lengthen the dots and dashes to 40 ms and 100 ms, respectively, the ratio of dash to dot length still being 2.5 to 1. However, if, owing to an increase in speed, the dots and dashes are shortened to 5 ms and 15 ms, respectively, the same +10 ms bias would result in dots 15 ms in length and dashes 25 ms in length. The ratio of dash-to-dot length would then be about 1.7 to 1, and greater difficulty would be experienced in reading the signals than for the usual ratio of 2.5 or 3 to 1.

Figures 14*a* and *b* show the effects on signal length of relay biasing current and line current variations. In the first figure, the line current is held constant at 60 ma, while the normal biasing current (line *B*) is increased (line *A*) and decreased (line *C*). In the second figure, the biasing current is held constant and the normal line current is increased (high line current) and decreased (low line current). It is evident that, in the first condition, increasing the biasing current decreases the signal length and decreasing it increases the signal length; and, in the second condition, increasing the line current increases the signal length and decreasing it decreases the signal length.

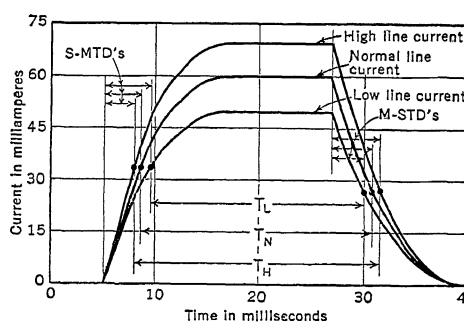

FIG. 14*b*. Effect of Line Current Magnitude on Signal Length (Courtesy Bell System)

Characteristic distortion results from various causes, which are usually different from those associated with bias distortion. Assume a telegraph system, in which the sending battery potentials are equal and opposite in sign and in which the marks and spaces are formed by corresponding currents, equal but opposite in sign. Also, assume that, owing to the characteristics of the given system, the current is slow in building up to the normal mark or space value. If the current does not have time to reach its final value on the short signal elements, the first mark following a long space may be shortened. Under this condition, it is obvious that interchanging the functions of the positive and negative current will not alter either the sign or the magnitude of the resulting distortion, and the distortion is called characteristic distortion, indicating it is a function of the signal combination and fixed characteristics of the system, which causes remnants from a given signal element to affect succeeding elements.

Depending on the speed of operation, telegraph signals are frequently of insufficient duration to permit the line current for a given signal to change from one steady state to the other, i.e., from a maximum positive to a maximum negative line current, or vice versa. In such cases, the transition M-S or S-M will occur while the current is changing, and this is designated as a *changing-current M-S or S-M transition*, both of which are shown in Fig. 15. It will be noted that, for this particular polar telegraph system, the time for the line current to change from one steady-state condition to the other is 33 ms, whereas the duration of the marking or spacing signal is only 22 ms. The net effect on the signal is to shorten it 2 ms, since the transition delay at the start of the signal is 10 ms (subtracts from the signal length) and at the end of the signal is only 8 ms (adds to the signal length). The total current change in either transition is 28 ma (+25 to −3 or −25 to +3); but, if the transmitted signal had been longer than 22 ms, the line current would have exceeded plus or minus 25 ma and at the end of the signal the transition delay

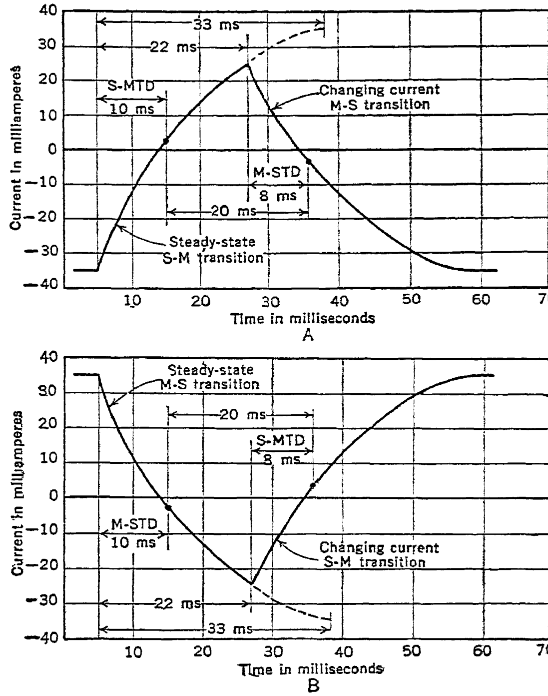

FIG. 15. Changing Current Transitions (Courtesy Bell System)

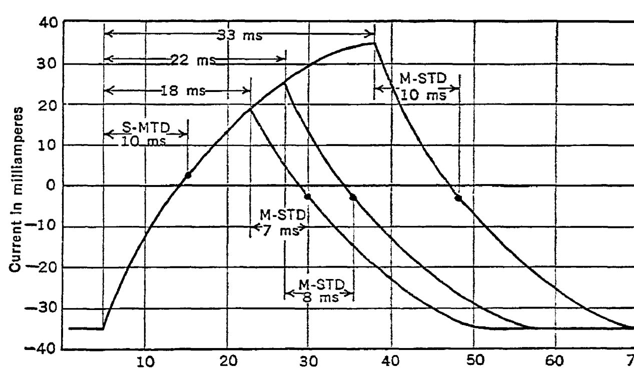

FIG. 16. Characteristic Distortion Effects on Signal Lengths at 40, 60, and 75 Speed Operation (Courtesy Bell System)

would have been greater, up to the limiting delay, resulting from the line current increasing, up to its steady-state value.

Also, if the transmitted signal had been less than 22 ms long, the line current would not have built up to 25 ma by the time the signal ended, and the transition delay at the end of the signal would have been less than for 22 ms. Figure 16 shows characteristic distortion effects on *marking signal length* at 40, 60, and 75 teletypewriter operating speeds. The time required for the line current to change from its maximum negative to positive value, and vice versa, is 33 ms, and the marking signals are 33 ms, 22 ms, and 18 ms long, respectively. Changing current transitions take place for all except the 33 ms signal (40 speed), for which the steady-state current values are just attained. It will be noted that the S-MTD values are the same (10 ms) for all signal lengths, but the M-STD values decrease with decreasing signal length. For similar *spacing signal lengths*, the M-STD values would be the same (10 ms), while the S-MTD values would decrease with decreasing signal length.

The amount of a changing current transition delay is thus dependent on the line current value at the start of the transition, and this line current value depends on the signal length or speed of transmission. The lengths of the received signals are obviously affected by these changing current transitions, and the magnitude of the effect is inversely proportional to the length of the sent signals. Since received short signals are shortened by this effect, the distortion is known as *negative characteristic distortion.* An opposite effect is possible, though not common, and may result, if the line current increases momentarily at the end of each transition to a value exceeding the steady state, owing to circuit characteristics and transient effects. This effect would tend to lengthen the received mark or space signal and would be known as *positive characteristic distortion.*

Some of the principal differences between bias and characteristic distortion are given in Table 1.

Table 1. Differences between Bias and Characteristic Distortion

Type of Distortion Is Affected by	Type of Distortion	
	Bias, ms	Characteristic
1. Length of signal....................................	No	Yes
2. For a given length of signal, whether the signal is marking or spacing.	Yes	No
3. Amount and arrangement of the circuit capacitance, inductance, and resistance.	No, except in neutral operation	Yes
4. Unequal marking and spacing line currents. Change in line current. Change in receiving relay biasing current. Ground potential difference between sending and receiving end.	Yes	No
5. Speed of transmission....................................	No	Yes
6. Usual operating variations, occurring frequently throughout the day, such as voltage fluctuations and relays requiring adjustments.	Yes	Not appreciably

Measurements of systematic distortion, in practice, will usually indicate that both bias and characteristic distortion are present, or the *total measured distortion with the circuit normal is:*

$$S1 \text{ (Total distortion, circuit normal)} = C \text{ (characteristic)} + B \text{ (bias)}$$

and the total measured distortion with the reversed condition is:

$$S_2 \text{ (Total distortion, circuit reversed)} = C \text{ (characteristic)} - B \text{ (bias)}$$

The characteristic component is $(S_1 + S_2)/2$, and the bias component is $(S_1 - S_2)/2$.

Referring to Fig. 17, assume that a repeated signal is being sent over a given circuit, consisting of a marking element 1 unit long and a spacing element 3 units long. If no distortion exists, this signal will be received exactly as sent. However, when measured with the circuit normal, the unit mark is found to be 15 per cent too long, as shown at A. If a measurement is now taken with the line conditions for marking and spacing reversed, this unit mark is found to be 5 per cent too long, as shown at B. By formula, the characteristic distortion C is 10 per cent, and the bias distortion B is 5 per cent, both with signs positive or marking. If, with the line conditions reversed, the unit mark was found to be 5 per cent too short, as shown at B', the characteristic component of the 15 per cent marking distortion (shown at A) would be 5 per cent and the bias component 10 per cent, both positive or marking.

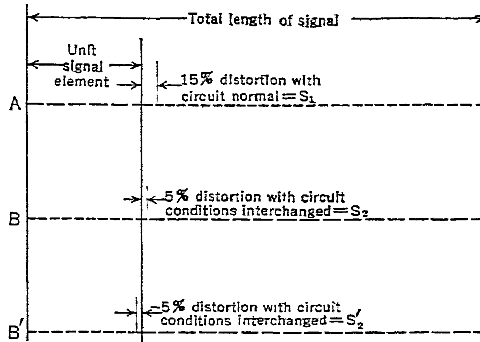
In practice, systematic distortion is usually determined, with the same methods as above, by measuring a repeated signal consisting of a short marking signal followed by a long spacing signal for the normal condition and then a repeated signal consisting of a short spacing signal followed by a long marking signal for the reversed condition.

Though the sign of the final value of characteristic distortion, as computed, is not important, the sign for bias distortion is always important and is indicated.

Fortuitous distortion is caused by such factors as crossfire, power induction, momentary battery fluctuations, line hits, break key operation, and similar effects. This type of distortion acts to alter the received signals by various amounts in an irregular manner. In transmitting miscellaneous signals, the combined effect of all distortion on the displacement of received transitions may result in signals, sometimes called "jitter," because of their rapid variations, or the effect may cause a complete breakdown in signal transmission.

Total distortion, for any given telegraph circuit, is usually a combination of its bias, characteristic, and fortuitous components, and the total distortion determines the quality of telegraph transmission. However, for reasons of design and maintenance, it is usually desirable to determine also the value of these components.

Telegraph distortion is usually given as a percentage of a perfect signal element of unit length. For manual operation, these elements or dots are usually sent at a rate of 12 or 13 dots per second, and their duration (taking into account the dot length interval between each two dots) is about 40 ms. For 60-speed teletypewriter transmission, the signaling rate is equivalent to about 22.7 dots per second, and the duration of the unit signal element, in this case, is 22 ms.



For A and B:

$$\text{Characteristic distortion} = \frac{S_1+S_2}{2} = \frac{15+5}{2} = 10\%$$

$$\text{Bias} = \frac{S_1-S_2}{2} = \frac{15-5}{2} = 5\%$$

For A and B':

$$\text{Characteristic distortion} = \frac{S_1+S_2'}{2} = \frac{15+(-5)}{2} = 5\%$$

$$\text{Bias} = \frac{S_1-S_2'}{2} = \frac{15-(-5)}{2} = 10\%$$

FIG. 17. Characteristic and Bias Distortion (Courtesy Bell System)

TELETYPEWRITER DISTORTION. *Distortion as it affects start-stop teletypewriter signals* must be considered in a somewhat different manner from that for other types of telegraph systems, because teletypewriter system operation differs fundamentally from the operation of other systems. Each teletypewriter operation (the transmission of a character), as previously described in this section, is initiated by the mark-to-space transition at the beginning of the start pulse of the received character. *It is important that each of the succeeding transitions in the character be correctly timed with respect to the first transition. Distortion causes the displacing of succeeding transitions* from their normal positions with respect to the start transition and thus reduces the margin of operation of the teletypewriter.

Bias distortion usually affects both the beginnings and ends of the received signal elements. However, the teletypewriter receiving mechanism starts on a *mark-to-space transition* (for each character received), and this transition is also affected by the same bias, so that succeeding mark-to-space transitions in the character will not be displaced with respect to the start transition, owing to bias. The *space-to-mark transitions* will be displaced with respect to the start transition by an amount equal to the total bias. With *marking bias,* all space-to-mark transitions will be uniformly displaced toward the start transition, whereas with *spacing bias* they will be uniformly displaced away from the start transition.

Characteristic distortion may displace both the received space-to-mark and mark-to-space transitions with respect to the start transition, depending on the signal combination, and recurs for the same signal combination. It may affect both ends of the teletypewriter orientation range, and when miscellaneous characters are received a distinction cannot be made between the characteristic and fortuitous components of the distortion.

Fortuitious distortion displaces miscellaneous received transitions by various amounts in a random manner, regardless of the signal combination. These effects may result in errors in received characters or, if severe, in complete circuit failure.

The total distortion is the displacement of a received transition from its correct time of occurrence, and it is equal to the *algebraic sum of the fortuitous distortion and the systematic distortion.* The *total distortion* determines the margin of operation of the receiving teletypewriter, and it is a *measure of the transmission quality of the received signals*

In teletypewriter operation, not only signal distortion takes place during transmission, but also *mechanical variations occur in the teletypewriter mechanisms* which affect the quality of signal transmission. The mechanical operation of the teletypewriter is described briefly in article 7 of this section, but, for the purpose of discussing distortion as it affects teletypewriter operation, some of the mechanical features of the teletypewriter must be referred to in this article.

Figure 18 shows some of the principal mechanical units of the selecting arrangement of a teletypewriter which determines the instant, in the duration of a given received signal element, when the actual selection takes place. For example, if the signal element being received is marking, the selection must be made at some instant during the time this

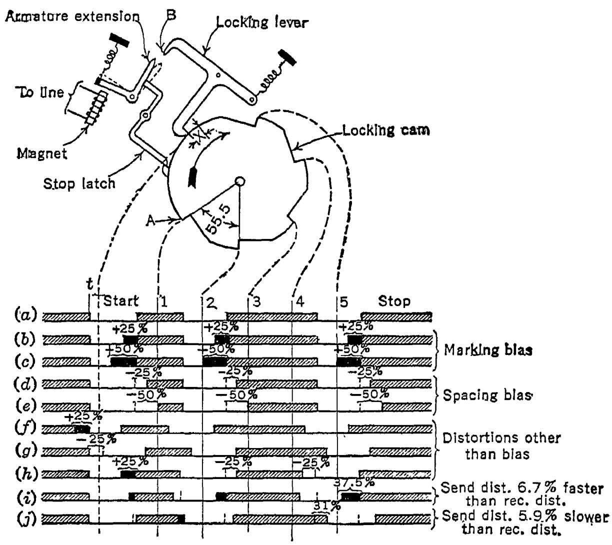


FIG. 18. Distortion Effects on the Selection of Teletypewriter Signals (Courtesy Bell System)

particular element is being received, in order that the code bar, corresponding to this selection, will be properly positioned and the character of which this element is a part will be correctly recorded.

The selecting mechanism includes: (1) the line magnet, which is operated by marks and non-operated by spaces; (2) the armature and armature extension, which are held in the position shown during marking and are released to the dotted position during spacing; (3) the stop latch, which stops the locking cam rotation after each revolution; (4) the locking lever, whose point *B*, during rotation of the locking cam, engages one side or the other of the end of the armature extension, depending on the position of the extension, thereby locking the extension momentarily, which results in the code bars being properly positioned; and (5) the locking cam, which is driven by a friction clutch and which, in a single revolution, causes the locking lever to be positioned five times, once for each of the five signal elements received, during the transmission of one character.

In the idle condition, the received signal is always marking and the magnet is energized, but the selector cam assembly is held stationary by the stop latch until the start pulse (always spacing) is received, when the stop latch is released and the cam starts rotating. The speed of rotation and the starting position of the selector cam assembly are normally so adjusted that the first depression on the locking cam (point *A*) will arrive at the locking lever point (which rides the cam) at about the instant the middle of the first selecting signal element is being received. At this instant the locking lever point (riding the cam) moves into the cam depression, and the lever point *B* moves forward to lock the armature and its extension in one of the two positions they may occupy at that instant. The position of the armature extension determines which of the two line conditions, marking or spacing, will be recorded for the signal element being received, and the position of the corresponding code bar. As the cam rotates, a similar selection takes place as the locking lever enters each of the five depressions on the cam and the corresponding code bars are positioned in succession. The final arrangement of the five code bars results in the selection of one and one only type bar, which, when actuated immediately after completion of one revolution of the locking cam, prints the sent character on paper. The final pulse of the train of signal elements (for each character received) is always marking and somewhat longer (1.42 units) than the preceding six elements (1.0 unit each). During this pulse, the stop arm on the receiving selector cam assembly strikes the stop latch, and the assembly is then held stationary until the next start pulse is received for the next character.

When a start pulse is received, a small increment of time will elapse before the selector cam assembly attains full speed, owing to such factors as the inertia of moving parts and clutch slippage. This delay is compensated for by slightly decreasing the distance between the point at which the locking lever rests on the locking cam, and point A on the cam, from what the distance would be if these factors were not present. This adjustment is represented by the distance x, as shown on the cam surface in Fig. 18.

The teletypewriter is usually equipped with an *orientation or range finder device*, which permits rotating the stop latch with respect to the locking lever, thus changing the time of selection with respect to the start signal. The range finder moves the stop position either forward or backward and has a pointer which moves along a scale, the scale being calibrated in percentage (0 to 120) of a unit signal element. *If the pointer is moved toward the lower-numbered part of the scale, the time between the start and selecting points is reduced* and the time of selection is advanced toward the beginning of each selecting element. *If the pointer is moved toward the higher-numbered part of the scale, the time between the start and selection is lengthened* and the time of selection is moved toward the end of each selecting element. For an ideal teletypewriter, whose mechanism acted instantly and selected exactly the corresponding instant of each signal element, the range finder could be moved over a range of 100 per cent, if perfect signals were received, without causing errors in the received signals, as shown by (*a*) in Fig. 18. Moving the range finder, in effect, shifts the solid vertical lines with respect to the signal elements, and for (*a*) the time of selection could be changed, without error, by ± 50 per cent. Practically, teletypewriter specifications require the overall range to be at least 72 per cent without error for perfect signals.

Distortion in teletypewriter signals, as previously stated, is usually some combination of bias, characteristic, and fortuitous distortion. Theoretically, if bias exceeds 50 per cent in (*c*) and (*e*) of Fig. 18, errors will result in the recorded signal, but, from a practical standpoint, the bias tolerance is of the order of ± 40 per cent with perfect received signals because of allowances that must be made for other variations.

Internal bias may exist in a teletypewriter as the result of such factors as improper adjustment of the line relay or receiving magnet. This bias reduces the orientation margin more when receiving perfect signals than when receiving signals with a bias equal in magnitude but opposite in sign. In order to minimize this bias effect, the range finder should be set at the point where signals having equal marking and spacing bias just cause errors.

The effect of shortening the start pulse by 25 per cent, (*f*) in Fig. 18, is equivalent to lengthening the stop pulse and retarding the points of selection for the succeeding signal elements by the same amount. The effect of shortening the end of the stop pulse by 25 per cent (*g*) is equivalent to advancing the points of selection for the succeeding signal elements by the same amount. The effect of advancing the beginning of element 1 and of retarding the beginning of element 3 and the ending of element 4, as shown by (*h*), will not result in errors in the received character if the range finder is set at its midpoint. The effect of speed variations where the sending machine is faster than the receiving machine is illustrated by (*i*), and where the reverse is true is shown by (*j*). The most probable error, in both cases, would be in the proper selection of element 5, since, in the first condition, part of the stop pulse is received on the 5 position, and, in the second condition, either element 4 is extended into position 5 or element 5 is so delayed in starting that it would not be properly received in its normal position. The effect on teletypewriter margin of speed variation is mostly at one end or the other of the orientation range, depending on the relative speeds of the sending and receiving machines. Though the speed differences in Fig. 18 are shown large for purposes of illustration, actually these differences are normally about $1/2$ per cent or less.

The orientation range limits are determined by the various distortions present for a given teletypewriter circuit. It is not possible to judge these distortions *quantitatively* by the limits obtained when more than one type of distortion exists. However, assuming low machine bias, these limits do give a good indication of the *quality* of the received signals. If the limits are reasonably definite, some fixed distortion, such as bias or speed difference, is generally present, while, if there is a certain range at each limit over which certain characters are consistently in error, characteristic distortion is indicated. If there is a range over which errors occur, but not consistently on certain characters, fortuitous distortion is most likely present.

TELEGRAPH SYSTEMS

By John D. Taylor

Telegraph systems employ various types of telegraph equipment and connecting mediums and various methods of transmission. Direct-current telegraph systems are used extensively in land wire operation and in conjunction with radio channels, while low- and high-frequency carrier telegraph systems utilize both land wire lines and radio channels as mediums of transmission. Radio telegraph systems make use of radio channels between radio transmitting and receiving equipments and usually wire line extensions between such equipments and the telegraph circuit terminals.

6. DIRECT-CURRENT SYSTEMS

Open-wire telegraph channels are generally obtained by using bare telegraph wires. They may also be provided by simplexing or compositing open-wire telephone circuits, as shown in Figs. 1 and 2, respectively.

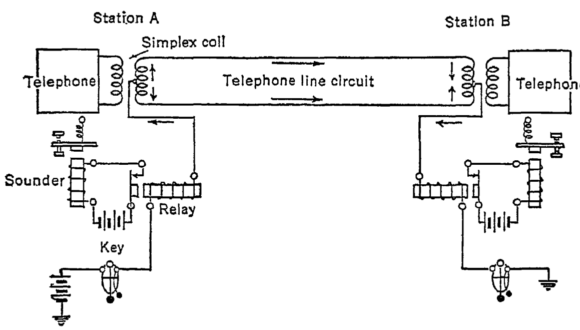

Fig. 1. Telegraph Circuit on Simplexed Telephone Circuit (Courtesy Bell System)

The simplex arrangement is shown in Fig. 1. The arrows represent the telegraph line currents, which divide equally at the junction of the two halves of the line windings of the repeating coil at A and travel over both line wires of the telephone circuit to the repeating coil at B, where they again combine at the junction of the two halves of this coil before passing to Station B telegraph equipment. This equal division of the current is possible only if the two halves of the line side of each coil are identical electrically and the two line wires have identical electrical characteristics. To the extent that these conditions are not met, the current will not divide or combine equally at the coils and a residual induced current will flow in the drop windings of the repeating coils, causing interference (*Morse thump*) in the telephone circuit. In practice, Morse thump becomes objectionable only when faults occur.

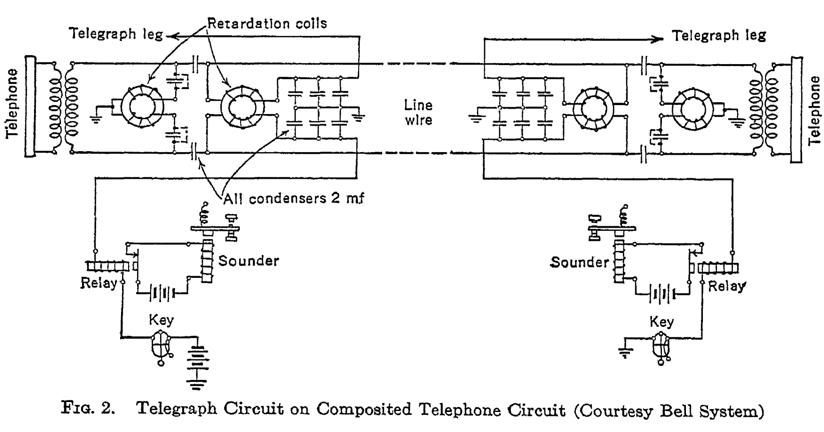

Fig. 2. Telegraph Circuit on Composited Telephone Circuit (Courtesy Bell System)

The composite arrangement is shown in Fig. 2. One grounded telegraph channel is obtained from each line wire of the telephone circuit by connecting composite sets at each terminal of the circuit in such a manner as to maintain the balance of the circuit and avoid excessive telegraph current flow in the line and drop windings of the repeating coils, which current would cause Morse thump. The equipment on the two sides of the circuit must be well balanced and the line wires must be closely identical electrically to prevent telegraph signals from interfering with the telephone service. With this arrangement each telegraph channel is independent of the other and is usually so operated.

The composite set has a retard coil in series with the telegraph leg and capacitance between the leg and ground to prevent sudden changes in signal current value being impressed on the line wires and causing current surges (clicks) in the telephone circuit. Also, the series condensers in the telephone circuit prevent direct current from reaching the repeating coils and assist in reducing clicks, while the retard coil-condenser bridge on the drop side of the series condensers functions to prevent *crossfire,* a condition where the telegraph signals on one wire of the circuit induce potentials on the other wire that interfere with the telegraph signals over it.

A schematic diagram of a neutral telegraph circuit is shown in one form in Fig. 6*a*, article 4. This circuit operates with current flowing in either direction for the marking condition and no current flowing for the spacing condition. Both sending and receiving relays usually operate local sounder circuits, which produce the recognized audible dots and dashes of the Morse or Continental telegraph codes by the armature of the sounder striking its front and back contacts, corresponding to the marking and spacing conditions. Neutral telegraph operation is also employed in teletypewriter and teleprinter service on many of the shorter circuits.

The receiving station may break the circuit (stop the transmission of signals) by opening the sending key, which silences both sending and receiving sounders and indicates to the sending station that the receiving station desires to send signals.

A number of intermediate stations may be connected in series in the single wire line, the number depending on the sensitivity of the line relays, the battery voltages applied, and line conditions, such as resistance and leakage.

The single line repeater, a schematic diagram of which is shown in Fig. 3, may be employed over long single wire circuits. This repeater functions to receive weak signals from the line from either direction and repeat them with normal voltage to the line in the other direction. The signal transmission circuit through the repeater is shown by heavy lines. Operation of the *west station key causes relay A to repeat signals to the east circuit,* and operation of the *east station key causes relay A′ to repeat signals to the west circuit.*

Opening either station key interrupts current flow in both east and west lines, and, unless auxiliary circuits were provided in the repeater,

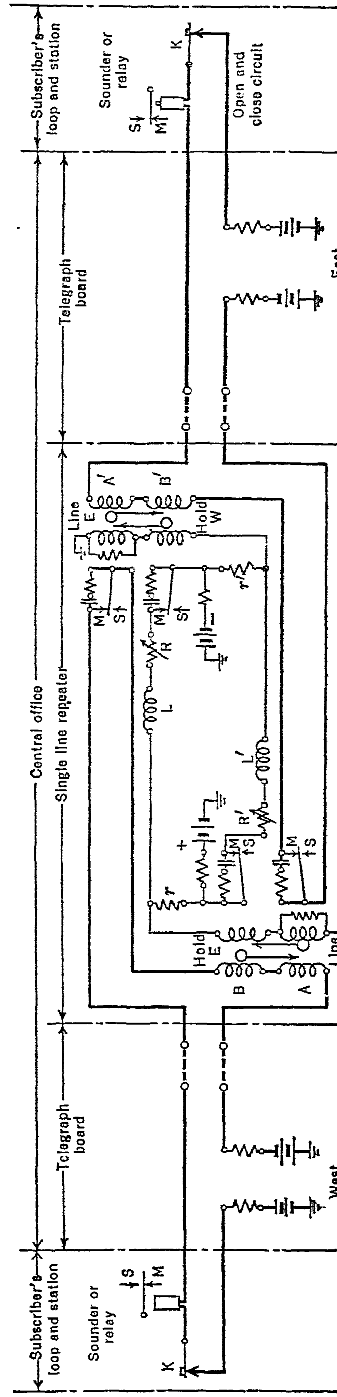

FIG. 3. Single Line Repeater Using Polar Relays—Connected to Open and Close Type Circuits (Courtesy Bell System)

both circuits would open and remain open, and the system would be inoperative. To prevent this condition, a biasing and a locking circuit are provided (see Fig. 3) for each direction of transmission. Each biasing circuit operates the armatures of the line and control relays, with which it is associated, to spacing, when the circuit through the line windings of these relays is opened during the transmission of signals. However, the locking circuit is so designed that, for *east-to-west transmission* with the east circuit open, the biasing current reverses direction in the biasing windings of the line west relays and the armatures of these relays are held on marking, thus maintaining the east circuit closed at the repeater, regardless of the position of the east station key. The locking circuit functions oppositely for *west-to-east transmission.*

A break feature (see Fig. 3) is provided, so that the receiving station may interrupt the sending station, as desired, by opening the receiving-station key.

The one-way polar telegraph circuit, shown in Fig. 9, article 4, usually employs −130 volts for marking and +130 volts for spacing signals to a distant polar receiving relay. This circuit operates from the central office to an outlying point and is used in certain cases where a one-way service only is required, such as in the transmission of news copy.

Two-path polar operation consists essentially of two one-way polar circuits operating in opposite directions.

Polarential operation provides for true polar operation from the central office to an outlying point and a modified polar operation in the opposite direction. The advantages of polar over neutral operation (particularly self-compensation of line leakage) are thus obtained with relatively simple equipment arrangements at the outlying point.

Figure 4 shows a type A polarential telegraph circuit, in which true polar signals are transmitted from the central office, and ground and −130 volt battery (in series with a

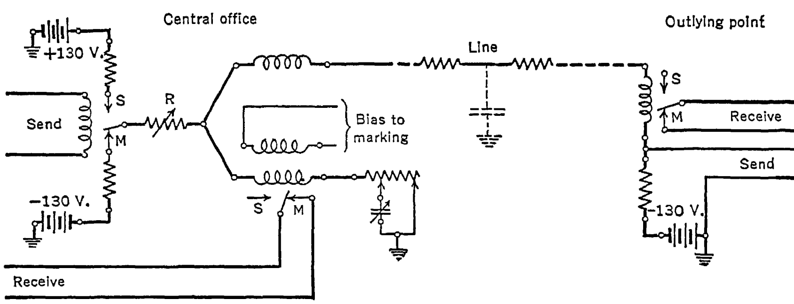

FIG. 4. Type A Polarential Telegraph Circuit (Courtesy Bell System)

total added resistance of 990 ohms) are applied in transmitting marks and spaces, respectively, from the outlying point. In this case a repeater is not used at the outlying point, as is more commonly done in type A operation.

During transmission from the central office, the circuit is closed to a direct ground at the outlying point through the sending contacts (in this case, the contacts of a teletypewriter) while the central-office receiving relay is held on its marking contact by a marking biasing current. This current is adjusted to one-half the effective spacing current when a spacing signal is being sent from the outlying point. During transmission from the outlying point, the ground, applied for a marking signal, has no effect on the central-office receiving relay, provided that the line and artificial line are balanced at the duplex set, and this relay is held on its marking contact, while negative battery, applied through the resistance for a spacing signal, produces an effective spacing current in the central-office relay. This current is the net result of current flowing in the central-office relay windings from (1) the outlying-point battery and (2) the central-office battery, due to the duplex balance being upset by the 990-ohm resistance in series with the outlying-point battery.

The variable resistance R at the central office is adjusted so that the spacing line battery at the outlying point is higher than the potential applied to the apex of the duplex at the central office, thus insuring line current reversal when a spacing signal is transmitted from the outlying point and home copy if a teletypewriter is employed.

Figure 5 shows a simplified type B polarential telegraph circuit, in which true polar signals are transmitted from the central office, and ground and +130 volt battery are used in transmitting marks and spaces, respectively, from the outlying point. This circuit is more nearly self-compensating for line leakage than the type A circuit.

When transmitting from the outlying point over a dry (no leakage) line, the marking line current does not affect the central-office receiving relay, if the balancing network at the central office exactly balances the line electrically.

For a spacing signal from the outlying point, aiding positive battery, applied to the line, results in an effective spacing current $E/(R_1 + R_2)$, where E is the outlying battery potential and $R_1 + R_2 = R_L$ are as shown in Fig. 5. The marking biasing current in the central-office receiving relay is adjusted to a value equal to $E/2R_L$.

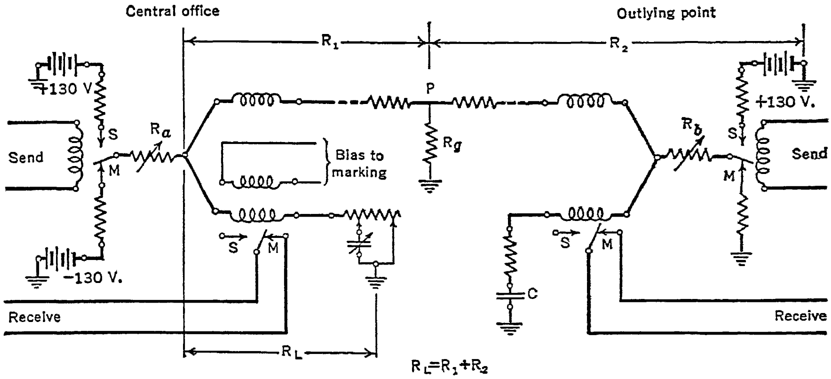

FIG. 5. Type B Polarential Telegraph Circuit (Courtesy Bell System)

During transmission over a *wet line* with leakage R_g (shown at P on the line), R_a (at the central office) may be adjusted to maintain the potential at the apex of the relay windings at the same value as for the dry condition when transmitting a spacing signal from the outlying point. Thus, as a result of the compensating effects of the R_a adjustment, the received signals at the central office are not affected. If R_1 is greater than $2R_2$, complete leakage compensation is not possible, unless the central-office battery voltages are made higher than the outlying battery voltage or other compensation is provided. For this purpose, R_b is provided for maintaining R_1 less than $2R_2$.

The bridge arm, with a resistance in series with condenser C, is provided at the outlying point to neutralize reverse current surges through the receiving relay winding when the outlying sending relay armature moves from space to mark. Such surges would tend to cause false breaks (kick off) of the receiving relay and mutilation of the home copy.

Metallic telegraph circuit operation generally utilizes telegraph cable pairs or open wires, or, when telephone facilities are involved, it is customary to composite them to secure the necessary telegraph channels. The avoidance of interference between telegraph

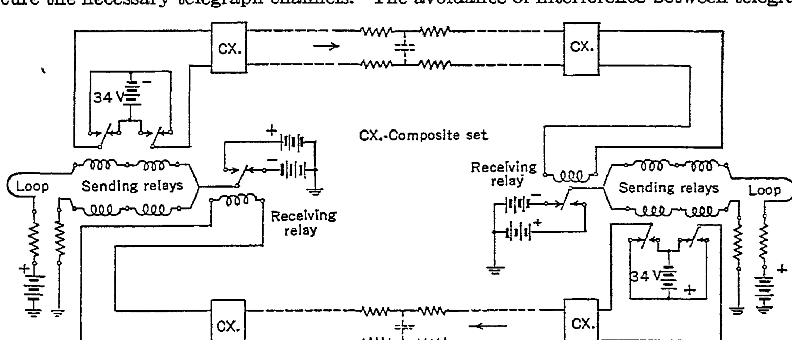

FIG. 6. Four-wire Metallic Telegraph Circuit (Courtesy Bell System)

and telephone circuits and of crossfire between telegraph circuits in cables generally requires that the telegraph current values be comparable to those on the telephone circuits and that metallic circuit operation only be employed. Such operation may employ two wires or four wires, pairs, side circuits, or phantoms.

In four-wire operation, as shown in Fig. 6, separate paths are employed for the two directions of transmission, and artificial balancing lines are not required, as in two-wire operation. These differences generally improve transmission over that of the two-wire arrangement, since balance between the conductors and an artificial line is not a factor. Owing to the use of four composited channels, as compared to two such channels for two-wire operation, the possibilities for conductor and equipment troubles are greater with four-wire operation. In general, four-wire telegraph circuits may be superposed on two-wire telephone circuits of lengths ranging from about 500 to 1000 miles, or on longer four-wire telephone circuits. Very long four-wire telegraph circuits are not composited throughout their entire length because of prohibitive low-frequency delay distortion introduced by the composite sets.

Duplex systems may be of the earlier *bridge* type or the later, more commonly used differential type. Both these systems employ arrangements of telegraph apparatus for terminating telegraph circuits at the central office which permit the simultaneous transmission of telegraph signals in both directions over a single wire with ground or metallic return and without the signals in one direction interfering with those in the opposite direction.

Since bridge polar duplex operation is rapidly being discontinued and is expected to be of little interest in the future, its description is omitted from this handbook. However, occasional reference is made to it for purposes of comparison in the following paragraphs, which relate to differential polar duplex operation.

Figure 7 shows schematically the *differential type* set, arranged for full duplex operation. The receiving relay has two equal windings, one being connected in the real line and the

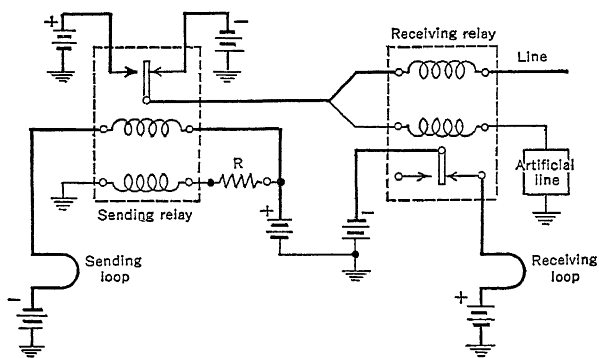

FIG. 7. Terminal Differential Duplex Set Arranged for Full Duplex Service (Courtesy Bell System)

other *differentially* in the artificial line circuit. Sending current from the station battery divides at the apex of the receiving relay windings and flows equally in the real and in the artificial line circuits, assuming these are balanced. Since the receiving relay windings are differentially connected, the station receiving relay is not affected by this current flow. However, current from a distant station does operate the receiving relay at the home station, since it flows through the windings of this relay in a series aiding relation from the line through the balanced arms and the artificial line to ground. Similarly, the receiving relay operates at the distant station from incoming line current from the home station. Under these conditions full duplex operation is attained.

In the differential-type duplex set, the sending relay has both an operating and a biasing winding. With the sending loop key closed, the magnetic fields produced by these two windings are opposing, but a resistance R in series with the biasing winding limits its current to about half that in the operating winding and the armature is accordingly held to the marking contact (negative). When the loop key is opened, only the biasing winding is effective and the armature moves to its spacing contact (positive).

Duplex systems, employing the ground for one side of the circuit, are affected by variations in line constants due to temperature and humidity changes, but the balancing artificial lines associated with each duplex set usually may be adjusted to compensate for such variations. Duplex systems provide all the advantages of polar operation in both directions of transmission, but they also necessitate higher-grade supervision and greater maintenance than some of the simpler systems, such as in neutral operation.

The differential duplex system has largely superseded the older bridge duplex system because of several advantages of the differential over the bridge type. The differential system includes a simple differential duplex repeater for use at intermediate points on long telegraph circuits; in the bridge system, two terminal sets, requiring considerably more equipment, must be used at such points. Intermediate differential repeaters may be employed on circuits having bridge polar type sets at their terminals, or bridge polar intermediate repeaters may be used on circuits having terminal differential sets at their terminals.

One of the most important advantages of the differential over the bridge system is the ability of its polar relays to respond rapidly to signals, particularly at the higher operating speeds. These relays, in addition to being more sensitive than the relays ordinarily used in bridge polar sets, have a special third winding which forms part of a *vibrating circuit* and materially increases the relay response. The vibrating circuit, shown in Fig. 8, includes the third winding of the receiving relay, whose armature is connected to the midpoint of the winding. One outer terminal of this winding is grounded through a condenser, and the other outer terminal is grounded through a resistance. Batteries of opposite polarity are connected between ground and the relay contacts.

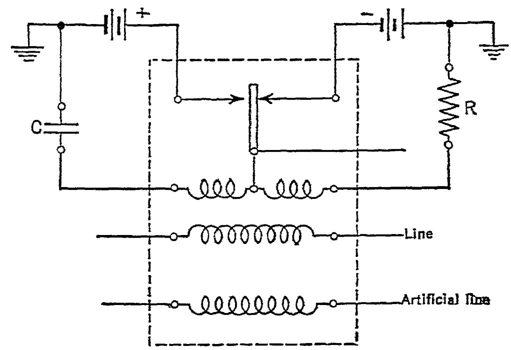

FIG. 8. Vibrating Circuit of Differential Relay (Courtesy Bell System)

Assuming that no current is flowing in either the line or artificial line windings of the receiving relay, the relay armature moves back and forth continually between the two contacts. However, with current flowing in the line and artificial line windings in normal operation, the armature does not vibrate freely as before, but the vibrating circuit aids in speeding up the armature action, as the received line signals cause it to move between its marking and spacing contacts. The free speed of vibration is governed by the parameters C and R, which are usually adjusted so that the frequency of vibrations is slightly greater than the line signal frequency.

Half duplex operation, which provides for operation in only one direction at a time, requires a means for breaking the circuit from either terminal and for utilizing one loop for both sending and receiving signals. Either the bridge- or differential-type system may be employed for this service, but each requires a different circuit arrangement of the duplex set from that required for full duplex operation. In the bridge-type system, the principal additions required are a control relay, holding coil for the pole changing relay, and a repeating sounder; for the differential-type system a control, break, and neutral relay are added. The change from full duplex to half duplex, or vice versa, for either system is readily accomplished by means of switches provided with the duplex sets.

Figure 9 shows a schematic diagram of a terminal differential duplex arranged for half duplex service. The control relay functions on incoming signals to prevent the sending

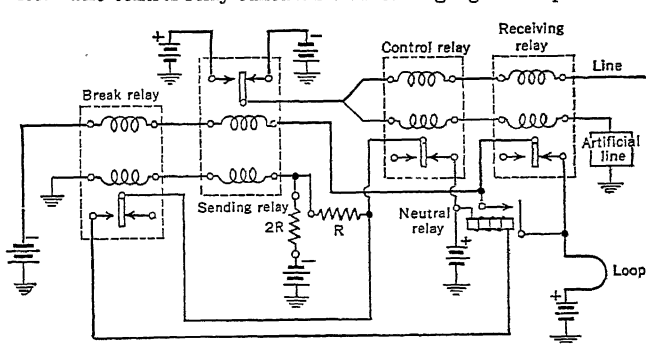

FIG. 9. Terminal Differential Duplex Set Arranged for Half Duplex Service (Courtesy Bell System)

relay from operating when the loop is opened and closed by the receiving relay. Two oppositely poled batteries are connected to the biasing winding of the sending and break relays, and the resistances R and $2R$ are so adjusted that, with the control relay contact closed, the positive (spacing) battery will be in control and the sending relay will operate in the same manner as in full duplex operation.

When signals are being received from the line, a marking signal closes the loop, and current flows from the loop through the sending relay operating winding. When a spacing signal opens the local loop at the receiving relay contacts, no current can flow through the sending relay operating winding. However, the control relay also operates in unison with the receiving relay (since their windings are in series), opening the positive (spacing) battery at its armature contact and permitting negative (marking) battery to take control of the sending and break relays through resistance $2R$. Thus, the sending relay armature is held on its marking contact for either incoming marking or spacing signals.

If the local operator wishes to *break* the circuit while incoming signals are being received, the local loop circuit is first opened by opening the sending key. The next spacing signal received with the loop open would be ineffective, since the signal would normally open the loop at the receiving relay contact. The next marking signal received with the loop open would operate the receiving and control relays, and positive (spacing) battery would be applied to the biasing windings of the sending and break relays through the control relay armature contact and resistance R. Since there is no current flowing through the operating windings of the sending and break relays with the loop key open, both relays operate to spacing. Positive battery is then applied to the line through the sending relay spacing contact, which results in a break signal to the distant operator.

The break relay functions to insure a continuous break signal to the line as long as the local loop key is open, regardless of subsequent signals received from the line. Assuming that one of these signals is a spacing signal, the receiving and control relay contacts will open, which would permit negative (marking) battery to take control of the sending and break relays and marking battery to be applied to the line through the sending relay marking contact if a secondary circuit was not provided. Marking battery applied to the line would interrupt the break signal. However, positive current is maintained through the biasing windings of the sending and break relays as soon as the break relay operates to spacing (which it would do on the preceding incoming marking signal), since positive battery is then applied through the neutral relay, spacing contact of the break relay, resistance R, and the biasing windings of the sending and break relays to ground.

The neutral relay in this secondary circuit functions to prevent the possibility of the circuit becoming inoperative owing to the sending and break relays at both terminals becoming simultaneously operated to spacing. Under this condition, neither operator could regain control of the circuit, since the loop circuits at both terminals would be open at the receiving relay contacts. Operation of the neutral relay which occurs when the control relay is opened after the break relay is operated to spacing short-circuits the receiving relay contacts, so that the sending and break relays will be operated to their marking contacts when the associated loop key is closed.

The upset duplex method of operation between a central office and an outlying point employs polar transmission generally from the central office to the outlying point and

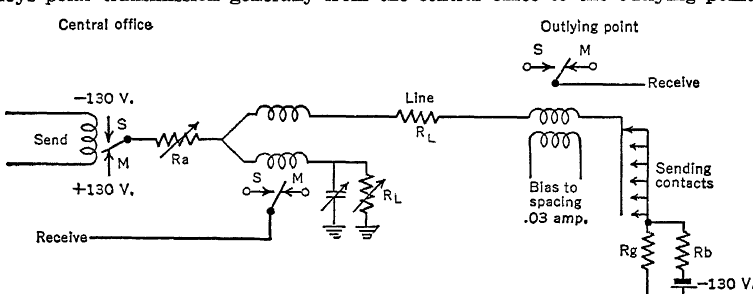

FIG. 10. The Upset Duplex Method in Telegraph Operation (Courtesy Bell System)

neutral transmission in the opposite direction. Transmission in either direction is affected by line leakage, and transmission to the central office is subject, in general, to the same limitations as for a neutral circuit employing a single line repeater. Because of polar operation in one direction and the application of wave-shaping units at the outlying point only, this method offers an improvement in operation over the neutral circuit with a single line repeater.

Figure 10 shows the upset method of operation, employing a duplex set, arranged for half duplex operation at the central office and a teletypewriter (neutral operation) at the outlying point. The teletypewriter normally operates on 60 ma of line current in an open and close loop circuit, and its line relay requires a spacing biasing current of 30 ma. The algebraic sum of the marking and spacing line currents while sending to the outlying point must equal 60 ma, in order to meet the requirements for operation under the upset method. Also, when receiving at the central office (neglecting the effects of series inductance and bridged capacitance on the line), the effective spacing current in the receiving relay with the outlying point key open must equal the effective marking current in this relay with the outlying point key closed. In practice, it is generally necessary to adjust these spacing and marking currents in the receiving relay, since the inductance and capacitance effects cause unsymmetrical wave shapes and cannot be neglected.

The **duplex repeater** is employed at intermediate points in long circuits to maintain proper operating currents in duplex telegraph systems. The distance between repeater points depends on a number of fixed and variable factors, such as the type of line facilities, interference from extraneous sources, line leakage, coordination of transmission levels, types and quantities of central-office equipment involved, line operating speeds, and maintenance considerations. Figure 11 shows schematically an intermediate differential duplex repeater circuit for grounded operation.

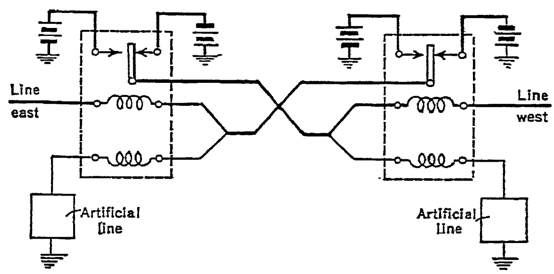

Fig. 11. Schematic of Intermediate Differential Duplex Repeater (Courtesy Bell System)

For 60-speed start-stop teletypewriter operation, the maximum lengths of single composited line sections of 104 mil and 165 mil copper line wire, over which it should be practicable to operate either the differential duplex or two-path polar systems without intermediate repeaters, will be roughly within the range of 170 to 300 miles and 250 to 450 miles, respectively. For any given section, the maximum length depends on a number of variables, such as the types and quantity of terminal and intermediate equipment used, the line conditions, and maintenance schedules and type of personnel.

Where thump, flutter, and crossfire considerations permit, 60-speed differential duplex or two-path polar operation is usually feasible in cable over a composited 13 or 16 gage wire with crossfire neutralizing networks or over a 19 gage simplexed pair or phantom for distances up to about 100 miles.

The quadruplex system permits four messages, two in each direction, to be transmitted simultaneously over a single grounded circuit. One transmission in each direction is secured in the same manner as has been previously described under the heading Duplex Systems, article 6. These two channels and the associated sending and receiving apparatus are called the *polar side of the quad.* The two additional transmissions (one in each direction) are obtained by varying the strength irrespective of the direction of the line current, and by receiving the signals, thus sent, on a neutral relay, which responds to impulses of large amplitude irrespective of polarity but remains unaffected by impulses of smaller amplitude. These two channels and the associated equipment are designated the *neutral or common side of the quad.*

The schematic circuit of the differential quadruplex is shown in Fig. 12.

Normally a resistance is in series with the pole-changing relay, and a leak to ground is connected to the line, to preserve the proper ratio between the marking and spacing current of the common side. When this resistance is short-circuited, and the leak resistance removed by the contacts of the transmitting relay, in response to the operation of a sending key which controls it, the line current is increased to its maximum value. The neutral relays in the receiving circuits are adjusted so that they will respond to the stronger signaling currents but will be unaffected by the weaker ones. Momentary release of the neutral relay at the instant the direction of line current is reversed by operation of the distant pole-changing relay is prevented by the discharge of a condenser through a special holding winding.

The normal operating currents in a quadruplex set are 10 to 20 ma for the polar relays and 30 to 60 ma for the neutral relays. A ratio of 1 : 3 or 1 : 4 between the spacing and marking current is required to insure good operation.

Although employed quite extensively at one time, the quadruplex system is now used but little, because it was found impossible to maintain uninterrupted operation of the

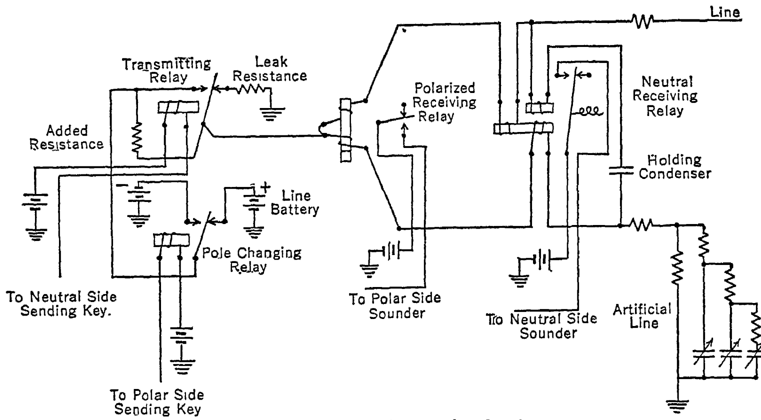

FIG. 12. Differential Quadruplex Set

common side during periods when damp weather or other causes lowered the line insulation sufficiently to reduce the ratio between the operating and non-operating currents.

The common side of a quad is also more susceptible to interruption by inductive interference from adjacent circuits.

The bridge principle, described under duplex systems, may also be utilized in a quadruplex system.

7. AUTOMATIC TELEGRAPH SYSTEMS

Start-stop systems, employing the *teletypewriter* and *teleprinter* equipment (similar type units of the Bell System and Western Union Co., respectively) for sending and receiving telegraph signals, are so named because of the method of operation. This equipment usually employs the seven-element code, of which the first element is a start pulse, the seventh element is a stop pulse, and the other five elements represent the character. Thus, the sending and receiving units are synchronized after each group of seven pulses (elements) is received, constituting the transmission of a character.

Usually, the teletypewriter or teleprinter installation at a subscriber location consists of an electromechanical unit, with or without a keyboard resembling that of a standard typewriter, and having a typing mechanism for printing received messages on a paper page or tape. At receiving-only stations, the sending keyboard is not required. In some cases, the subscriber may perforate a tape, using a *keyboard-equipped perforator*, the perforations representing coded characters of the desired message. This tape may at the same time or later be passed through a *tape transmitter*, which, being connected to the line, sends pulses over the line corresponding to the characters of the message. Also, incoming code pulses may be received by a *reperforating machine*, which perforates a tape with the five-element code representing the received characters. Figure 13 shows a sample of perforated tape.

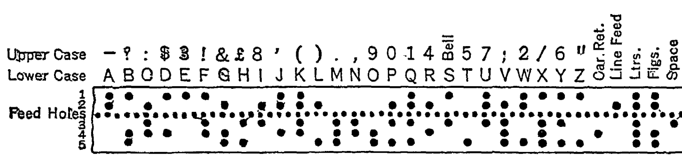

FIG. 13. Teletypewriter Code Perforated in Tape

The teletypewriter sending unit now in general use consists principally of a keyboard with key levers extending over five notched selector bars, and a start-stop mechanism of driving and driven shaft, universal bar, cams, eccentrics, levers, and pawls. Figure 14 shows the general mechanical arrangement of the start-stop mechanism.

Figure 15 shows the details of the key lever, which, when pressed down, positions the selector bar, which, in turn, moves the *locking latch head* forward or back. This latch will either prevent the *contact lever* from closing the *transmitter contacts* (latch head forward) or permit the contact lever to close these contacts (latch head back), *when the associated* *selector cam depression arrives at the proper projection on the contact lever.* Thus, as a key lever is depressed to send a particular character, the *universal bar* is moved down, causing the mechanism (Fig. 14) to function and the selector cams to start rotating. At the same time, the five selector bars and locking latches are positioned by the key lever, and each

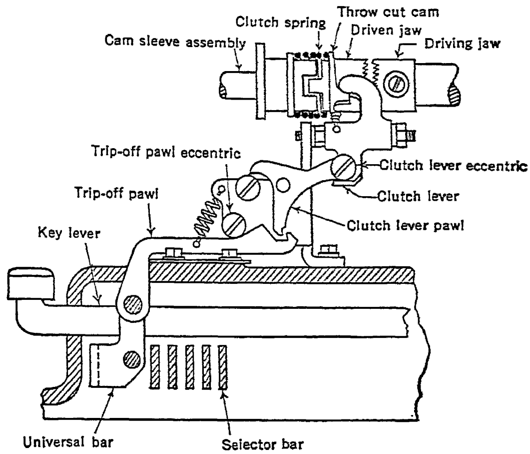

FIG. 14. Start-stop Mechanism of Teletypewriter Sending Unit (Courtesy Bell System)

of the five contact levers is either locked or left unlocked, so that, as the selector cams make one revolution, each set of transmitter contacts does not close or does close. If the contacts do not close, a spacing signal (no current) is sent over the line, and if the contacts close a marking signal (current) is sent over the line.

Release of the key lever after it has been fully depressed causes the driven jaw to be thrown out of engagement with the driving jaw upon completion of one revolution of the

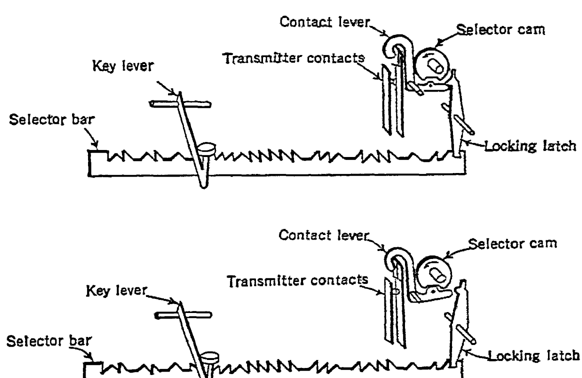

FIG. 15. Positioning of Transmitter Contacts by Operating Key Lever of Teletypewriter Sending Unit (Courtesy Bell System)

cams, and the rotating movement stops. The mechanism is now ready to send the next character.

The teletypewriter receiving mechanism now generally employs a single selector magnet and a group of six rotating cams, so spaced angularly on a shaft that each cam functions at the instant the corresponding signal pulse is being received.

Figure 16 shows the mechanical arrangement for translating the selector magnet operations into the positioning of the code bars. When the open pulse is received, the magnet armature releases. This operates a latch (not shown), allowing the cam shaft to rotate. The spacing of the cams on the shaft is such that, as the first of the five pulses of the code signal is being received, the first cam engages the projection on the code bar operating lever associated with the first code bar and rotates it slightly in a counterclockwise direction. Assuming that the received No. 1 pulse is marking, the armature will be operated, and the movement of the code bar operating lever will lift the *sword* and cause its upper right-hand projection to strike the right-hand end of the armature extension. The sword will then rotate in a clockwise direction on its pivot at *A*, so that, when the selector cam clears the code bar operating lever and allows the latter's spring to return it to normal, the sword point will be forced against the left-hand projection of the *T lever*, rotating it in a counterclockwise direction and moving the No. 1 code bar to the right. If the received No. 1 pulse had been spacing, this code bar would have been moved to the left.

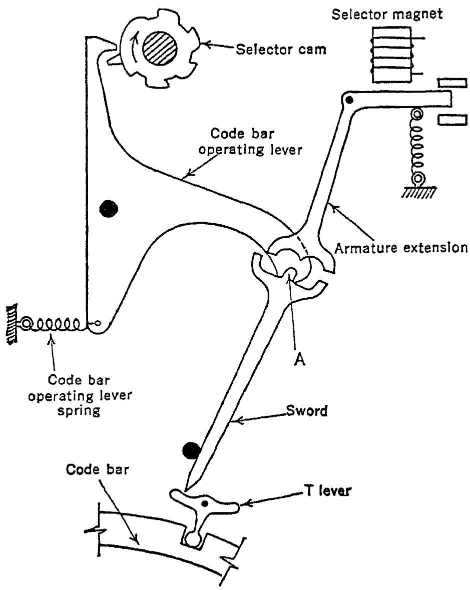

FIG. 16. Teletypewriter Receiving Selector Mechanism, Illustrating Positioning of Code Bars (Courtesy Bell System)

In like manner, the other four code bars are properly positioned and the sixth cam releases a clutch, allowing the printing mechanism to operate, as shown in Fig. 17. The five code bars have been positioned to the right or left in accordance with the five code pulses received, which represent a particular character. The code bar slots will then line up so that the pull bar for that character will center in these and only these slots and will engage the main bail. This bail is then moved forward, causing the pull bar to move forward and the type bar head to be driven against the paper or tape in the teletypewriter.

After completion of one revolution of the rotating cams, the rotating movement stops, owing to action of the stopping mechanism, and the teletypewriter is then ready to receive the pulses for the next character.

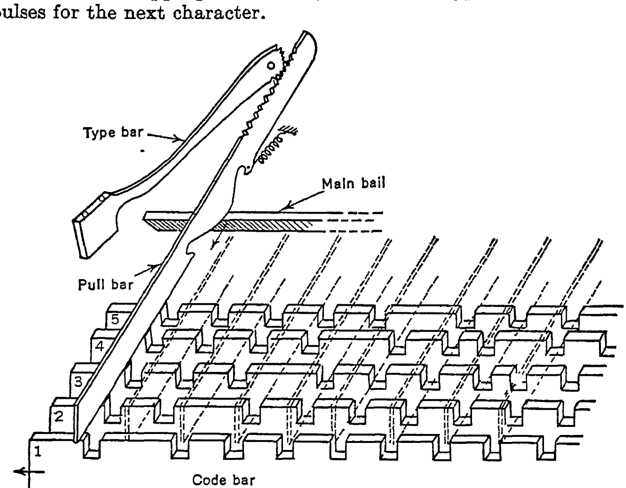

FIG. 17. Teletypewriter Receiving Mechanism, Illustrating Selection of Symbol (Courtesy Bell System)

Power for mechanically operating both the teletypewriter and the teleprinter is generally secured from the 110-volt commercial supply at their location, these machines being equipped with either d-c motors, a-c series motors, or a-c synchronous motors. The last type of motor is available for use with 50- or 60-cycle power and is the preferable type where the power frequency has the usual close regulation. The power consumption is about 115 watts at 115 volts.

The line signaling circuit usually requires about 60 to 70 ma of direct current for magnet and line relay operation, and the remote control circuit (if provided) about 50 ma.

The regenerative repeater may be employed (1) at intermediate points in long commercial or private line teletypewriter circuits, (2) at points where it is desirable to divide a teletypewriter circuit into several sections because of possible distortion from a large number of sending stations connected to the circuit, and (3) at teletypewriter exchanges for switched connections and for furnishing service to subscriber teletypewriter loops having a relatively high transmission coefficient.

Start-stop teletypewriter signals, composed of one start and five signal pulses of equal unit length and one stop pulse of 1.42 units length (teleprinter signals are composed of seven pulses of equal unit length), are sent from the originating motor-driven distributor or other sending device with mechanical precision. However, as these signals progress over a telegraph circuit several telegraph repeater sections long, the distortion accumulates section by section, so that, unless corrected, the distorted signals received at the circuit terminal would result in message errors.

The regenerative repeater located at one or more intermediate points in a long teletypewriter circuit, as required, retimes and reshapes the received distorted signal pulses and retransmits them, as though they were directly from the originating machine.

Figure 18 shows a schematic of the circuit for one two-way regenerative repeater arranged to repeat signals from east to west or west to east, but not in both directions

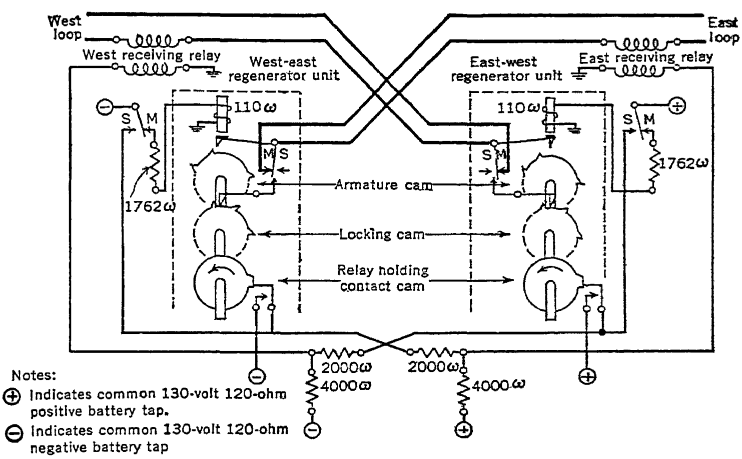

FIG. 18. Schematic Circuit of the Regenerative Repeater, Arranged for Half-duplex Operation (Courtesy Bell System)

simultaneously. For full duplex operation, the circuit requires two one-way regenerative repeaters. The loop circuits are arranged to receive and transmit neutral signals from the terminal duplex telegraph repeaters between which the regenerative repeater is usually connected. Each loop termination contains the line winding of a polar receiving relay and the sending contacts of a regenerator unit in series. Each receiving relay armature controls a local battery circuit to energize the magnet of the regenerator unit through the marking contact. When the receiving relay armature moves to its spacing contact, the receiving relay armature in the opposite loop is locked to marking.

The regenerator unit has both sending and holding contacts, the latter being controlled by a cam in such a way that they are open only when the cam assembly is near the stop position. During retransmission of the signal elements of a complete character, the holding contacts, being closed, apply battery of opposite polarity through a potentiometer to the receiving relay biasing winding of the loop, into which the signals are being retransmitted. Reversal of current in this biasing winding holds its armature to marking, thus preventing repetition of the retransmitted signal back through the regenerative repeater toward the originating terminal.

Since the length of the retransmitted signals is timed mechanically by the locking cam, the outgoing signal length is normally independent of the incoming signal length. As long as that part of the received pulse corresponding in time to the release of the magnet armature is not affected by distortion, the outgoing pulse will be undistorted.

The multiplex system, a development of 1915, functions to divide the line facility time of a given telegraph channel (between two terminal points) among several telegraph circuits. The usual manually operated teleprinter (or teletypewriter) circuit line signal speed is inherently much less than the speed capabilities of a high-grade telegraph trunk. To utilize such capabilities efficiently, the trunk time may be allotted among two, three, four, or more telegraph circuits on a full duplex basis. When four transmitting and four receiving terminals are operating simultaneously at 66 words per minute over one trunk line, this line is handling 528 (8 × 66) words per minute, thus enormously increasing its efficiency over single teleprinter circuit operation. One multiplex channel may be operated in each direction over a duplexed circuit or carrier channel, each of which provides two separate telegraph paths. This system, because of its high efficiency of operation, is generally employed over heavily loaded telegraph trunk lines.

A code is used in which every character consists of 5 equal-length impulses, each of which may be either positive or negative, thus yielding 32 separate combinations. The code as it appears in a perforated transmitting tape is shown in Fig. 13. The black dots, representing perforations in the tape, correspond to marking impulses, and the blank spaces correspond to spacing impulses. One of the 32 possible combinations, 5 positive or spacing impulses in succession, has no character assigned to it, and is transmitted continuously when no messages are being sent. Two combinations, designated "letters" and "figures," are used respectively to cause the printer to print lower-case or upper-case characters, thereby increasing the total number of characters that may be transmitted.

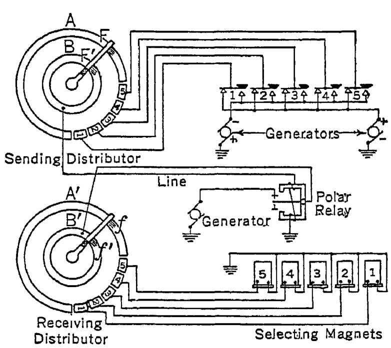

FIG. 19. Schematic Diagram of the Multiplex System

A schematic of this system is shown in Fig. 19. Each of five contacting levers in a transmitter is connected to correspondingly numbered equal-length segments of a distributor, which are successively connected to the line through the rotating brushes F, F' and an unsegmented collector ring B. During the time the brushes are traversing another part of the distributor, the transmitter levers are positioned to correspond with perforations in the transmitting tape. After the brushes have passed over those segments and transmitted the signal combination to the line the tape is advanced to the next set of perforations and the cycle of operations is repeated. Auxiliary or local segments (not shown) in the distributor are used to step the transmitter ahead at the proper point in each revolution of the distributor.

The received signals operate a polarized relay, whose armature applies current from a local generator to the brushes f, f' of a receiving distributor, which comprises a solid collecting ring B' and a segmented ring A'. Five segments of this ring occupying about the same angular position as the sending segments are connected to five correspondingly numbered magnets which control the operation of the printer. The sending and receiving brushes at opposite ends of the line are rotated in nearly exact synchronism, and their angular positions are so adjusted by automatic means that the receiving brush will make contact with one segment at the instant a pulse is received from the similarly positioned sending segment, thus operating the corresponding selecting magnet. Therefore, at each revolution of the brushes the five printer magnets will be operated in sequence to reproduce the identical combination set up on the transmitter levers.

One or more additional sets of transmitters and printers, similarly connected, provide several independent channel transmissions during one complete revolution of the brushes, so that by proper choice of the number of channels the full capacity of a line may be utilized, while the individual channels are operated at speeds that will not exceed the capabilities of the operators or apparatus.

The transmitters are controlled by a perforated sending tape (Fig. 13), prepared by the operator on a perforator which has a keyboard similar to that of a typewriter. Two types of printers are used. One, known as a page printer, is similar to a typewriter and is equipped with automatic means for returning the carriage and for feeding the paper to print the message in page form; the other prints the message in a continuous line on a narrow paper tape, which is gummed on the reverse side to permit of its being readily pasted on message forms.

Distributor brushes are rotated by a synchronous impulse motor of the LaCour type, which is supplied with impulses of constant frequency generated by the contacts of an electrically driven tuning fork. Slight variations in motor speed are compensated for by applying a precise phase correction controlled by intelligence signals received from the distant terminal. Since synchronism is maintained between the sending and receiving terminals, the standard start and stop pulses (of the teleprinter) are not required for the multiplex circuit, but other local control pulses are employed.

Multiplex channels are operated commercially at speeds from 50 to 80 words per minute (one word averages 5 letters and a space, which is equivalent to 15 cycles per word). The number of channels used is determined by the traffic load and type of circuit available. On duplexed land lines a maximum of four channels in each direction is permissible. Three channels can be satisfactorily operated on carrier channels spaced 170 cycles apart, and four multiplex channels may be applied on carrier channels spaced 200 cycles apart. Two to eight channels may be successfully operated on submarine cable, depending on the type of cable and terminal equipment.

The line frequencies for various speeds and number of channels in each direction are given in Table 1.

Table 1. Line Frequencies

5-letter Words per Minute	Line Frequency, cycles per second				
	8 Channels	6 Channels	4 Channels	3 Channels	2 Channels
50	100	75	50	37.5	25
60	120 *	90	60	45	30
70	140 *	105 *	70	52.5	35
80	160 *	120 *	80	60.0	40

* Not used commercially.

Special repeaters are not required for the operation of multiplex on duplexed circuits less than 1000 miles long, as the regular duplex repeaters are usually satisfactory. On longer circuits, or in those which contain more than three duplex repeaters in succession, the signals are likely to be distorted sufficiently to cause frequent errors and require excessive attention to the apparatus. In such circuits a regenerative repeater is usually employed at every third or fourth repeater point.

The varioplex system, a Western Union Telegraph Co. development, is an automatic telegraph system which provides for the connection of up to 40 individual telegraph circuits or subchannels, having variable message loads, over a single high-capacity telegraph trunk circuit, to other individual telegraph circuits or subchannels at one or more distant points. The actual number of subchannels operated over a single varioplex trunk is limited mainly by practical considerations, one important factor being the total message load presented to the trunk at any one time.

Though the cost of this service to the patron is relatively low, the patron has, in effect, a private high-grade telegraph connection to the distant party. The installation for each patron consists of a sending teleprinter and a receiving teleprinter, thus providing simultaneous two-way service. Character counters, connected to the sending legs of each subchannel, determine the number of words sent, for billing purposes.

Messages are transmitted over a given subchannel by operating the keyboard of the sending teleprinter, and messages are received over a separate subchannel and automatically printed by the receiving teleprinter on a page or tape. Any patron may send a message at any time, as desired, and the other patrons in a given varioplex system may do likewise. All the messages are received at the central office in the varioplex terminal equipment and transmitted in sequence over the varioplex trunk to its distant terminal, which automatically distributes each message to the proper distant subchannel, over which it reaches the patron for whom it is intended.

The varioplex terminal equipment may be classified as (1) individual to each subchannel, (2) common to all connections, and (3) part of the varioplex trunk circuit.

Figure 20 shows a schematic of a two-channel (*A* and *B*) varioplex circuit with eight patron offices and teleprinters *TPR* at each terminal of the circuit for one direction of transmission only. The opposite direction is similarly provided. The principal equipment units at sending terminal X for each subchannel include a reperforator *RPF*, tape transmitter *XTR*, sending chain relays *SA* and *SB*, and sending control relay *SCO*. Common equipment units include two banks (five relays per bank) of sending relays *A* and *B* and a segmented distributor sending ring (five segments per varioplex circuit channel).

The principal equipment units at receiving terminal Y include, as common equipment, a segmented distributor receiving ring (matches the segmented sending ring), two banks (five relays per bank) of receiving relays A and B, and two local transmitting devices TA and TB (each an arrangement of vacuum tubes). The individual subchannel equipment includes receiving chain relays RA and RB and receiving control relay RCO.

Five sending and five receiving relays (banks A and A or B and B of Fig. 20) are associated with the five respective segments of each channel. These relays function in such a manner that, if teleprinter characters are being sent by one or more patrons at station X, positive or negative potentials will be applied by each relay to its corresponding segment at station X, causing positive or negative pulses (combination determined by the

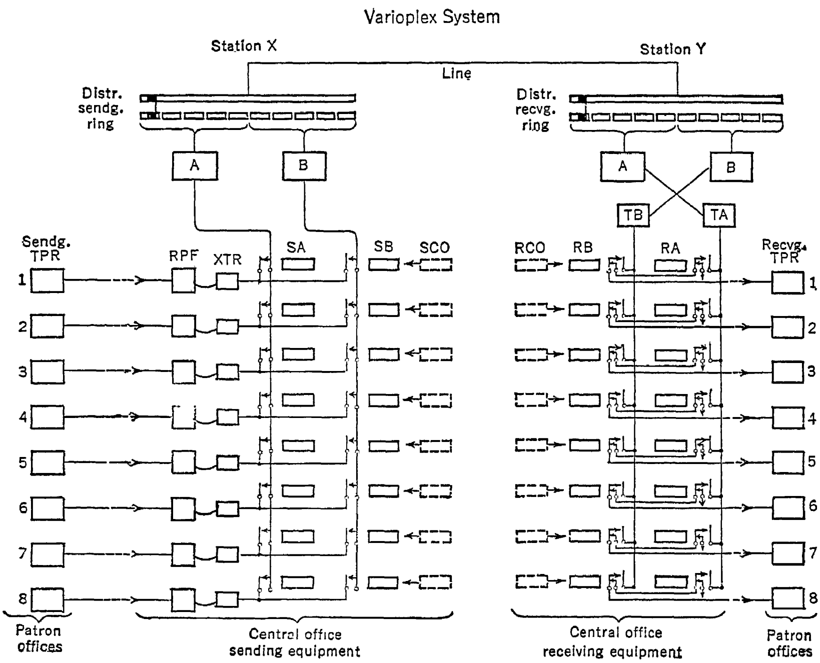

FIG. 20. Schematic of Two-channel (Double-type) Varioplex Circuit (Courtesy Western Union Telegraph Co., Electrical Communication and O. E. Pierson)

character being sent) to be transmitted over the line to station Y, as the sending brushes pass over the segments connecting them, one by one, to the line.

At station Y the distributor brushes rotate in close synchronism with the distributor brushes at station X, and each receiving segment is connected through the line, for a short interval of time, to its corresponding sending segment on the distributor rings. As the pulses are received at station Y, the receiving relays are operated or released, depending on whether the pulses are positive or negative.

The relay RA or RB of a given subchannel will operate in unison with the relay SA or SB of the corresponding sending subchannel and will remain operated during selection of a character by the receiving bank relays A or B. The two relays RA and RB of each subchannel control their subchannel circuit through their contacts. This circuit is closed to a fixed potential, when both relays are in their released positions, but is disconnected from this potential and is connected to device TA or TB, upon operation of RA or RB, respectively. Devices TA and TB are controlled by the contacts of the bank relays A and B, respectively, and by a segmented ring (simplex ring) of the receiving distributor.

Assuming that a given RA relay is in its operated position, pulses from the receiving simplex ring segments actuate the input circuit of the vacuum tube unit TA in accordance with the selected character stored in relay bank A, causing a signal combination to be transmitted over the connected subchannel to the associated teleprinter, which prints the character sent.

No distinction is made with respect to which varioplex channel is used for the transmission of a character from any given sending teleprinter. Successive characters are sent alternately over the two channels, one character being supplied by each subchannel in turn. After all patrons who are sending have transmitted one character, the cycle of operation is repeated. Successive characters from a given subchannel may be transmitted over either varioplex channel.

Relays *SA* and *SB* operate in a cyclic manner, characteristic of the counting chain type of relay circuit. A local ring of the distributor furnishes two pulses per revolution, one pulse for operating each chain relay. Each chain relay is locked in its operated position after being actuated by one of these pulses, and, whenever any chain relay is actuated, any other previously operated relay in the same vertical row (Fig. 20) is released. Not more than one *SA* or *SB* relay is operated at one time. Also, the circuit is such that not more than one relay can be operated in the same horizontal row. If all eight subchannels were sending at the same time, the chain relays would operate progressively upward, starting with *SB* relay 8, then *SA* relay 7, *SB* relay 6, and so on. Thus, in four revolutions of the brush each of the eight sending subchannels would transmit one character. This cycle of operations would be repeated as long as signals were being sent.

The *SCO* and *RCO* relays operate in unison, by means of special signals sent over the line, to remove from the operating chain circuits their associated *SA* and *SB* and *RA* and *RB* chain relays, respectively, when these chain relays are not functioning. This removal does not affect the other chain relays, which are operative. Thus, by controlling the *SCO* and *RCO* relays, so that they remain operative if traffic is available at the transmitter, and inoperative if such traffic is not offered, the main line circuit time is made available only to those subchannels having a simultaneous need for it, and the cycle of operations is speeded up. The *SCO* relay is controlled through a collating arrangement which "reads" the character in the transmitter, causing the sending control relay *SCO* to operate or release, depending on the type of character.

If the line between stations *X* and *Y* is capable of transmitting satisfactory signals at a rate of 800 characters per minute, the two distributors for the two-channel varioplex circuit are adjusted to a speed of 400 rpm. This method may be employed for all high-speed automatic circuits to divide the total traffic capacity of a circuit into smaller and more practical components.

Reperforator switching systems are primarily switching arrangements for use in large message relay centers. These systems not only reduce to a minimum the time required in relaying messages through such centers but also substantially increase the message capacity of trunk lines and facilitate personnel training problems. This equipment is now in operation in a number of the main telegraph centers in the United States, and installations are in progress in other large centers.

The reperforator switching system of recent design consists principally of: (1) receiving equipment, which prints the incoming characters on and perforates them in a tape; (2) crossoffice trunking circuits, by means of which the received message is transferred to a sending position; and (3) the sending equipment, which retransmits the message to its destination or to a second relay center.

Incoming and outgoing transmission as handled by the reperforator-switching system is usually at the rate of 66 words per minute; the rate over the crossoffice trunks is 150 words per minute, thus permitting rapid clearance of messages from the receiving positions. The high rate over the crossoffice trunk is due to the use of a five-wire trunk, permitting the sending of a five-element character at a time. Since the attendant has only two switch operations to perform in order to relay a message through an office having this system, the time required in handling the message is only a matter of seconds. The message is passed through the office entirely on tape, no manual receiving or sending being involved.

If an outgoing channel selected for the transmission of a message is idle at the time of selection, there is no delay at this channel in retransmitting the message. If the channel is busy and no other channel is selected for the message, the tape from the sending reperforator is automatically stored in a specially constructed narrow glass compartment and is fed out through the line transmitter automatically, as soon as the busy channel is available.

Special centers, known as "spillover" and XV centers, of the switching office are provided to handle messages that are abnormally delayed for various reasons, such as circuit trouble, destination office closed, incomplete address, and uncertain routing, or to handle messages of an emergency or special nature. These centers contain switching turrets and printer perforator receiving positions of the same general type, as previously described.

Subcenter switching systems (Western Union Telegraph Co.) are employed, where a number of branch offices and private line patrons are localized in an area some distance from the nearest main switching center. In order to eliminate delays in handling the messages originating from these sources, and to reduce operating costs which would occur if the messages were collected at a local office by messenger or otherwise and thence transferred to a switching center, subcenter switching units, as required, are installed in such areas to extend the local lines automatically direct to the main switching center over a small group of trunks. Usually the number of trunks required is about one-third the number of local telegraph stations served.

In this sytem, the patron's teleprinter sends *outgoing messages* to the main switching center direct, the local line being automatically switched through the subcenter. A direct circuit from the main center to the patron is established for incoming messages by the main-center attendant dialing the patron's line number over an idle subcenter trunk, which is automatically connected to the patron's line through switches at the subcenter.

In Teletypewriter Exchange Service (TWX) in the Bell System, line concentrating units are usually employed for serving areas, such as described above. These units are arranged for automatic switching of two-way message service between a group of subscriber lines at an outlying center and a manual teletypewriter switchboard over a small group of trunks. One such unit has a capacity of 30 lines, which appear on the verticals of three 10 by 10 crossbar switches. The trunks appear on the horizontals of these switches. A 100-line unit is also available.

Private line switching and intercommunicating systems are useful in extensive telegraph leased wire networks, such as are employed to connect a number of widely located stations and offices in large industries or governmental agencies. These systems perform a service in handling telegraph messages somewhat comparable to that which private branch exchanges perform in handling telephone messages. The systems are attractive to large users because of their simplicity to operate and freedom from trouble.

The larger private line switching systems of the Western Union Telegraph Co., receive messages on printer perforators, which feed the perforated tape into a sending tape transmitter. This transmitter is connected to the desired outgoing line by means of a plug-ended cord and jack.

When a message is being received at a given unit, the attendant notes its destination on the tape and inserts the plug of the cord circuit associated with that unit in one of two multipled jacks in which the outgoing line terminates. Two jacks are provided for each line so that, if one of the jacks is in use and a second message is received for that line, the connection may be made for this message in the idle jack and the message will be sent as soon as the first message has been cleared.

Perforator and transmitter units are frequently provided for the patrons, where it is desired to prepare messages in advance by perforating them in a tape and transmitting them at the same time or later.

Fully automatic message switching systems in which the first characters of the code serve to control the switching equipment have been developed and are now in operation.

Intercommunicating systems, as provided by the Bell System for private and governmental users, employ teletypewriter station equipment and teletypewriter switchboards, at which *connections between stations or between a station and a trunk* are established manually by means of cord circuits. The operator is provided with a teletypewriter by means of which incoming calls are answered and outgoing connections are established by typing on a keyboard. The station may have a page type sending-receiving teletypewriter, or a sending-receiving typing reperforator, for printing characters on and perforating them in a tape ($^{11}/_{16}$-in. wide), with which is associated a transmitter-distributor, or other combinations of sending and receiving equipment may be provided.

Teletypewriter Exchange service (TWX), as established throughout the United States by the Bell System for public use, provides both large and small switching centers interconnected by trunk circuits of suitable grade.

Thus, two TWX subscribers, being provided with the necessary equipment, may communicate with each other by written message from one part of the country to another over a vast network of lines and equipment, somewhat similar to that established for nation-wide telephone service.

Transmission limitations, with respect to overall connections, are important factors in furnishing a satisfactory general teletypewriter exchange service, as discussed in article 16.

Teletypesetting, a process of automatically setting type, is accomplished by perforating in a tape the copy material to be set in type, and then feeding the perforated tape into a transmitting device which actuates a typesetting machine. The tape may be perforated locally or by a perforator receiving automatic signals of the proper code over a telegraph circuit from a distant point. The six-unit code is used in the transmission of the characters, and special teletypewriter or teleprinter equipment arranged to send and receive this code is employed, providing page copy for checking purposes.

8. ALTERNATING-CURRENT TELEGRAPH SYSTEMS

Alternating-current telegraph systems employ both wire and radio channels for the transmission of telegraph signals.

Voice-frequency carrier telegraph systems operate within the lowest carrier frequency (voice) range of about 250 to 3150 cycles.

One such system, now in common use, provides up to 18 two-way telegraph channels having carrier frequencies from 255 to 3145 cycles, spaced 170 cycles apart. This particular system operates on a four-wire line basis over various types of facilities, such as loaded four-wire cable circuits, open-wire physical circuits on a four-wire basis (noise conditions permitting), and the different types of carrier telephone channels under suitable conditions.

Figure 21 shows the principal elements of a telegraph channel from the sending to the receiving telegraph terminal for the particular eighteen-channel system referred to above. At the sending terminal, the marking signal closes the line circuit at the step-up transformer and the carrier current is transmitted over the line to the receiving terminal, where it is amplified and detected, and finally operates the receiving relay to marking (−). For

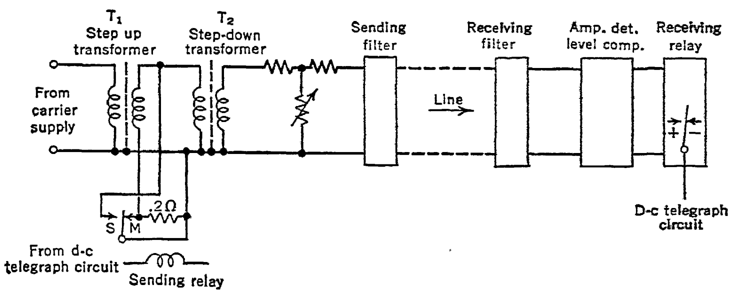

FIG. 21. Principal Elements of a Carrier Telegraph Channel (Courtesy Bell System)

the spacing signal, the input of transformer T_2 is short-circuited at the step-up transformer, and no carrier current reaches the line. The receiving relay is operated to spacing (+), when no current is being received from the line. The 0.2-megohm resistance inserted in series with the line winding of transformer T_1 assists in reducing the carrier to the line and lessening the load on the carrier supply during spacing in this system. The send and receive filters pass only the carrier frequency assigned to the particular channel with which they are associated.

The *telegraph level* at a given point on the circuit is the power at that point due to a single steadily marking channel and is expressed in decibels referred to 1 milliwatt (dbm). If frequency distortion is present, the level refers to a channel operating at or near 1000 cycles, which is the *nominal* telegraph level. The telegraph levels on the line section of a circuit, in general, must be high enough to override line interference and low enough to prevent modulation and crowding, which introduce objectionable interference in other systems. The sending and receiving levels in the same telegraph system should be such that cross-induction will not occur between the sending and receiving branches in the terminal cabling and equipment.

Specific telegraph level (STL) of a circuit used alternately for telephone service is numerically equal to the power of one telegraph channel (in dbm) at a point of zero telephone transmission level. At present in the Bell System, this level is −16 db for type C carrier (except in certain cases) and −21 db for other telephone facilities. The proper selection of the *STL* in any given case is highly important in the application of telegraph to telephone circuits, because of the dependency of the satisfactory operation of both services, when related, on this factor.

The telegraph signaling speed that can be obtained on a carrier channel depends on the band width or frequency range of the channel. With wider bands, higher signaling speeds per channel are possible but fewer channels are obtained. When the carrier channels are spaced 170 cycles apart, each channel will allow telegraph signaling at speeds of 35 to 40 cycles per second, which permits of the operation of a three-channel multiplex working at 50 words per minute per multiplex channel. Thus, a twelve-channel carrier system operated in this way would have a total capacity of 1800 words per minute in each direction simultaneously. With 300-cycle spacing between carrier channels, telegraph speeds as high as 75 cycles per second may be obtained on each channel, which permits the operation of a four-channel multiplex at 75 words per minute per multiplex channel. An eight-channel system of this type has a capacity of 2400 words per minute in each direction simultaneously.

Voice-frequency carrier systems are usually operated over four-wire circuits, one pair being used for the channels working in one direction and the remaining pair for channels working in the opposite direction. They may be operated on two-wire circuits, however, by transmitting the lower half of the carrier frequencies in one direction and the upper half in the opposite direction in a manner similar to the high-frequency carrier, which is described in this article.

Standard voice or carrier telephone repeaters are employed for voice-frequency carrier telegraph systems assigned to voice or carrier telephone facilities. These repeaters take the same spacing as would be employed if the facilities were assigned to telephone circuits.

Carrier supply for the different carrier telegraph frequencies in the type of system shown in Fig. 21 is now generally furnished by vacuum-tube oscillators, although some motor-driven multifrequency generator sets are still in service. One vacuum-tube oscillator unit has a capacity for as many as 50 carrier telegraph channels normally but for a short time may supply a much greater number of channels. Harmonic control is provided for the vacuum-tube oscillator supply to limit high peak line currents, which would tend to overload the telephone repeaters and, in carrier systems, cause interchannel interference.

Voice-frequency carrier transmission is sometimes employed between a teletypewriter office and an outlying teletypewriter station, particularly where a d-c telegraph channel cannot be satisfactorily provided.

In this system, a carrier frequency of 690 cycles transmitting from the office and 1640 cycles transmitting from the station is used. Carrier current is transmitted for spacing and no current is transmitted for marking signals. The break relay at the office can thus be omitted, since the sending relay opens the receiving circuit during transmission of a spacing signal, which holds the receiving relay on its marking contact. Also carrier current is not sent over the line from either terminal while the receiving circuit at that terminal is connected to the line.

Filters are required at both terminals, in order to prevent echo current effects from reaching the detectors and causing false signals.

The series resistance across the low-pass filter at the station provides for spacing signal feedback to the station amplifier detector circuit and permits obtaining a home copy of the outgoing-station message.

The operation of this carrier system does not affect the usual telephone circuit transmission over the line and is not materially affected by reasonable amounts of line leakage or by earth potentials, crossfire, or power induction in the circuit.

High-frequency carrier telegraph systems for open-wire application have been employed by the larger communication companies for a number of years. The ten-channel open-wire systems of the Bell companies are no longer standard, owing to the improvements and economies secured from the eighteen-channel voice-frequency system described above.

The Western Union Telegraph Co. has developed a series of carrier telegraph systems specially designed to fill the requirements of the domestic telegraph system. A number of these systems are in operation (1947), and additional systems are being installed rapidly in a modernization program in which carrier operation will replace d-c telegraph operation for trunk circuits and will substantially reduce the number of wires and pole lines required for the telegraph service. These systems include (1) a portable type for establishing short temporary or emergency channels, (2) a low-cost four-channel system for distances not greater than two repeater sections, and (3) four types of multichannel, long-distance trunk systems. The basic, standard unit of the trunk carrier systems is a 3000-cycle voice-frequency band extending from 300 to 3300 cycles. The four trunk systems are (1) the 7.5-kc type E with one voice-frequency band in each direction, (2) the 15-kc type F with two bands in each direction, (3) the 30-kc type G with four bands in each direction, and (4) the type WN with 32 bands in each direction and requiring a transmission band of 150 kc in each direction. Types E, F, and G are open-wire systems designed for two-wire operation and with frequency allocations (for 300-cycle channels) as shown in Fig. 22. The type WN is designed for use with a two-way microwave radio relay circuit.

In multiband systems, only one band can be transmitted in its original frequency position (300 to 3300 cycles); all other bands must be transferred or translated to separate positions in the available frequency spectrum of the transmission medium. This can be accomplished by modulating each of the bands requiring translation by a separate secondary carrier of appropriate frequency. Such a method is wasteful of the frequency spectrum because of the increasing inefficiency (in absolute band width) of selective filters as the frequency is increased. The Western Union systems utilize the spectrum more efficiently by employing a plural or tandem method of modulation in which the voice-frequency bands are translated in groups, thus requiring only broad group filters at the assigned position in the frequency spectrum. The secondary carrier or translation frequencies are supplied by amplified harmonics of a high-stability, low-frequency oscillator.

Although these carrier systems are designed primarily for operation over Western Union facilities, they are readily adapted to operation on any wire or radio transmission system that provides a suitable transmission band. Furthermore, the individual voice-frequency bands can be repeated or patched at will between the four types of Western Union multiband systems, Bell System facilities, and equivalent facilities of other companies.

The voice-frequency bands may be utilized for high-speed facsimile telegraph transmission or for operation as a telephone circuit, but they are ordinarily channelized for

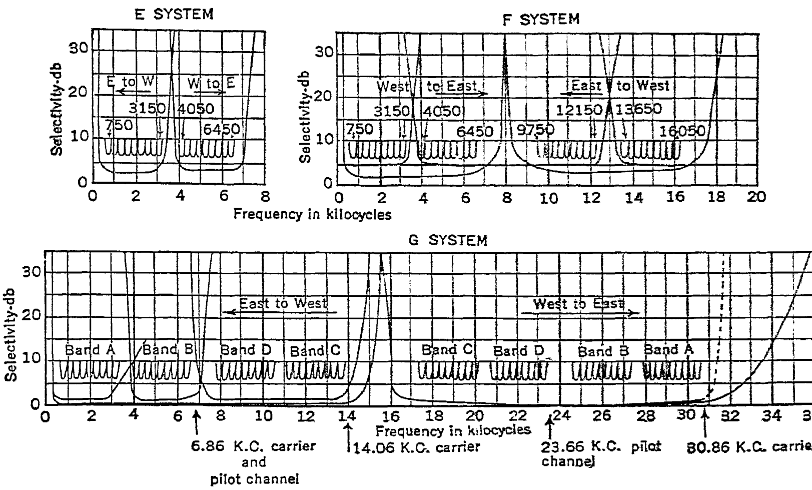

FIG. 22. Frequency Allocations for Three Types of Carrier Telegraph Systems (Courtesy Western Union Telegraph Co., A.I.E.E., F. E. D'Humy, and P. J. Howe)

printer or other code telegraph operation. Two types of channelization are employed, providing (1) nine-wide-band channels spaced 300 cycles apart and suitable for four-channel multiplex operation at speeds up to 75 cycles per second, and (2) eighteen narrow-band channels spaced 150 cycles apart and suitable for teleprinter or two-channel multiplex operation. Present trends are away from the relative mechanical complexity of multiplex telegraphy and toward teleprinter operation; consequently, narrow-band channels only are now being installed.

The following description deals with narrow-band channels, but it also applies generally to the basically similar wide-band equipment. The sending terminal of each channel includes a vacuum-tube oscillator, which supplies the channel carrier frequency. The d-c telegraph signals are impressed or superposed on the carrier by modulation. The carrier telegraph systems of other companies use amplitude modulation, as did the early Western Union systems. For amplitude-modulated (a-m) operation, the channel carrier frequency is transmitted for a marking signal and interrupted for a spacing signal. Western Union has introduced, and now uses exclusively, frequency modulation for carrier telegraph transmission. In f-m transmission, the frequency of the channel oscillator is controlled by the d-c telegraph signals being transmitted. Marking and spacing signals cause the frequency to swing down and up, respectively, 35 cycles from midchannel frequency. The transitions between marking and spacing frequencies are not instantaneous but are very abrupt, with the frequency increasing and decreasing smoothly between the lower and upper limits. This action results in true frequency modulation, and the modulated carrier current appears at the output of the channel transmitting filter constant in amplitude but varying in frequency.

At the distant corresponding channel terminal, the carrier is selected by the receiving filter and amplified, after which it passes through an amplifier limiter, a frequency discriminator, and a rectifier circuit, which restores the marking and spacing frequencies to their original d-c form. The vacuum-tube limiter circuit maintains a constant-amplitude output for received levels in a range between -50 and $+10$ dbm.

In comparison with a-m transmission, f-m transmission is definitely less susceptible to interference, and the received signals are immune to the influence of level variations encountered in transmission.

The original f-m channel terminals contained transmitting and receiving relays. In the latest type of narrow-band equipment, the relays have been eliminated and operation of the channel terminals is completely electronic. This change, together with other simplifications, has effected a considerable reduction in size and cost of equipment.

Transmission losses in the open-wire systems between sending and receiving terminals are compensated for by vacuum-tube repeaters, spaced at suitable intervals along the line. Average wet-weather losses are limited to about 25 db between repeaters. Reflection losses at junctions of open wire and incidental intermediate or terminal cables are limited by impedance-matching networks. Loading of short cables to reduce attenuation losses is no longer favored. Networks are provided at repeaters and terminals to equalize the losses at different frequencies, so that the attenuation is substantially uniform over the carrier band.

Telegraph circuits can be operated across the United States entirely by carrier without requiring a regenerative repeater at any point. The type G system provides, in each direction, on a single pair of wires 72 teleprinter circuits or 144 multiplex channels having a total capacity of 4750 and 9500 words per minute, respectively, in each direction. The other systems provide capacities proportionate to the number of voice-frequency bands employed. The radio relay system with its 576 carrier channels handles 38,000 words per minute each way.

9. FACSIMILE SYSTEM

Facsimile, as defined and discussed in detail elsewhere in this handbook, is a process whereby such objects as a picture or a sheet of paper containing printing or writing are electrically scanned, and the electrical currents thus generated are transmitted by wire or radio to a receiving device which reproduces, as a print or on a specially prepared paper, the original picture (in black and white) or the printing or writing. The following brief discussion applies to facsimile as used in telegraph operation only.

Facsimile transmission of messages, as employed by the Western Union Telegraph Co., is known as *telefax* service or transmission. This type of service was considered desirable by the telegraph companies for many years, but the recording systems used, employing photographic, chemical, or other processes, were too costly or slow for the general handling of telegrams.

In recent years, the Western Union Telegraph Co. developed for its use a facsimile recording paper, with the trademark *Teledeltos.* This paper has a conducting coating of a light gray color which is marked in black by the passage of an electric current through it. The paper is used dry, requires no processing, is not affected by light or ordinary moisture conditions, and produces immediately a clear-cut permanent record. Simple Telefax recording equipment receives the incoming amplified facsimile currents and applies them directly to the paper by means of a stylus riding on the surface of the paper.

The Telefax equipment thus far developed is of several different types and has been designed primarily to provide maximum convenience for the general public. However, trunk-line Telefax is being used to some extent between large centers, as between Chicago and New York. These trunk circuits have been used mainly for the transmission of drawings, sketches, copy for publication, editorial corrections, and commercial messages. For good-quality Telefax transmission, a frequency band width of about 2500 cycles is required. The line loss at the maximum frequency used should not exceed about 25 db.

10. MISCELLANEOUS TRANSMITTING AND SIGNALING SYSTEMS

The ticker system is designed to furnish stock, bond, and grain quotations and pertinent news items to brokerage, investment, and private offices during trading hours.

The ticker, which does not include a transmitting keyboard, is otherwise quite similar in principle to the start-stop printer, the chief points of difference being in the form of type wheel used and the method employed in shifting from letters to figures. An eight-unit code is used. The first impulse of each group starts the printer; the second impulse determines by its polarity whether letters or figures are to be printed; the succeeding five pulses determine the particular character to be printed; and the eighth pulse is the stop pulse, which allows the distributing mechanism to come to rest in preparation for the next succeeding signal group. The tickers are controlled by a single transmitter at the central distributing point. Normal operating speed is from 450 to 500 printed characters per minute.

The teleautograph system is employed principally by banks, railroads, department stores, and similar businesses. This system provides a means by which messages, written in longhand at one station, may be reproduced simultaneously at one or more stations at various locations without material distortion of the original characters.

The principle on which this system operates is shown in Fig. 23. The transmitter consists of a stylus, which is mechanically connected, through two sets of levers and appropriate swivel joints, to the contact arms of two variable rheostats in such a way that the horizontal and vertical components of the stylus movements are translated into corresponding current variations in two lines connecting the receiver. At the receiver, the variations in the line currents produce similar movements in two coils or "buckets" within a magnetic field. The movements of these coils are communicated through a system of levers to a writing pen which reproduces the movements of the sending stylus.

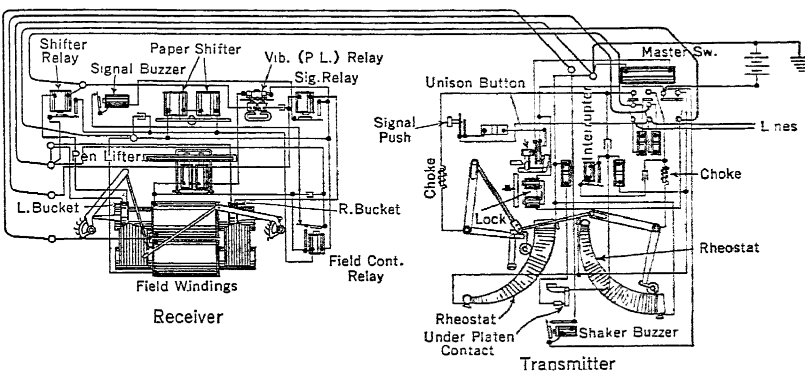

FIG. 23. Schematic Diagram of the Telautograph System

The pen is lifted from the paper and the paper is shifted to provide fresh writing surface by magnets, which are controlled by superposed alternating current supplied by a buzzer located in the transmitter.

Two grounded circuits are required, one to transmit the current variations representing each of the two components of the stylus motion. As many as 100 receivers, arranged to be controlled by one or more transmitters, may be operated in multiple on a pair of wires. The speed of operation is determined entirely by the rapidity with which the operator can write. The line potential is usually 120 volts with one side grounded, and current depends upon the resistances of transmitters and receivers. One type of equipment, which normally operates on 100 ma, is adapted for use on wires not exceeding 700 ohms resistance each. Another type requires only 60-ma line current and will operate well on lines up to 1200 ohms resistance, although in a few extreme cases operation has been maintained on lines having resistances as high as 1800 ohms.

Messenger call circuits are employed for summoning telegraph messengers to pick up messages at various locations and deliver them to the telegraph office for sending.

Signals are transmitted by a call box, which consists of a spring-driven clockwork mechanism arranged to turn a pair of notched contact wheels through one complete revolution each time the box is operated by turning and releasing a winding key, as shown in Fig. 24. The contact wheels are arranged both to open and ground the line when transmitting signals, and to restore the line to its normal closed ungrounded condition upon coming to rest. The call boxes are connected in series with a line having both ends terminated at the central office in relays which operate a buzzer and a register for recording the signals on a paper tape. Switches S_1, S_2, and S_3 are provided to change the line, battery, and register connections to permit of receiving signals from the call boxes even during times when the line circuit may be accidentally open or grounded or both. Only the simultaneous occurrence of a fault on both sides of a call box or group of boxes will prevent the transmission and correct reception of signals. The normal line current in call circuits is 50 ma, and, for satisfactory service, not more than 50 call boxes should be included in any one circuit. Signaling speed usually does not exceed 4 impulses or 2 cycles per second.

Though many technical advances have been made in the art of telegraphy, the messenger call box, of which there are over 300,000 in the United States in offices, hotels, and other public places, still plays an important part in the collection of commercial telegraph messages.

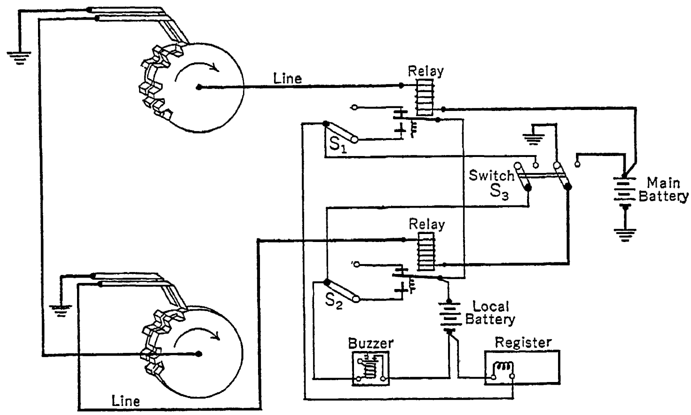

FIG. 24. Schematic Diagram of a Messenger Call Circuit

Clock circuits are employed in furnishing telegraph time service. The clocks at subscriber premises are driven by springs which are wound periodically, usually once each hour, by a small electric motor operating on dry batteries. The minute and second hands are arranged so that they may be moved to their 12 and 60 positions, respectively, by the operation of a synchronizing magnet. The synchronizing magnets of the clocks are connected in series in a grounded circuit terminating at the central office on the contacts of a transmitting relay or a synchronizing machine which sends a synchronizing impulse 1 sec long once every hour, in response to the operation of contacts of a *master clock*. The transmitting circuit is arranged to give an audible signal if the synchronizing impulse fails to be transmitted owing to line failure. The clocks mechanically lock their synchronizing mechanisms in the inoperative position except for two or three minutes immediately preceding and following the time at which the synchronizing impulse is to be received, so as to protect the clocks from being set to a false position by accidental crosses between the line and power circuits. The normal line current is 250 ma, and approximately 60 clocks may be operated on one circuit.

Naval Observatory time signals are regularly distributed to all parts of the United States by the Western Union Telegraph Co. over about 200,000 miles of wire network. These signals provide the means for maintaining some 2000 master clocks, so that they continuously indicate time to a practical degree of accuracy.

Railroad communication systems employ the latest types of telegraph as well as telephone and radio facilities for the control of train movements and the general business of the railroads. The telegraph facilities used are, in general, similar to those previously discussed in this section and will not be considered further here. Special arrangements of telegraph facilities are employed by the railroads to meet their special needs.

SUBMARINE CABLE TELEGRAPHY

By John D. Taylor

Submarine cables interconnect all the earth's continents for the transmission of telegraph messages.

One large telegraph company has more than 30,000 miles of ocean cable, some of it lying at a depth of nearly 3 miles. This company laid its first cable in 1873 and its latest cable in 1928. The North Atlantic is spanned by 14 cables, and 6 cables extend between North America and the Azores, where connections are made with Europe and, via the Cape Verde Islands, with Africa and South America. There are other cables between the United States and Mexico, South America, and the West Indies. Three cables span the Pacific Ocean.

11. CABLE DATA

The first transoceanic cables laid were of the non-loaded type. It was not until 1924 that the first loaded cable was placed, and this cable connected New York with Horta, Azores Islands.

Non-loaded cables of the deep-sea type usually consist of a single copper conductor, which may be solid, stranded, or a combination of both, to provide greater flexibility, as shown in Fig. 1. This conductor is encased in gutta-percha * insulation, covered with servings of jute yarn over which steel armor wire sheathing is placed to provide mechanical strength and protection. The armor wires are covered with inverse layers of jute over which an outer covering of compound is applied. The overall diameter of deep-sea cable varies from about 3/4 in. to 1 1/2 in., depending on the size of conductor and the construction employed.

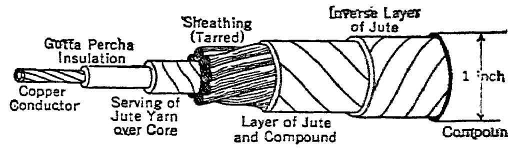

Fig. 1. Non-loaded Submarine Cable Construction

Table 1 shows certain properties of non-loaded cables now in operation.

Table 1. Certain Properties of Non-loaded Deep-sea Cables

Weight, pounds per nautical mile		Diameter of Conductor, mils	Diameter over Gutta-percha, mils	Resistance, ohms per nautical mile at 75 deg fahr	Capacitance, microfarads per nautical mile
Copper	Gutta-percha				
70	120	70	252	16.90	0.272
107	120	86	258	11.05	0.316
107	166	86	298	11.05	0.280
130	130	95	270	9.10	0.334
140	140	99	280	8.45	0.335
160	150	106	291	7.40	0.345
180	160	112	302	6.58	0.351
200	180	114	318	5.92	0.339
225	225	124	354	5.25	0.332
275	225	138	360	4.30	0.363
350	300	151	412	3.38	0.347
500	315	180	432	2.37	0.398
650	400	203	487	1.82	0.398
700	360	211	470	1.69	0.435

The *shore ends of ocean cables* are usually of the twin-conductor type, a cross-section of which is shown in Fig. 2. The second conductor in the end cable is used to extend the circuit ground terminations out into deep water for the purpose of minimizing extra-

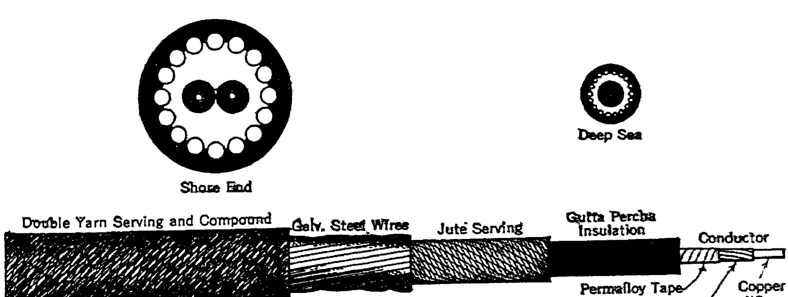

Fig. 2. Loaded Deep-sea Cable Construction

neous ground disturbances from power circuits and natural causes. Since the end sections of cable usually rest in shallow water and are subject to severe water action and other

* Deproteinized rubber has been employed as a substitute for gutta-percha, and a synthetic insulation of polyethylene is being experimented with.

disturbances near shore, the construction is much heavier than for the deep-sea sections, both in armoring and jute layers, so that the overall diameter may be as large as 4 in.

Loaded cables, in their make-up, closely resemble the non-loaded cables just described, the principal difference being that the copper conductor or conductors (for twin conductor) are spirally wrapped with a thin, high-permeability tape of Permalloy (alloy of nickel and iron) (see Fig. 2). This tape uniformly and continuously loads the copper conductors and results in material signal transmission improvements (over the non-loaded cable), such as lower and more uniform attenuation with frequency and less distortion.

Table 2 shows certain properties of loaded cable now in service.

Table 2. Certain Properties of Loaded Deep-sea Cables

* Approximate values.

12. OPERATION

Long non-loaded submarine cables (the longest being about 3500 nautical miles) have high values of resistance and capacitance, which attenuate and distort the telegraph signals to such an extent that, until recently, the usual methods of land line operation could not be employed.

Early methods of transmission employed a modified form of bridge duplex with artificial line, giving duplex operation, and electromechanical types of receiving equipment.

Signals were transmitted in the cable Morse Code from a perforated tape by a transmitter and a group of associated relays, arranged to apply positive or negative battery or ground to the apex of the bridge circuit of the duplex set in accordance with the code.

The receiving instrument first used on transatlantic cables was a moving-coil-type mirror galvanometer, connected as such in the bridge duplex circuit. Because of its sensitivity and favorable signal-shaping characteristics, this instrument was used for many years, until replaced by the siphon recorder, which recorded on a moving paper tape in ink the variations in magnitude of the incoming signals. The recorder was later supplemented by (1) various types of magnifiers, which amplified the received signals before the signals reached the recorder, and (2) sensitive cable relays, such as the drum and gold-wire types, which permitted dispensing with manual relay operation at repeater stations.

These developments, together with the application of regenerative repeaters, extending to the period immediately after World War I, made possible greater signaling speeds, but with recorder operation it was still necessary to transcribe messages manually from the recorder tape at the receiving terminal. Satisfactory operation required that the unbalance current in the receiving arm of the bridge should not exceed one-sixth the value of the received signaling currents, thus necessitating the maintaining of a duplex balance between the cable and artificial line within about $^1/_{100}$ per cent.

Because of the high cost of submarine cables, intensive study and experimental work have been continuous, new techniques and devices being sought for increasing the efficiency of these cables. The electromechanical receiving equipment was necessarily fragile to respond to weak signals, and the gain of the magnifiers was relatively low as compared to electronic amplifiers. Attempts in 1918–1919, to apply vacuum-tube signal-shaping amplifiers to improve signal reception did not result favorably, mainly because of (1) high level disturbances existing at that time on duplexed non-loaded cables, due to interference and duplex unbalances, and (2) the fact that suitable electrical networks, equivalent to or better than the mechanically tuned moving coil, were not available.

With the laying of the first loaded oceanic cable in 1924, higher signaling cable speeds were possible, limited by recorder operation and other terminal equipment. Concentrated effort toward improving this equipment resulted in the development of a signal-shaping amplifier and a multiplex printer system suitable for high-speed loaded-cable operation. This equipment was installed on the first and subsequent loaded cables, resulting in raising the message capacity of these cables as much as three to eight times over that of the older, non-loaded systems. These loaded systems are still giving satisfactory service.

The substantial gains made in cable message transmission through development of the loaded-cable system called forth increased effort toward bettering the non-loaded cable performance. The results so far attained have been successfully applied quite extensively in the North Atlantic and in the Alaska communications cable systems, having been accelerated by the needs of World War II.

The improvement program in non-loaded submarine cable operation has included (1) conversion from cable code recorder operation to five-unit code printer operation, (2) replacement of magnifiers with vacuum-tube signal-shaping amplifiers which permit the use of rugged land-line-type polar relays, and (3) improvements in duplex artificial line networks and in the technique of balancing. Thus, the advantages of more nearly automatic operation, increased circuit speeds, and reduced maintenance at cable stations have been secured.

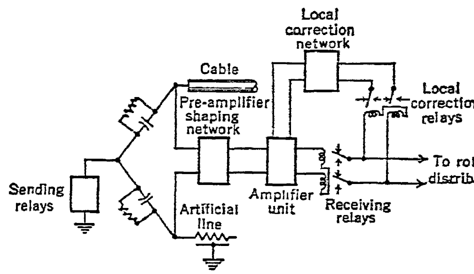

FIG. 3. Typical Arrangement of Terminal Units for Duplexed Non-loaded Cable (Courtesy Western Union Telegraph Co., A.I.E.E., and C. H. Cramer)

The printer system standardized for non-loaded cables is fundamentally similar to the loaded-cable system but more nearly resembles the land line multiplex. It makes use of the tape transmitter, rotary distributor, synchronizing mechanisms, and printers, thus providing for integrated operation with land line systems. It differs from these latter systems in that it is applied to single as well as multichannel operation, whereas the land line system requires start-stop seven-unit code printers for single-channel use; and on long cables the printer signals are transmitted at a speed such that pulses of unit or dot length are received at very small amplitude and, in effect, are considered as absent.

The receiving networks are adjusted to respond to signals two or more units long, so that, from the standpoint of signal reception, the fundamental received frequency is one-half the transmitted dot frequency. The receiving relay operates on a three-position basis, remaining at the zero position for dot signals, which are reinserted synchronously by the receiving rotary distributor. The attenuated-dot method of transmission, though appearing to permit doubling the cable output as compared with normal multiplex transmission, only approaches such output as a limit. Actually, the increase in letters-per-minute circuit speed is only about 80 per cent over that attainable with normal transmission, because, with attenuated-dot transmission, the received signals are more susceptible to interference and more difficult to shape. With this method, the five-unit code used in land line multiplex functions as a 2.5-unit code, giving a net gain over the 3.7-unit recorder Morse code.

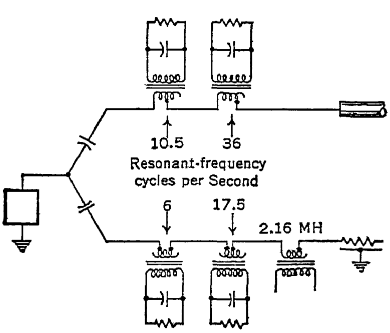

FIG. 4. Typical Arrangement of Resonant Balance Networks (Courtesy Western Union Telegraph Co., A.I.E.E., and C. H. Cramer)

The cable printer system is flexible in that individual channels may be terminated, extended, or combined with other channels to satisfy traffic requirements and the transmission speeds of the available circuits. Channel efficiency may be increased by the application of land line automatic systems.

Figure 3 shows a typical arrangement of important terminal units for duplexed non-loaded cable, including a pre-amplifier shaping network, an amplifier unit, receiving relays, and a local correction network. Resonant balance networks, as shown in Fig. 4, are also provided in a balanced arrangement between the series condensers and the bridge points of the receiving circuit.

The pre-amplifier shaping network, shown diagrammatically in Fig. 5, has been designed to meet certain requirements which permit satisfactory printer operation on long non-loaded cables at the highest practicable speeds, the more important being:

1. A higher standard of receiving accuracy, continuity, and reliability of operation than with recorder operation.
2. The ability to equalize or restore the received frequency components of the signals to an approximation of the original amplitude and phase relationships.
3. Passing only the narrowest band of frequencies, consistent with avoiding undue characteristic distortion and with limiting the effects of extraneous interference and duplex unbalance voltages. Direct currents and alternating currents of near-zero frequency must be rejected, in order to avoid effects from earth currents, particularly as a result of magnetic storms.
4. A shaping network electrically symmetrical with respect to the duplex bridge or electrically isolated from the bridge.
5. Network elements designed for a wide range of adjustment.
6. Amplifier gain and output sufficient to operate rugged polar relays, similar to those used in land line systems.

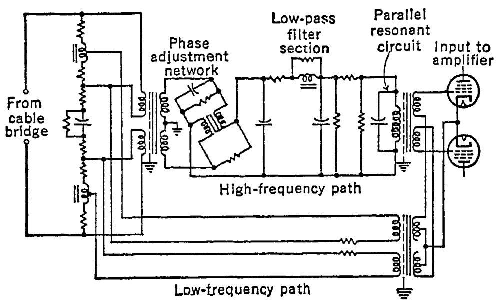

Fig. 5. Pre-amplifier Signal-shaping Network (Courtesy Western Union Telegraph Co., A.I.E.E., and C. H. Cramer)

This pre-amplifier network, when properly adjusted, passes a band of frequencies, including those components required for good signal shape, properly proportioned and phased, and largely or almost completely suppresses those frequencies below the fundamental received frequency. The first branch of the network, being symmetrical and directly across the duplex bridge, is tuned to about 1.5 times the received frequency. The remaining elements of the network, being isolated from the bridge by shielded transformers, are arranged in two paths which combine at the amplifier input.

The lower frequencies pass to the amplifier over the low-frequency path with little, if any, further shaping, while the higher frequencies pass to the amplifier over the high-frequency path, in which they are further shaped by a bridge-type phase-adjusting network, a low-pass filter for added suppression above the required signal band, a parallel resonant circuit tuned to 1.5 times the received frequency, and suitable resistance controls. The phase-adjustment network provides the required wave-front steepness with less higher-frequency components, thus permitting further discrimination against unwanted frequencies.

The amplifier unit is of the three-stage resistance-capacitance coupled, pushpull type with two stages of voltage amplification. Frequencies below those received from the shaping network are suppressed. The maximum voltage gains and available overall gains are 83 db and 103 db, respectively. The amplifier output is adequate for operating the latest land-line-type polar relays.

Two standard two-position relays function in unison as a three-position relay, in accordance with usual cable practice, but the circuit is readily convertible, if desired, to receive two-current signals.

E. Complete signal, $C + D$.

Fig. 6. Received Signal Resulting from Transmission of Long Signal over Non-loaded Submarine Cable (Courtesy Western Union Telegraph Co., A.I.E.E., and C. H. Cramer)

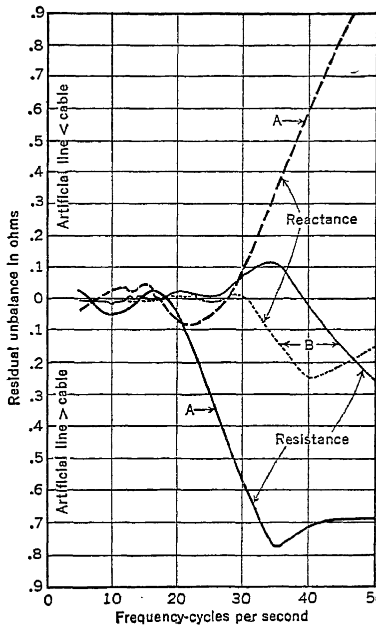
Figure 6 shows the shapes of the component signals in the formative stages and the shape of the complete signal at the amplifier input. Curve *C* shows the signal shape as it leaves the pre-amplifier network, at which point signals of the fundamental received frequency are fully shaped but longer signals would be badly distorted because of lack of low-frequency components. The local correction network (Fig. 3) functions to restore these components under control of the receiving relays. The shaped local correction voltages, curve D, are added to the received signal in the grid circuit of the output stage of the amplifier, resulting in the fully shaped and complete signal, curve E.

For loaded-cable systems, essentially all signal shaping occurs in the pre-amplifier and interstage networks, but there is some deficiency in the very low-frequency components. The method of shaping employed with the non-loaded cable systems not only affords greater immunity from low-frequency disturbances but simplifies amplifier design and stability and eliminates slow transients (wandering zeros).

Duplex operation of non-loaded cables, giving greater total message capacity, is normally used. With the advent of modern amplifiers, extraneous interference and duplex unbalance levels limit signaling speeds. If unbalance is governing, maximum capacity is obtained by using unequal speeds in the two directions of transmission, but duplex unbalance is at present less of a factor, owing to improved artificial lines and balancing methods.

The basic ocean cable artificial line is still about the same as it was at the beginning of duplex operation. The lumped series resistances and shunt capacitances, simulating corresponding cable constants, have been subdivided and arranged for greater flexibility of adjustment. Modern artificial lines of American design are subdivided so that the lumped values of resistance and capacity increase progressively as their distance from the head (point nearest the apex) of the artificial line increases.

The cable circuit parameters include inductance and effective resistance, which vary with frequency because of the earth-return path characteristics, and are known as the *sea-return impedance*. These factors, though small, are important in high-accuracy balancing of the near end of the cable. By using tapered resistance values in series with the shunt capacitance elements of the artificial line sections, the sea-return impedance can be simulated over a relatively wide frequency band and the propagation constant of the sections to which these resistances are added is not materially changed.



A. Before insertion of networks of Fig. 4.
B. After insertion of networks of Fig. 4.

FIG. 7. Frequency Characteristic of Unbalance on a Transatlantic Cable (Courtesy Western Union Telegraph Co., A.I.E.E., and C. H. Cramer)

However, in order to meet balance requirements, further refinements in duplex balancing are necessary. Slow reversals are transmitted, and observations of the residual unbalance transient are made with a cathode-ray oscillograph or ink recorder. In the final adjustments, unbalance at operating speeds is also observed. The artificial line adjustments have their limitations (which are not usually the same for different cables), because of inadequacy of artificial line, interferences, or other factors.

Corrective resonant networks are designed to secure the ultimate duplex balance needed for satisfactory operation. These networks, Fig. 4, supplement the artificial line and provide an impedance, which can be effectively controlled as to magnitude and width of frequency band. The networks are designed in accordance with a frequency characteristic of the residual unbalance.

This frequency characteristic is obtained by taking electrical measurements, directly across the duplex bridge over the important frequency range, of the effective residual impedance unbalance at the head of the artificial line. Several of the single networks are usually used, some of them being inserted in series with the cable and some of them in series with the artificial line and adjusted, as required. Final adjustment is made in the usual artificial line controls.

Figure 7 shows the frequency characteristic of unbalance on a transatlantic cable before and after insertion of the corrective resonant networks and the final adjustments. The balance has been improved by these networks over the most important frequency band, with the greatest improvement at the higher frequencies.

Crossfire between cables usually occurs if two or more cables land at the same point and extend underground to the cable station with small separation. This interference is controlled by applying simple corrective networks at the cable station. If two cables land at different points and are laid closely parallel for some distance, the corrective problem is more difficult, requiring more complex networks.

With the techniques that have been developed for improved duplex balances and the correction of crossfire, extraneous interference, mostly of natural origin, becomes controlling in signal speed. Natural interference is picked up in the shallow-water end sections of cables, its magnitude varying widely from cable to cable, depending on the depths and distances encountered. Receiving earths of the non-loaded cables are usually located up to several miles from shore. The twin-conductor end sections of cable greatly assist in limiting the interference and could be extended further into the ocean, but the cost would be correspondingly increased.

Some improvement in interference levels has been obtained by increasing the sending voltages, restricted until recent years to about 50 volts, up to 90 to 120 volts, now in common use by some of the cable companies.

Signal-shaping amplifiers of the type just described are being used on many of the longer transoceanic cables; short-cable amplifiers are employed for short connecting cables.

On certain duplex-operated non-loaded cables, the sum of the letters-per-minute speeds in the two directions now averages in printer operation over 40 per cent more than with the previous recorder speeds. The average net increase in the message capacity of these cables, considering short-cut methods permissible in recorder but not printer operation, is over 30 per cent. In one case, it is expected that the ultimate speed in printer operation when three-channel multiplex equipment is available will be 750 letters per minute in each direction of transmission.

In loaded cables, the channel speed is usually 250 to 300 letters per minute, the number of channels per cable varying between 4 and 8, depending on the cable make-up. One loaded cable, about 2300 nautical miles long, operates at 65 cycles per second and provides 5 one-way channels, each with a capacity of 312 letters per minute.

Power equipment consists of storage batteries and charging-equipment installations of the capacities and sizes necessary to provide both regular and emergency power at the cable stations. The d-c voltages range from 90 to 120 volts.

TELEGRAPH EQUIPMENT

By John D. Taylor

The telegraph central office is the centralizing point which, for its particular area, directs and regulates the movement of telegraph messages. From such points, the operating personnel also maintains constant supervision over the proper functioning of and needed repairs to equipment and outside plant.

13. CENTRAL-OFFICE EQUIPMENT

Central-office equipment for telegraph operation consists of a wide variety of equipment units and associated facilities. The types and amounts of equipment at any given central office vary over a wide range, depending mainly upon its importance in the general telegraph network, the message volume handled, and the nature of the traffic. Some of this equipment has previously been described and will not be discussed further here.

In a large office, the principal classifications of equipment may be considered to include:

1. *Terminal equipment for open-wire lines*—entrance cables, protector and distributing frames, and testboard (Western Union designation is line-terminal switchboard).

2. *Intermediate operating equipment*—repeaters, concentrators, and system apparatus, such as multiplex, varioplex, reperforator-switching, carrier, and Telefax.

3. *Operating positions*—teletypewriter switchboard (Bell System designation), operating tables or positions for Morse, multiplex, and teleprinter sending and receiving apparatus, tape perforators, reperforators and transmitters, Telefax terminals, telephone lines, and switching facilities.

4. *Message-handling equipment*—belt conveyors between incoming and outgoing operating positions and distributing centers within an office, and pneumatic-tube terminals from branch or other message-handling centers to the main office.

5. *Power equipment*—power-generating equipment, such as rectifiers and motor-generators, power switchboards, power distributing systems to power-operated units, storage batteries, and emergency power plants.

6. Building equipment—lighting, heating, ventilation, elevator service, personnel quarters, and many other items of this nature.

The equipment layout in an office should provide a minimum travel time of the operating personnel in their regular work and should limit wiring and cabling requirements between equipment units.

Protector (main) frames provide for termination of the entrance cables through which the open-wire lines extend into the central office, either directly on protectors or on terminal blocks, from which the lines are connected to protectors. The protectors, consisting of heat coils (or fuses) and carbon block discharge gaps, function to prevent excessive foreign currents or voltages from damaging the central-office cables and equipment, as discussed in more detail in Sections 10 and 17. Office circuit fuses are also provided to prevent excessive office currents from damaging the equipment or wiring.

Testboards or line-terminal switchboards, to which the lines are extended from the protector frames in cable, are designed to terminate the telegraph circuits, entering an office, in jacks for testing, patching, and other purposes, as required in maintaining and operating these circuits. Certain central-office equipment units, battery taps, and special-purpose apparatus are also terminated at such boards and may be associated with or disconnected from the various circuits, to meet operating needs. In the *older-type boards* telegraph-circuit layouts are usually established in part by means of patching cords; in the *latest-type boards*, these circuits are wired through groups of jacks, individual to each circuit, eliminating the need for patching cords, except for testing or establishing other than the normal circuit layout.

Intermediate distributing frames have mounted, on their two sides, terminal blocks, to which the various equipment units in the office are wired. Office cables also extend from these frames to testboards and line-terminal switchboards and to telegraph operating positions and teletypewriter switchboards, so that by means of crossconnections on these frames circuits may be connected to the various testboard and switchboard jacks, operating positions, and equipment units, as desired.

Teletypewriter switchboards employed for the purpose of establishing connections between teletypewriter subscribers consist principally of positions equipped with jacks, cord circuits, and a keyboard sending and receiving teletypewriter, which may be associated by means of keys with any cord circuit on the position.

The operator handles connections somewhat like an operator at a manual telephone switchboard position, the principal difference being that the incoming calls are answered and extended to the called subscriber by operating the teletypewriter, with the assistance of similarly equipped distant operators, if necessary.

These boards are designed to serve as few as 10 lines (mostly for private networks) or as many as 2040 subscriber lines and 600 intertoll trunks, when the outward, inward, and through traffic is handled at one board.

In order to improve transmission from a central office to a teletypewriter station, a wave-shaping network, consisting of resistance, inductance, and capacitance of various values and combinations, depending on the type of loop and connected equipment, is frequently inserted in the side of the loop connected to the repeater at the central office. Wave-shaping networks are also employed, as required, at the stations. These networks assist in restoring the received signal wave to its original shape.

The jacks, cords, and plugs used at telegraph switchboards and testboards for testing, patching, and establishing connections may be of standard types, such as those in manual telephone testboards and switchboards. However, where low-resistance conductors with greater service margins are needed, these units are frequently of heavier construction. The number of conductors will vary between different boards, depending on the circuit requirements.

Telegraph repeaters employing polar transmission are standard for d-c trunk-line terminal sets; they usually operate on a full duplex basis with ground return. Other types of repeaters are used at intermediate trunk-line points for transmission reasons. The operating functions of repeaters have been discussed in article 6.

Repeaters are used in various arrangements in circuits, the name by which they are designated indicating the manner in which they function, such as a combination duplex-duplex half repeater, terminal duplex-duplex half repeater, and high-speed polar duplex, high-speed single-line, and regenerative repeater. One form of repeater provides for receiving, recording, and, when the outgoing circuit is clear, retransmitting telegraph signals, which, in effect, is equivalent to storing signals. Special types of repeaters serve other purposes, such as connecting multiplex channels to other channels and loops.

Relays perform vital functions in the operation of telegraph circuits and equipment. The modern high-speed polar relay operates efficiently and with precision. Figure 1 shows a common type of polar relay for use in high-speed d-c telegraph circuits. Figure 2 shows a plug-type polar relay, commonly used in d-c telegraph line circuits. Many other types of relays are employed in telegraph circuits, each designed to perform its particular function.

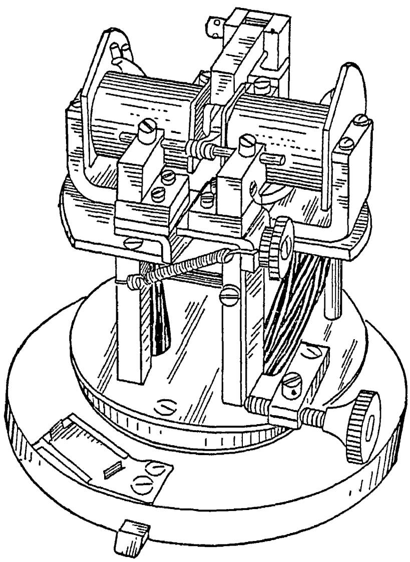


FIG. 1. Typical High-speed D-c Telegraph Polar Relay (Courtesy Western Union Telegraph Co., A.I.E.E., F. E. D'Humy, and P. J. Howe)

Multiplex distributors, as previously explained in this section, are devices having segmented and solid ring face plates, with which rotating brushes are in contact, and by means of which telegraph signals from one or more circuits are transmitted over a single telegraph line in sequence on a time-sharing basis. The face plates are removable and may be changed as desired to meet operating requirements.

The brushes are mounted on a shaft, driven by an impulse motor, which is synchronized with the motor of a multiplex set at the distant line terminal. For this reason, the start and stop pulses are not required, as they are for the teleprinter or teletypewriter, and only a five-unit code is employed per character for each circuit operating over the multiplex line.

The shaft between the motor and the brush assembly consists of two parts joined together by a magnetically operated ratchet device, by means of which the angular position of the brushes with respect to the motor rotor may be changed in steps of 1 $^1/_2$ angular degrees. The change may be made with the motor operating, if desired. A mercury-filled flywheel mounted on the motor shaft provides stability of rotation. The various connections to the distributor are brought out to multicontact bayonet-type plugs to provide for rapid replacement of the distributor in case of trouble. Figure 3 shows one type of multiplex distributor.

The *shaft speed* is determined by the required channel speed. For four-channel operation in each direction, at a channel speed of 66 words per minute, the shaft speed is about 396 rpm. However, the total message capacity for the line is 528 words per minute.

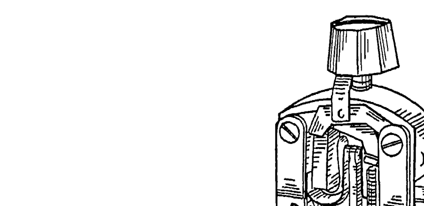

FIG. 2. Typical D-c Telegraph Relay for Line and Other Circuits (Courtesy Western Union Telegraph Co., A.I.E.E., F. E. D'Humy, and P. J. Howe)

Synchronization of speed between two multiplex sets at opposite ends of a multiplex circuit is accomplished by means of a *driving fork* associated with each set. This fork is magnetically vibrated and equipped with contacts to generate impulses from a d-c supply for operating the motor of the set. The frequency of vibration of the fork, and hence the motor speed, may be altered by changing the position of weights clamped to the fork tines. The normal fork frequency (without weights) is about 60 cycles per second, corresponding to a distributor speed of about 360 rpm. Forks with shorter tines are used for high-speed circuits. Figure 4 shows a drawing representative of a driving fork.

The **tape perforator** consists of a perforating mechanism, actuated by a keyboard unit, in which each individual key lever, with certain exceptions, is designated with an upper-and lower-case character. By operating the key levers when the perforator is in its operating condition, the characters corresponding to the keys operated will be punched in a paper tape in the standard five-unit code.

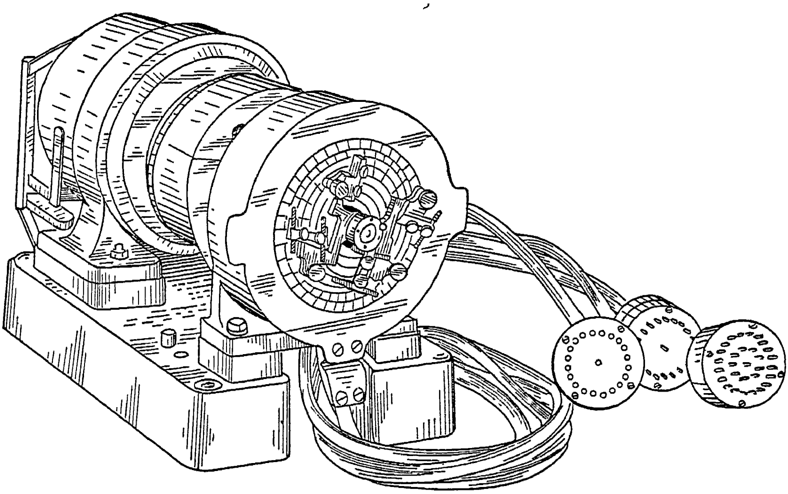

FIG. 3. Typical Rotary Distributor (Courtesy Western Union Telegraph Co., A.I.E.E., F. E. D'Humy, and P. J. Howe)

In one type of perforator design, a punch block contains six small cylindrical metallic fingers or punches, between the die plates of which block the tape is fed (see Fig. 5). A punch hammer, operated by a magnet, forces the punches through the tape as it passes the punch holes in the die plates. As each character is punched, the tape is moved forward one space by a pawl and feed roll, and the succeeding character is then punched. Five of the punches are for code perforations, and the sixth punch provides the feed holes in the center of the tape.

Between the punch hammer and the five punches are five punch bars, which are connected by bell cranks to five U-shaped bars (loops), pivoted at each end and held by

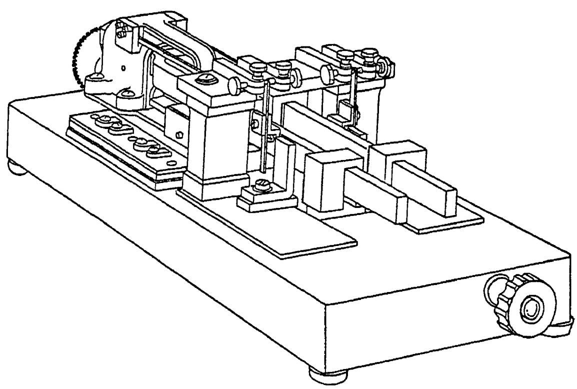

FIG. 4. Driving Fork Used in Multiplex Systems

means of springs so that their greatest length is in a horizontal position directly beneath the keyboard.

Attached to the lower edge of each key lever is a piece of metal, called a comb, which is cut out, so that depressing a key will cause its comb to strike the top edge of one or more of the loops and move them downward. The combs are cut differently for the different keys, resulting in a different combination for each key depressed.

The depression of any loop moves the corresponding punch bar from in front of its punch so that, when the punch hammer is operated by the magnet, the corresponding punch does not operate and the tape is not perforated by that punch. A sixth (power)

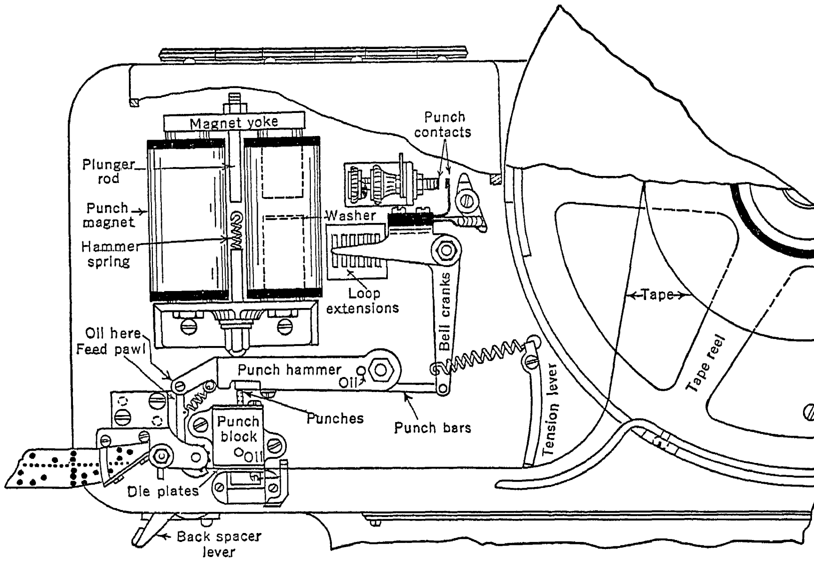

FIG. 5. Perforator Punching Mechanism (Courtesy Bell System)

loop, operated when any key is depressed, energizes the punch magnet, which actuates the punch hammer.

This perforator also provides for moving the tape backward for correction of errors and for indicating end of a line, so that the carriage return key can be operated to start a new line at the distant receiving machine.

The **typing reperforator** is a device for receiving messages from a telegraph circuit or transmitter and recording them in tape by five-unit code perforations and by printing the character on the tape above the corresponding perforations.

The **transmitter and transmitter-distributor** are devices for translating code perforations in tape into electrical impulses, which are transmitted over a connecting medium to a receiving device for interpretation as signals of intelligence. The perforations may be in a five-unit, six-unit, or other code, depending on the particular circuit requirements.

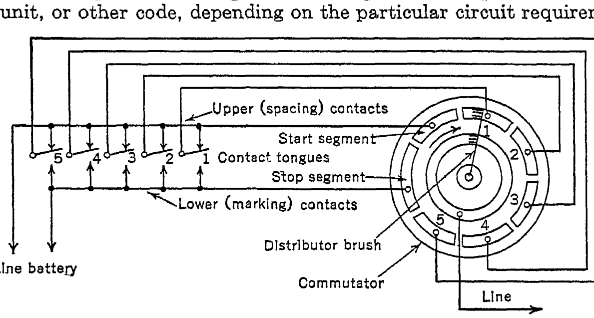

FIG. 6. Diagram Showing Transmitter Contacts Wired to Distributor Segments (Courtesy Bell System)

In the transmitter-distributor the tape transmitter establishes the code combinations to be transmitted, and the commutator distributor sends out these combinations over the line, as marking and spacing impulses, in their proper sequence and at the desired speed. Both units are driven by the same speed-regulated motor.

For one type of five-unit code transmitter-distributor, the five contact tongues (see diagram in Fig. 6) of the transmitter move between two sets of contacts, one set marking and the other set spacing. These tongues and the multipled marking and spacing contacts are connected to distributor segments. In "make-break" operation, battery is connected to the marking contacts only.

The tongues are mechanically connected to the ends of five pivoted contact levers, each of which has three extensions *A*, *B*, and *C*, as shown in Fig. 7. In the unoperated position of the contact lever bail (the position shown in Fig. 7), the contact lever springs pull down on the *A* extensions, causing the tape pins in the *C* extensions to press up against the tape but the upper contacts remain closed. Since the tape pins are spaced the same distance apart as the tape perforations, any pin will then pass through the tape if there is a perforation in the tape above it. When a pin moves through a perforation, the *A* extension is permitted to move down slightly under action of its spring, thus opening its spacing and closing its marking contact by the movement of its contact tongue. Where there is no perforation in the tape above a pin, the pin is held in its normal position against the

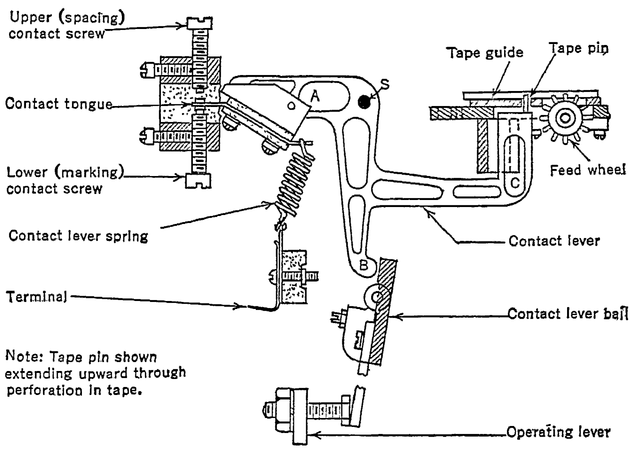

FIG. 7. Tape Transmitter Mechanism (Courtesy Bell System)

tape and its contact tongue remains on spacing. Thus, the code perforations in the tape determine the setting of each of the contact tongues either to marking or spacing, and hence the polarity of the distributor segments connected to the tongues.

After each character is transmitted, the contact tongues are reset to spacing by operation of the operating lever and contact lever bail. This bail moves the *B* extensions to the left, withdrawing the tape pins to a position below the tape guide surface, thus moving the contact tongues upward. Also, after each character is transmitted, a sixth (feed) lever is actuated, causing the tape feed mechanism to move the tape forward a distance equal to that between the character punches in the tape.

An automatic stop is mounted on the transmitter-distributor base to stop the transmitter if the associated perforator operation is interrupted or if its speed becomes less than that of the transmitter. This avoids tape mutilation by the transmitter. The stop consists of a light metal lever, suspended over the tape loop between perforator and transmitter, which is raised when the loop becomes tight, opening the control circuit of the transmitter.

Message conveyors are employed in the larger telegraph central offices to reduce the travel and handling time for messages that must be transported from one location to another in the same office or building. In the largest centers, the total number of messages handled daily may average 300,000 or more.

Pneumatic tubes provide a rapid and efficient means of transporting the original copies of messages, being commonly employed between branch and central offices and for intradepartmental use in large central-office buildings.

14. STATION EQUIPMENT

Station equipment intended for telegraph purposes is of various types and designs to meet the needs of the customer. A number of the equipment units are also applicable for use at customer premises, such as the teletypewriter, teleprinter, perforator, typing reperforator, transmitter-distributor, Telefax, ticker, clocks, and various other units. The station equipments discussed in the following paragraphs are additional to those previously discussed.

Printers. Two types of teletypewriters of the start-stop, five-unit code type have not been previously described. One is a motor-driven, single-magnet, fixed paper carriage, typebar, page printing type, operating normally at speeds of 240 to 368 operations (40 to 60 words) per minute. The paper may be in single sheet rolls, usually 8 or 8 1/2 in. wide, or two or more carbon copies may be made by using the proper paper assemblies.

The other is a teletypewriter, used where not more than one carbon copy is required and where a smaller machine than the first is desired by the customer. This machine is a motor-driven, single-magnet, moving paper carriage, typewheel, page printing type, operating normally at 368 operations per minute. It uses paper 8 1/2 in. wide, which may be multiple wound for one carbon copy.

Radio-interference-suppression apparatus (filters), consisting of inductance, capacitance, and resistance, are employed in station equipment, usually in a parallel-series relation, across various make-break contacts in the teletypewriter or teleprinter. One type of suppressor reduces induction at broadcasting frequencies, and another type provides suppression at both broadcasting and higher frequencies.

Selectors are used on important circuits to provide a convenient means for calling attendants at repeater or terminal stations to the circuit when trouble develops. They are also used on Morse wires and concentrators to enable one station to call another without calling in all the other stations on the same circuit. The selector, Fig. 8, contains a

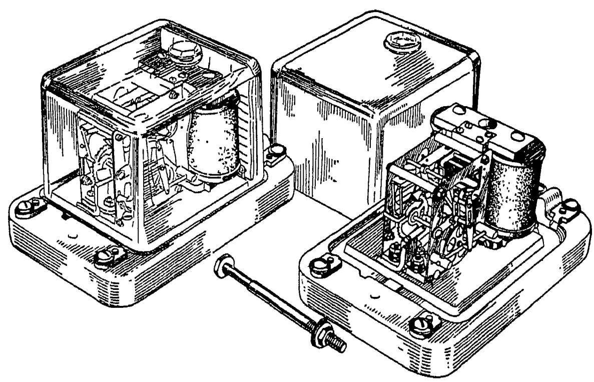

Fig. 8. Typical Telegraph Selector

magnet, normally connected with the line or line relay, which controls a mechanism arranged to close a set of local contacts only when the magnet is operated by the particular combination of impulses for which the selector mechanism is adjusted. The local contacts of the selector may be used to operate either visual or audible signals or to place the local receiving apparatus in an operative condition. Signal combinations for operating the selectors may be transmitted manually with a Morse key, or special clockwork-driven calling keys may be used for the purpose.

In Morse telegraphy manual operation is employed, but, owing to the growth of automatic transmission of messages, Morse operation is confined mainly to occasional local services over short-haul telegraph facilities, such as those to sporting-event locations, railroad-station offices, and small towns.

Morse circuits are operated either single or duplex, as conditions may require. Where several such circuits terminate at a central point, they are usually connected into a concentrating unit by means of which one operator can handle all the circuits so concentrated.

Figure 9 shows sketches of a Morse sending key, sounder, and relay.

The sending key has two contacts, normally held open by a spring, which are closed by manually depressing a key lever, which also depresses the spring. When the key is released, the spring causes the contacts to open. A second lever operates horizontally to close the circuit at the key when the key is not in use.

The sounder consists of an electromagnet and an armature which moves a sounding lever between two adjusting stop screws, the assembly being mounted on a sound-amplifying base. When the magnet is energized, the armature is drawn down until its stop screw contacts the metal frame, producing an audible click. When the magnet is de-energized, the armature is restored to its unoperated position by spring action, its outer end striking the upper stop screw, which produces a click.

Two of these clicks separated by a short interval are interpreted by the operator as a dot. For a longer interval between clicks (usually three times the interval between dots), the signal is interpreted as a dash. The armature travel and restoring spring tension can be adjusted to suit the operator.

Local sounders operate in local sounder circuits; they may be of low resistance (about 4 ohms), requiring an operating current of about 250 ma, or of high resistance (100 or 400 ohms), requiring operating currents of about 60 and 30 ma, respectively. *Main line sounders* are designed for operation in series with the main line circuit. These sounders may be adjusted so that their operation is not materially affected by line leakage, usually encountered, and their resistance may be 30, 100, or 120 ohms, depending on circuit requirements.

The relay consists of an electromagnet having one or more windings arranged to move an armature, which operates between a set of contacts. Signaling impulses, passing through the operating winding of the relay, cause the armature to move to its proper contact, in accordance with the type of impulse received, thus repeating the sent signals in a local circuit connected to the relay contacts.

The type of relay shown in Fig. 9 usually is equipped with a magnet having 25, 100, or 150 ohms resistance.

TRANSMISSION-MAINTENANCE

By John D. Taylor

15. TRANSMISSION STANDARDS

Signal transmission is considered perfect in any telegraph circuit or connection if the received effective marks and spaces or dots and dashes are exactly the same length as the sent marks and spaces or dots and dashes. In practice, signals which may be nearly perfect as sent are affected during transmission by circuit constants, such as the inductance, capacitance, resistance, and leakage of the line conductors, by equipment characteristics, and by various forms of interference. It has been found that, with present operating arrangements, bias changes, large fortuitous distortion (usually termed "hits"), and smaller but more frequent fortuitous distortion (see discussion in Article 5) are the principal causes of transmission impairment.

In designing telegraph facilities, both line and equipment, the general problem is to provide a satisfactory grade of service in the most economical and convenient manner that will meet public and operating needs. The trend is toward automatic transmission in the telegraph just as it is in the telephone field, in order to increase the speed of service most efficiently.

Because of the many types of facilities employed in the telegraph plant, different telegraph circuits affect telegraph signals differently, and, in order for the signal transmission to be satisfactory in any given circuit layout, it is necessary to know in advance what these effects will be.

Since, in the present state of the art, distance is not a limiting factor in the transmission of telegraph signals, direct telegraph circuits may be provided from any point to any other point in the world by choosing the proper equipment and transmitting media for such circuits.

16. TRANSMISSION COEFFICIENTS

One of the large communication companies in the United States in 1926 developed a system (since improved) of transmission ratings of telegraph circuits and equipment, based on signal-distortion measurements and on experience gained from operating performance. This system is based on the fact that, since the distribution of distortions follows the normal distribution law, ratings or coefficients, chosen as proportional to the mean-squared values of the distortions, could be added directly to give the overall coefficient for any combination of circuit units for which coefficients were available.

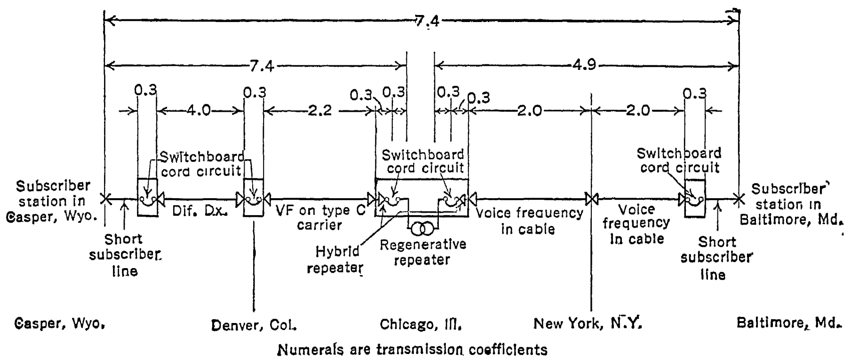

FIG. 1. Diagram of Typical Teletypewriter Exchange Service Connection Requiring a Regenerative Repeater (Courtesy Bell System)

The magnitude of these coefficients was selected so that, for satisfactory signal transmission, the overall combined coefficient should not exceed a value of 10. Where this value was exceeded in a given circuit layout, it would be necessary, by some means, to reduce the signal distortion. For start-stop telegraph equipment, the regenerative repeater is available for correcting signal distortion. It is customary to insert them in a circuit or at the junction of circuits to limit the overall coefficient to 10, as shown in Fig. 1.

Duplex telegraph repeaters of the differential type are employed at intermediate points in long d-c telegraph circuits with ground return to increase signal strength. These repeaters are usually spaced about 250 miles apart, although this distance varies over a comparatively wide range, depending on the types of line facilities, equipment, interference, operating speeds, and other factors involved. These intermediate repeaters do not correct distortion but repeat the signals through from section to section. For this reason, regenerative repeaters or other distortion-correcting devices are generally required every two or three repeater sections.

17. CROSSFIRE

Crossfire neutralization between polar duplex grounded telegraph circuits is necessary where this form of electrical interference becomes objectionable. As the speed of operation increases, crossfire between such circuits assumes greater importance.

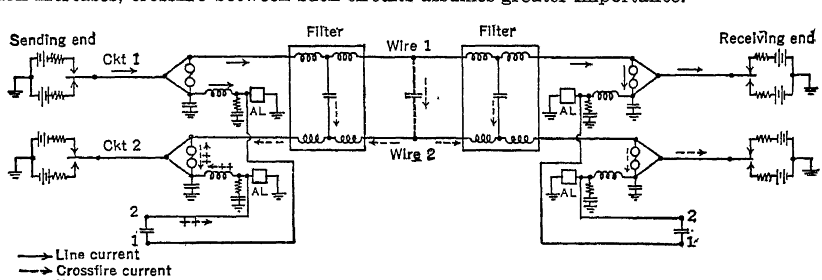

FIG. 2. Neutralization of Crossfire Current at the Sending Terminal (Courtesy Bell System)

Crossfire is caused by the mutual inductance and capacitance between the telegraph circuits and by leakage. Though the major part of this interference is due to the close physical relation between the paralleling open wires and cable conductors, some of it results from couplings in equipment common to two or more of the paralleling conductors, as in composite sets, line filters, and loading coils. In general, the magnitude of the interference is proportional to the length of the line wire and cable conductor parallel. In cable, the coupling is much greater than in open wire, and, if more than two duplex telegraph circuits are derived from one quad, the crossfire usually becomes prohibitive, even for comparatively short distances, unless neutralization is applied.

Figure 2 shows one method of neutralizing crossfire currents at the sending end without affecting these currents at the receiving end of a polar duplex circuit. Figure 3 shows one

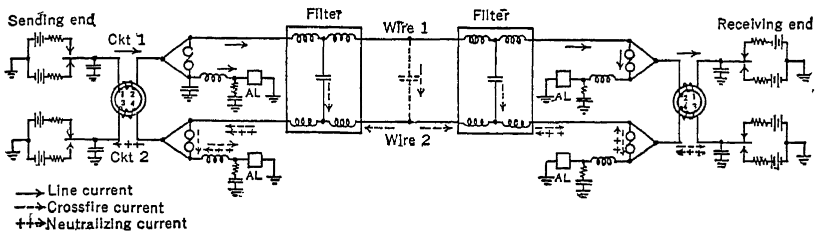

FIG. 3. Neutralization of Crossfire Current at the Receiving Terminal (Courtesy Bell System)

method of neutralizing crossfire currents at the receiving end without affecting these currents at the sending end of a polar duplex circuit. In some cases, neutralization at the sending or the receiving end only will be sufficient; in the more severe cases, both methods will be required.

For sending end neutralization, a properly adjusted condenser is employed between the artificial lines of the two circuits shown, causing currents to be set up between them in an opposing direction to the crossfire currents. For receiving end neutralization, a transformer is inserted in the apexes of the two duplex sets, which, by proper poling and adjustment of the coupling, sets up currents opposing the crossfire currents.

18. MAINTENANCE

The proper maintenance of telegraph facilities plays a vital part in providing the public with telegraph service of a satisfactory grade. For this purpose, various types of testboards and testing equipment have been developed and routines established to insure that the facilities are properly maintained.

TESTING EQUIPMENT developed for maintaining telegraph facilities includes such principal units as:

1. *Monitoring machines* with sending and receiving units, for checking the transmission of telegraph signals.
2. *Test distributors*, sending substantially perfect signals for lining up and testing telegraph circuits and apparatus. One type is for the central-office and another for portable use.
3. *Automatic multiple senders*, providing sources of battery reversals and of test signals for teletypewriter circuits.
4. *Telegraph signal biasing sets*, providing sources of biased battery reversals and teletypewriter test signals of the inverse neutral type; also providing for measuring bias from a distant sending end.
5. *Telegraph transmission stability test set*, giving quantitative indications on a recording meter of the freedom from bias of a series of received reversals.
6. *Telegraph station test set*, for testing at outlying stations or small central offices, to indicate distortion of received signals and assist in determining wave-shaping network requirements.
7. *Telegraph transmission measuring set*, indicating directly on meters the distortion in signal reversals from start-stop machines. One meter indicates bias (average) distortion and another meter the peak value of the total distortion (instantaneous sum of bias, characteristic, and fortuitous effects). One type of set is for the central office and another is for portable use.
8. *Telegraph crossfire test set*, for determining the proper values of capacitance and resistance for neutralizing sending-end crossfire and the proper inductance couplings for neutralizing receiving-end crossfire between grounded polar duplex telegraph circuits.

9. *Hit indicators*, giving locked in indications of short-duration line disturbances, sufficiently large to cause or almost cause the receiving relay to leave its marking contact, or when an initial spacing impulse of a message is received from the line.

10. *Orientation-testing indicator (portable type)*, for adjusting the orientation of a certain type of regenerative repeater.

11. *Hit suppressor unit*, for preventing certain forms of interference on private-line telegraph facilities from being transmitted in a certain direction beyond the line section or sections in which the hits occur.

12. *Carrier telegraph test set*, for maintaining carrier telegraph systems, including filament circuit tests and a drift measuring circuit for compensator relay bias adjustments.

13. *Frequency-measuring devices*, for checking carrier frequencies used in carrier telegraph systems.

RADIO TELEGRAPH SYSTEMS

By J. L. Finch

In radio telegraph communications it is necessary to have a transmitter, and a receiver and an operator's position. For the less important circuits these are often located together under the control of one operator who alternately sends and receives messages. This method of operation is known as the simplex method. For more important circuits the transmitter and the receiver are arranged for simultaneous operation, and this is known as the duplex method. In the duplex method it is usually advisable to have the transmitter and receiver located at different points to reduce interference troubles. This arrangement becomes increasingly important as more transmitters and receivers are used. When it is necessary to locate the transmitters and receivers at the same point, as on shipboard, special precautions must be taken to prevent mutual interference and the frequency separation between transmitted and received signals must be kept relatively great.

When ratio communication is carried on to and from large cities it is the usual practice to have a central office in the city with both the transmitting and the receiving centers located well outside the city and connected by wire lines or by ultra-high-frequency radio control circuits.

19. CHOICE OF TRANSMITTER AND RECEIVER SITES

The sites are usually chosen where ample level space is available for directional antennas for each communication circuit planned. The availability of a dependable power supply and of reliable control channels is a further consideration. The receiving centers are usually located where man-made static is low. It is desirable that hills and mountains in front of the antennas do not rise at an angle of more than 3° for long-distance communication at short waves, although angles of as much as 5° can usually be tolerated. For shorter distances the angles may be greater. The land immediately in front of an antenna has a direct bearing on the vertical directivity and should be level. For long waves, mountains and valleys within a fraction of a wavelength have little effect on the antenna directivity.

20. CHOICE OF FREQUENCIES

The most desirable frequency to be used between any two points depends upon many factors which vary with time of day, season of year, position in the sunspot cycle, occurrence of magnetic storms, and location of the great-circle path over which the signals must travel with respect to the aurora areas centered about the earth's magnetic poles. These factors are mostly related to wave propagation and are described in article 10-23. Usable frequencies start at about 10 kc and extend as high as 30,000 Mc. The very low frequencies are propagated effectively and are relatively steady and consistent, but they require very large and expensive antenna systems, particularly at the transmitting end, in order to radiate even a small percentage of the generated power. At the receiving end extensive antennas are required to get good directivity and thus a favorable signal-to-noise ratio. Further, the transmitting antennas must be very sharply tuned in order to be efficient, and this fact limits their modulation capabilities to relatively low keying rates. It should be noted that propagation at frequencies from 50 kc to 30 Mc is subject to wide fluctuation.

Commercial companies have found it worth while to maintain and operate long-wave facilities which are already in existence for use during magnetic storms and to serve for re-establishing contact with the remote points after short waves have suddenly faded out.

Frequencies between 3 and 25 Mc have been found the most useful for long-distance communications. Those between 3 and 10–13 Mc are useful over these long distances when most or all of the radio path is in darkness while those from 10–13 to 25 Mc are useful when most or all of the path is in daylight. The lower of these frequencies are useful over shorter distances in the daytime. The same frequencies can be used successively in different parts of the world as the daylight and darkness areas progress around the earth.

Frequencies above 30 Mc are rarely useful for extensive periods for long distances (over 2500 miles) and those above 50 Mc can be relied upon as a rule not to carry to distant points on the earth's surface and so can be used over and over again on circuits separated by only a few hundred miles. Because signals at these higher frequencies will not bend very much, an optical path or one approaching an optical path between the transmitting and receiving antennas is necessary.

21. REDUCTION OF FADING EFFECTS

The use of short waves for communicating over long distances is very frequently beset with fading caused by the alternate addition and subtraction of the signal arriving over different ether paths. This is due to the varying phase relation of the arriving radio-frequency waves. It has been found that much of this fading is very local in character. When a signal has faded out at one location it may be coming in at full strength a few hundred feet away. Also when at a given point one radio frequency has faded out completely, another frequency only a few hundred cycles different being radiated from the same transmitting antenna may be coming in at full strength at this point. Receiving systems which employ two or more receiving antennas spaced apart geographically are known as *space diversity receiving systems*. The telegraphic signals received by each antenna are rectified and passed through a limiter which cuts off the tops of all the characters that would exceed a certain value. The various signals are then combined in such a manner that all of them must fade at once to cause a signal failure. When using three separated receiving antennas this diversity effect reduces the failures due to fading to a very small fraction of that suffered by the signal received on any one of the antennas. Systems that transmit two or more slightly different radio frequencies from one antenna are termed *frequency diversity systems*. In this case the same receiving equipment is used as otherwise, since the different radio frequencies being received are so close together that the receiver responds to all of them substantially equally. The limiting used is such that all frequencies must fade out at once to cause a signal failure. This system results in a very marked increase in the reliability of the circuit.

To obtain the different frequency components required in the transmitter output for frequency diversity it is usual to phase-modulate the carrier at an audio rate of about 600 cycles and with a maximum phase deviation of about 1 radian. This modulation results in the production of two side frequencies spaced 600 cycles each side of the carrier. The amplitude of each side frequency is a little less than half the amplitude of the unmodulated carrier. Phase modulation can be accomplished quite simply, and it does not necessitate reduction of the total power generated by the transmitter.

It is common practice to key two different transmitters operating at different frequencies with the same signals and to combine the outputs of two receivers at the traffic office to insure against service interruptions, particularly at the time of day when one of the frequencies is about to fade out and it is desired to replace it with another.

22. RADIO INTERFERENCE

Interference between radio channels should be eliminated by spacing the frequencies sufficiently far apart and by making the receivers selective enough to differentiate between the desired and undesired signals. The radiation at unauthorized frequencies such as at harmonics of the desired frequency wave must be avoided. In some types of transmitters, frequencies lower than the desired ones are generated and then the desired harmonic is radiated. The radiation of these lower frequencies must be avoided. Vacuum-tube transmitters are prone to generate spurious or parasitic frequencies. The radiation of such frequencies must be avoided. These parasitic frequencies often modulate the desired frequency wave, resulting in modulation sidebands which will be radiated with the desired wave if allowed to exist and will cause interference on other channels. Often when a transmitter is free from parasitic oscillations in the steady state, both marking and spacing, such oscillations occur during the transient period at the beginning and end of signaling characters. These oscillations are known as key-click parasitic oscillations. Other interchannel interference sometimes results from the modulation products or side frequencies generated by the keying, these being particularly noticeable at high signaling speeds and when the characters are square ended. To round the characters to reduce these side frequencies when using efficient class C amplifiers in the transmitter and with on-off keying is difficult and expensive. When using "frequency shift" or "two-tone" keying, however, the signal characters can be rounded quite simply and the objectionable side-frequency radiations greatly reduced. Two transmitters at the same station, particularly when operating at closely spaced frequencies, sometimes intermodulate each other and radiate signals in adjacent bands. This can usually be made negligible by reducing the cross coupling between the two systems.

Receivers may cause interference with other receivers, usually due to radiation from the first heterodyne oscillator into the room and into the receiver power wires and into the receiving antenna. It is particularly important to avoid radiation back into the antenna of a level of more than 1 microvolt when one antenna is used with a number of receivers at various and variable frequencies.

23. FREQUENCY SHIFT KEYING

It has been the general practice in the past to key transmitters by interrupting the transmitter output power. Recently equipment has been developed to take advantage of the "frequency shift keying" system, also known as the "two-tone keying" system. This method employs one radio frequency for "mark" and a second radio frequency for "space," each at the same power. The separation between the two is not critical. At present a separation of 850 cycles is in common use. To reduce key-click interference in adjacent channels it is desirable to shift the frequency of a single oscillator and at a rate only sufficient to accommodate the required keying speed.

In receiving frequency shift signals, amplitude variations are limited out by the use of a limiter stage. The resulting signals of fixed amplitude and variable frequency are impressed upon a discriminator the output of which may operate a relay device, tone keyer, or other utilization device. The limiter stage largely eliminates the effect of atmospheric or other interference whose strength is lower than 3 db below the signal.

Results have indicated that in practice the transmitter power can be reduced as much as 10 db, after adopting the frequency shift keying system, without degrading the service.

24. TRAFFIC OFFICE AND EQUIPMENT

In central offices carrying small volumes of traffic, particularly over radio circuits of inferior reliability, it is advantageous to have the transmitting and receiving positions located adjacent to each other. This is for convenience in asking and giving acknowledgments and for "breaking" the circuit. For handling larger volumes of traffic over a number of reliable circuits, it is advantageous to arrange the transmitting positions in one group and the receiving positions in another.

Intelligence can be transmitted over radio telegraph circuits in the Morse code or by means of automatic printers using their own special codes. For the simplest equipment Morse signals are transmitted by hand and received aurally and transcribed by hand or on a typewriter. For higher speeds and more reliable service automatic sending and receiving is used. The messages are punched on a typewriter-like machine known as a *perforator*. A sample tape is shown in Fig. 1. The tape is run through an *auto-head* device which has electrical contacts and which form the Morse characters corresponding to the letters punched. The received signals operate an ink tape *recorder*. These recorders commonly involve a moving tape with a pen pressed against it. The pen is retained in its lower position for "space" and in its upper position for "mark," making a record as shown in Fig. 1. Automatic Morse communication is practical at speeds of 20 to 500 words per minute.

For average speeds up to 40 or 50 words per minute one operator at the transmitting end perforates the tape and tends to the auto-head machine. At the receiving end one operator views this tape as the message is recorded and transcribes the messages on a typewriter. For higher speeds of transmission the tape must be punched by two or more operators and sections fed successively into the auto-head. The recorder tape must be divided between two or more receiving operators for transcription.

Automatic printers are advantageous in that they make it unnecessary for the operators to learn the code, they reduce human errors in transcribing from code signals, and they permit automatic transcription of incoming messages directly in a form suitable for delivery to the customer. Their use, however, eliminates the possibility of detecting errors

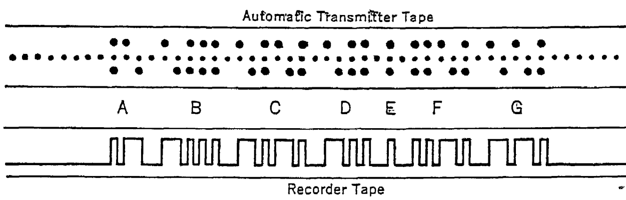

FIG. 1. Tapes for Automatic Sending and Receiving

due to mutilation of the signals introduced in the radio path. Frequently a trained operator can transcribe correctly a mutilated signal such as would cause a printer to make an error or to operate an error-indicating device. Further, the transmission speed is limited to that at which a printer will function properly, i.e., to speeds of 60 to 100 words per minute. The printers in general use employ a five-unit code and respond to any combination of signals whether mutilated or not. An error-indicating printer is in use which employs a seven-unit code. All operations use three marking and four spacing elements. Any other combination will operate an error-indicating device.

In connection with radio telegraphy it is customary to rate transmission speeds in words per minute, each word consisting of an average of five letters. More accurately, each word consists of 48 units * or minimum elements, each unit being taken as the length of one dot or one space between dots, and the length of dashes and spaces between letters being equal to three units. From this it can be calculated that when the auto-head is running at a rate to make 40 dots per second the transmission rate will be 100 words per minute. Similarly printer speeds are calculated on the basis of six operations per word, allowing five characters and one space per word.

MULTIPLEX. In order to make use of the high signaling speed capabilities of short-wave radio circuits and still enjoy the advantage of automatic printer operation at nominal speeds, means have been devised for dividing the total time available for transmission between two or more channels. This system is known as time division multiplex (see article 7). This system can also be used for Morse operation; it is advantageous because each channel can be copied as it comes in, and thus delays in message delivery caused by the necessity of dividing tape received at high speeds between two or more operators can be avoided.

MULTICHANNEL. A second method of obtaining more than one telegraph channel on a single radio circuit utilizes single-sideband equipment such as has been developed primarily for telephone service. Such a system can carry a large number of individual tones, each keyed as desired with printer signals or Morse signals and each separated from the others at the receiving end by means of wave filters.

Both the multiplex and the multichannel systems are more expensive initially and more costly to maintain and operate than single-channel systems, but they are worth while when large volumes of traffic are to be handled because they save space in the radio spectrum and at the same time provide for printer operation or Morse operation at speeds that can be transcribed currently.

* The term "baud" has, in some sections of the industry, been applied to these units. In the officially correct usage the baud is the unit of telegraphic speed or of rapidity of modulation corresponding to one minimum element per second.

25. CONTROL CHANNELS

The signals must be carried from the central office to the transmitting station, and from the receiving station to the central office, over suitable control channels. These channels can be carried over wire lines or over ultra-high-frequency radio circuits. When wire lines are available d-c signals may be used, either unidirectional or polarized (plus and minus), or keyed tone signals may be employed. The tone signals have the advantage that a number of them can be carried over one tone pair and separated by wave filters (see article 11-10). When ultra-high-frequency radio control circuits are used, keyed tone signals are employed. A number of similar groups of tone signals can be transmitted over a single radio circuit by a system similar to the voice-carrier system as described in article 17-9.

TONE KEYERS. The keying device or tape transmitter device in the central office usually closes an electric circuit by means of a pair of contacts for marking and opens it for spacing. This action is made to key a tone by means of a tone keyer such as that shown in Fig. 2. The equivalent results can be accomplished by purely electronic means

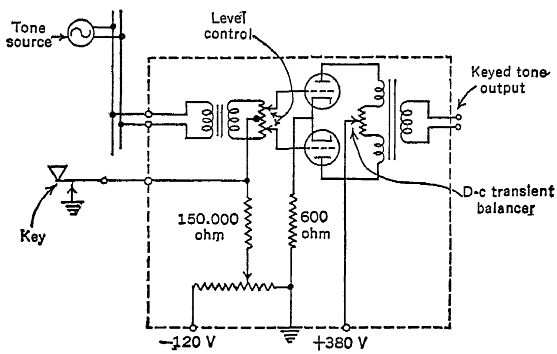

FIG. 2. Circuit Diagram of a Tone Keyer

applying the same general principles. Tone keyers are also used at the receiving station by means of which the incoming signal is made to key a tone for transmission to the central office.

TONE SIGNAL CONVERTERS. At the transmitting station the tone signals must be converted into d-c signals to key the transmitter. The device for accomplishing this is known as a *tone signal converter* and may take the form shown in Fig. 3. This embodies a

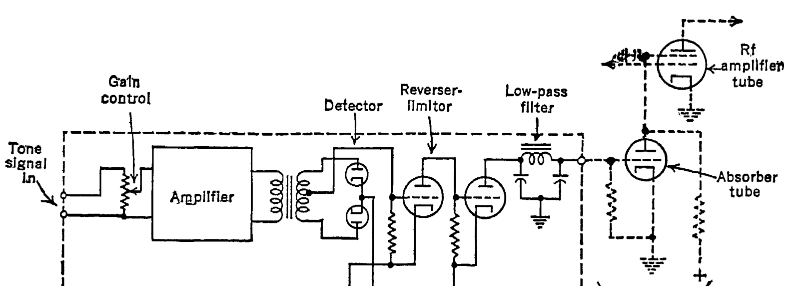

FIG. 3. Circuit Diagram of a Tone Signal Converter

threshold device for suppressing low-level noise and for preventing tails on the characters from causing "heavy" signals. It embodies a *limiter* for cutting off the tops of the signals and a low-pass filter to smooth out the rectified tone and thus to keep the signals from being modulated by the tone itself. The gain control is used for setting the level of the tone signals, which usually have been rounded by passing through the wave filters of the tone channel to give the correct "weight" of signals in the transmitter. Lowering the gain makes the signals lighter, and raising it makes them heavier.

RECORDER DRIVE. At the central office the incoming tone signals must be converted to direct current to drive the ink tape recorder or printer relay. The device for accomplishing this may take the form shown in Fig. 4. A simple tone rectifier circuit will usually suffice for driving the printer relay for printer service.

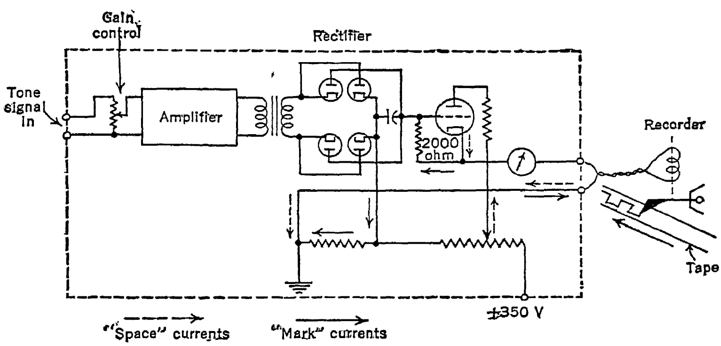

FIG. 4. Circuit Diagram of a Recorder Driving Unit

BANDWIDTHS. The transmission of keyed tone signals requires a definite band which must have a width roughly proportioned to the keying speed. Satisfactory service may be achieved by allowing for the transmission of no more than the first side frequency of the keying speed under stable input conditions and stable transmission characteristics such as are normally achieved in first-class lines. Thus for 125 words per minute Morse, i.e., a keying frequency of 50 dots per second, the usable channel width must be at least 100 cycles. For unstable conditions it is desirable to transmit the first, second, and third side frequencies. Thus, a 100-cycle band width will be suitable for speeds of 42 words per minute. In actual practice 100-cycle bands have been found suitable for speeds up to 60 words per minute.

SECTION 19

FACSIMILE TRANSMISSION AND RECEPTION

BY

MAURICE ARTZT

FACSIMILE TRANSMISSION AND RECEPTION

By Maurice Artzt

SCANNING SYSTEMS

Facsimile is defined to include all systems whereby a picture is broken into separate picture elements, these elements being transmitted by some connecting means to a distant recorder where they are reassembled into their original positions to form a copy of the original. The word "picture" in the above statement includes also diagrams, typing, handwriting, photographs, and any other form of printed or written material.

Three distinct operations are performed in the transmitting and recording of facsimiles: first, the breaking up of the picture in some orderly manner into its separate elements of varying shades, this process being called scanning; second, the transmitting of these elements to the recorder by means of signals arranged to represent the electrical equivalent of these elements; third, the rebuilding of these signals by a recorder into a printed copy of the original by a reversal of the scanning process.

A fourth part of a facsimile system, supplementary but very necessary, is a method of synchronizing the recorder and scanner. The timing of the signals received must agree exactly with the timing of the recorder, in phase as well as frequency, if the copy received is to be undistorted.

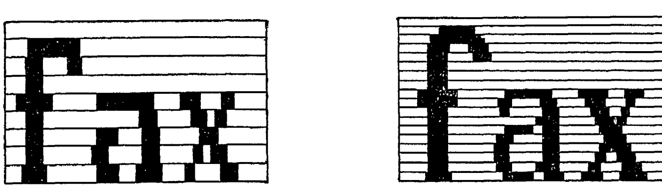
In the following articles the terms used are in accordance with the definitions and standards as set up in 1942 by the Institute of Radio Engineers. See the first reference in the Bibliography.

1. PICTURE ELEMENTS

In processing a picture by facsimile, the picture is resolved into dots, or picture elements, similar to the small dots used in printing a picture in a newspaper or magazine. These dots are obtained by "screening" in the printing process; they are obtained by scanning in facsimile.

Halftones in newspaper work have from 60 to 120 dots, or picture elements, per inch, whereas fine magazine printing may use as many as 250 dots per inch. In facsimile the limits are of about the same order, almost all present facsimile systems using 100 dots (or lines) per inch, as an average. Each picture element in a facsimile is sent as a separate signal. If the number of dots is too high, the speed of transmission is very slow; if too few elements are used, the detail will not be good enough. To send a picture of 100 dots per inch requires as many as 10,000 separate signals per square inch of surface covered.

Figure 1 illustrates the difference to be expected between 50 and 100 lines per inch, when the subject matter is ordinary typing. Some of the type would be unreadable if only 50



(*a*) 50 lines per inch (*b*) 100 lines per inch

FIG. 1. Difference in Detail for 50 and 100 Lines per Inch for Typewritten Letters

lines per inch were used, as can be seen by the poor formation of the *a*. The 100-line-per-inch detail, though not forming perfect letters, leaves no doubt as to their identity. In commercial facsimile, letters from ordinary typewriters often comprise the original, and approximately 100 lines per inch are necessary to insure readability.

Dots per inch and lines per inch are used interchangeably in the above paragraph, a practice which is not always permissible. Some facsimile systems break the subject up into dots and send a separate signal for each dot, whether white, black, or gray. Others, however, break the sheet up into parallel lines and send signals only for the black areas as encountered. Each line is then a continuous signal, varying in intensity with the shading of the original, and not made up of an exact number of picture elements as the dotted picture is. The detail limits are the same in either case, and the maximum number of picture elements per square inch is the same.

These picture elements, as observed by the scanner in the process of transmission, will be of two general types, either of the simple black-and-white variety, such as typing, line drawings, and so forth, or of the halftone variety, in which all shades of gray from white to black may occur. Two separate types of scanners are not necessary, but the amplifier equipment will sometimes be different. Any system capable of transmitting and recording halftones will also operate properly on a purely black-and-white original, but the reverse is not necessarily true.

2. SCANNERS

A facsimile scanning system includes an optical-mechanical scanner designed to project a small spot of light on the subject copy, to gather the reflected or transmitted light from

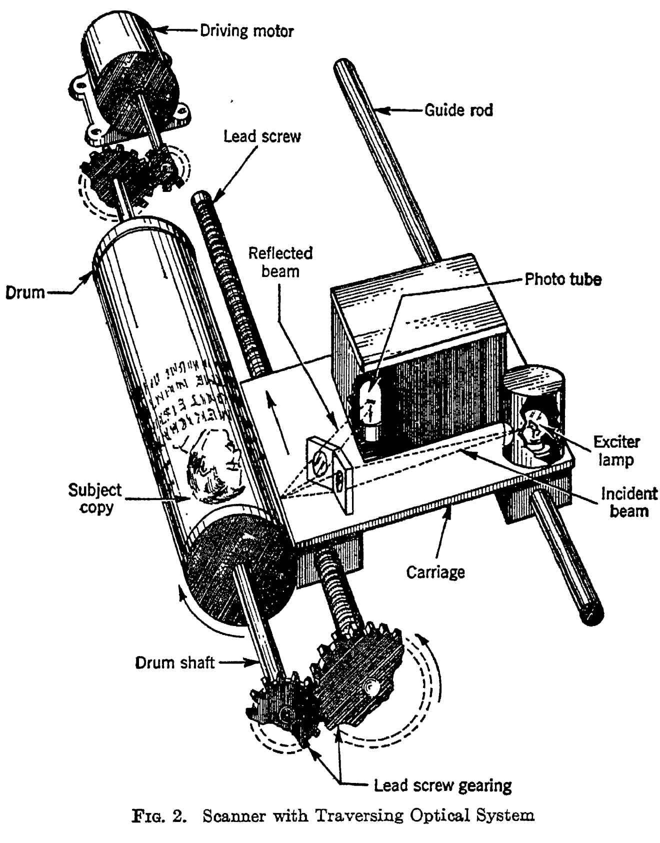


Fig. 2. Scanner with Traversing Optical System

the subject into a phototube, and to bring all parts of the subject under this scanning spot in some orderly manner. The signals generated in the phototube by the varying light values reflected from the copy are then either amplified directly or processed in other ways to form a usable electrical signal of a type suited for the particular application.

SCANNING METHODS. In the simplest form of scanning, regular lines are "ruled" across the sheet by this spot of light at some particular number of lines per inch, and signals are sent out representing each small area as it is encountered. The sheet is thus broken into a number of narrow lines, all of the same width, and these lines are transmitted one after another until the entire subject has been covered.

Scanning is generally done in only one direction and seldom back and forth. There are two reasons for this: first a unidirectional scanner is simpler to construct and requires less precision in gearing, and second the synchronizing system for back-and-forth scanning must be far more accurate.

The simplest form of the scanner, and therefore the one most generally used, consists of a drum upon which the original subject matter is wrapped, and an optical system arranged to project a small spot of light on the surface of the paper. This spot is usually somewhat smaller than the width of one scanning line. As the drum is revolved, the optical system is moved relative to the drum the width of one scanning line for each revolution of the drum. The entire subject is thus gradually passed under the scanning spot. See Fig. 2.

A phototube is arranged to pick up the light reflected from the surface of the paper, and this light reaching the phototube will be varied in intensity by the different areas of black, gray, and white that may be presented to view. The output of the phototube will be a minimum for black and maximum for white and will represent electrically the scanning of the copy. This phototube output is then applied to the input of the amplifier system.

All motions in the scanning process pictured in Fig. 2 are relative. Thus the optical system may be rotated in place of the drum, and the motion along the axis may be made by moving either the drum or the optical system relative to each other. All methods of bringing about this relative motion have been used.

In one commercial type of scanner used for news picture transmission the drum is revolved and moved along the axis by a lead screw cut on its shaft, and the optical system is stationary. See Fig. 3.

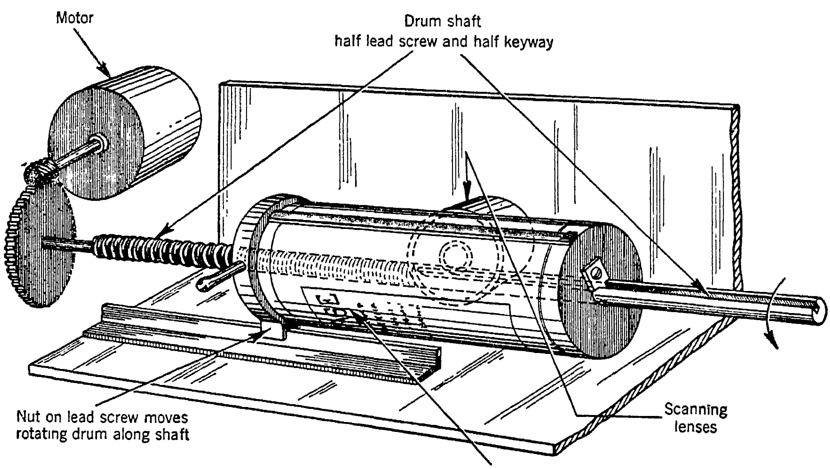

FIG. 3. Scanner with Stationary Optics and Drum Feeding for Line Advance

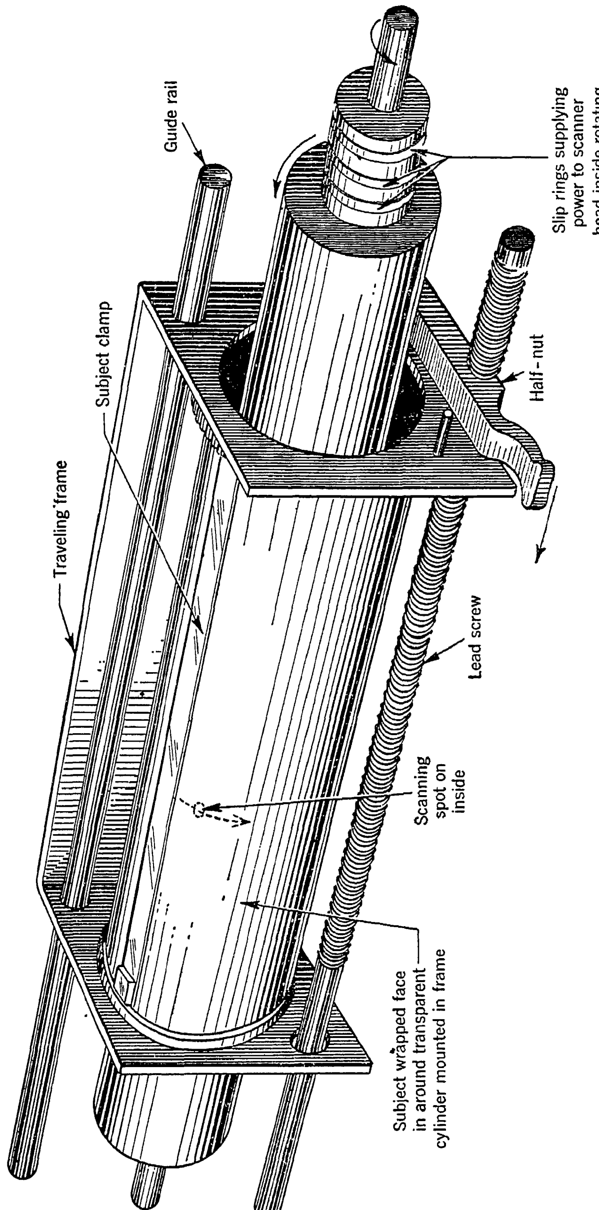
As facsimile speeds have increased, the time required to load the subject on a drum has become an increasingly greater proportion of the total time of transmission of the copy. Various ingenious methods of loading and scanning have been devised to minimize this loss of time. In one form of scanner designed for rapid loading, the subject is wrapped face in around a transparent cylinder, and the optical system is rotated inside this cylinder. See Fig. 4. By this method the scanning process does not have to be stopped to remove one subject and put another in place. Thus the time to resynchronize and rephase for the next subject is not lost, and the time between succeeding subjects is reduced.

In all scanners illustrated thus far the original must be of such size that it can be properly clamped on the scanning drum. Thus copy width must be approximately the circumference of the drum, minus the separation between clamps. The length is not so restricted and may be anything up to the length of the drum. Another type of scanner in which width is not restricted except as to a maximum value is shown in Fig. 5. The subject is placed face in on a stationary transparent semicylinder and held there by a curtain (not shown). Two microscopes and light pick-up systems are rotated and traversed inside to scan the copy. The two optical systems are set exactly 180° apart and in the same plane so that the signals



4

Fig. 4. Scanner with Internal Optical System and Drum Feeding for Line Advance

generated in the single phototube will be the equivalent of that from a single optical system scanning a complete cylinder. With this scanner, unloading and reloading takes only a few seconds as the copy is not clamped to hold it in place. As two optical systems are used the shaft speed will be one-half that of an equivalent drum scanner.

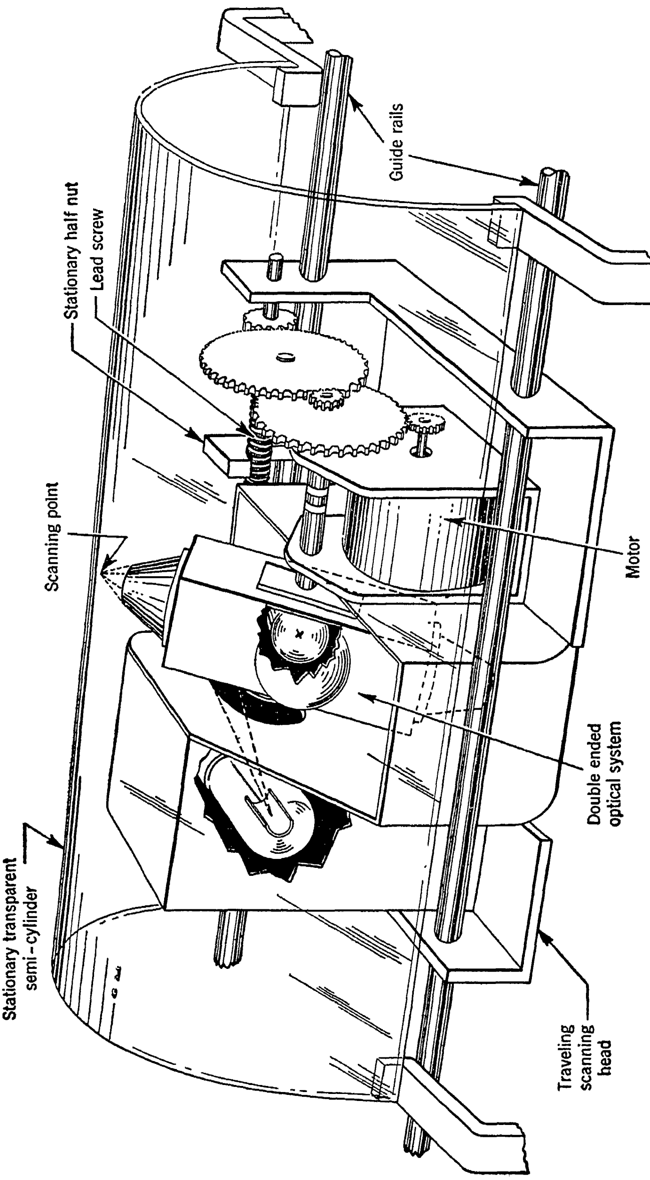


FIG. 5. Scanner with Internal Optical System Feeding for Line Advance

In one other type of scanner used for telegraph service reloading with the next message is accomplished by dropping out the drum and copy when scanning is completed and reloading with another drum containing the next message from a hopper feed. This is done automatically, and provision is made for accommodating a number of additional message-carrying drums so that the messages follow one another in rapid succession.

3. SCANNER AMPLIFIERS

The signals generated by the phototube will vary in amplitude with the shading on the subject being scanned, and in frequency with the speed of the scanning spot and the kind of subject copy. The highest frequency will be determined by the size of the smallest "dot" it is expected to transmit; the lowest frequency will be zero or a direct current to represent the large areas of white or black encountered in nearly all types of copy.

FREQUENCY SPECTRUM. The highest frequency is determined as follows: Take the width of the smallest "dot" it is expected to transmit and rule a pattern of lines of this width, separating them by the width of the dot. If the scanning is to be at 100 lines per inch then these lines will be 0.01 in. in width, 50 to the inch, and separated by 0.01 in. Such a pattern is shown in Fig. 6*A*. The fundamental keying frequency of the phototube current

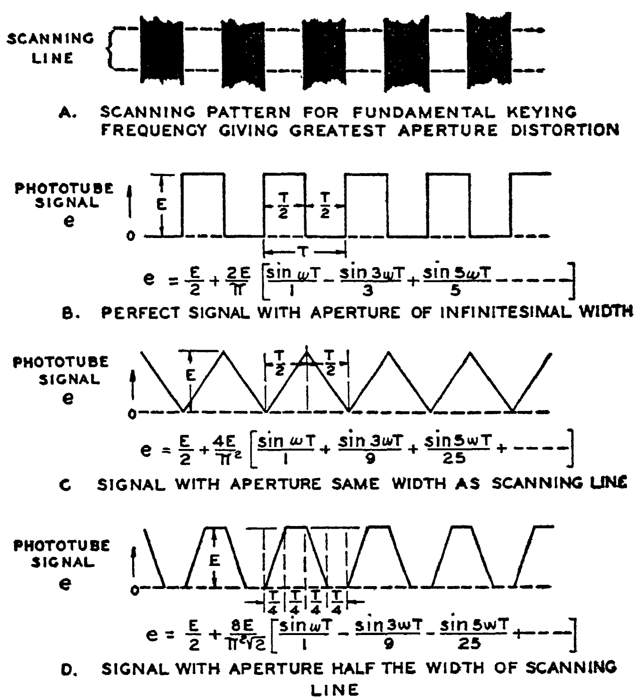

FIG. 6. Aperture Distortion of Signals

when scanning such a pattern would be 50 cycles per inch per second of spot speed. If the scanning line were 9 in. long and the drum speed 100 rpm, the fundamental keying frequency would be 50 x 9 x 100/60 = 750 cycles per second.

Higher harmonics of this fundamental keying frequency will be present as the subject scanned is a square wave pattern. If the aperture of the scanner were infinitesimal in width along the scanning line the phototube signal would be a square wave as in Fig. 6*B* and would be very rich in harmonics as shown by the Fourier series under this figure. This perfect signal is never realized in practice, nor is it desirable, for the greatly increased band width needed for transmission is not justified by the small increase in recorded detail over that obtained by carrying only the fundamental keying frequency.

As the aperture is made wider the higher harmonics become less important. When the aperture is the width of the scanning line the triangular wave in Fig. 6*C* is obtained. Here the fundamental is 81 per cent and the third harmonic 9 per cent as compared to 127 and 42.5 per cent for the square wave. When the aperture is one-half the width of the scanning line, a condition normally used in many scanners, the wave in Fig. 6*D* is obtained where the fundamental is 115 per cent and the third harmonic 12.75 per cent. When using this size of aperture very little difference can be noticed in the recorded copy whether the third harmonic is carried or suppressed. For a more complete analysis of scanning see Section 20, Television.

Almost all facsimile systems therefore carry only through the fundamental keying frequency as the upper limit of the band necessary for transmission. In the illustration given where this fundamental frequency was 750 cycles the signals from the phototube would have a frequency spectrum of 0 to 750 cycles per second. This then is the input signal to the scanner amplifier system, and, as the light reflected into the phototube is small, the input signal is usually very low in amplitude.

TYPES OF SCANNER AMPLIFIER SIGNALS. The type of amplifier used in either amplifying or processing the phototube signal will depend on the types of signal to be used in transmission, and this in turn will be governed to some extent by the transmission medium, whether it be wire line or radio. As the lower frequency limit is zero, ordinary a-c coupled audio amplifiers cannot be used. In order to carry this zero frequency or d-c component, the phototube signal is usually caused to modulate a carrier wave either in amplitude or frequency. For transmission over wire lines the carrier frequency will be chosen just high enough to carry the highest keying frequency. For radio transmission the radio carrier itself can be amplitude or frequency modulated directly by the facsimile signals, or a phone-type transmitter may be used and the facsimile modulation carried on an audio subcarrier as for wire line transmission. Finally, for short distances over wire line where no repeater stations or coupling transformers are used, a straight d-c amplifier may be used between phototube and line. As it is difficult to maintain drift-free operation of a d-c amplifier with sufficient amplification, this last method is seldom chosen.

The signals transmitted to the recorder may thus be of any one of the following types:

1. Subcarrier amplitude modulation (SCAM).
2. Subcarrier frequency modulation (SCFM).
3. Radio carrier amplitude modulation.
   a. Direct without subcarrier.
   b. With SCAM.
   c. With SCFM.
4. Radio carrier frequency modulation.
   a. Direct without subcarrier.
   b. With SCAM.
   c. With SCFM.
5. Direct-current signals.

For wire line transmission, signals of type 1 or 2 are commonly used, with 5 occasionally on short control lines, for instance between scanner and radio transmitter. It is more usual, however, if d-c signals are wanted to control a radio transmitter, to transmit signals of types 1 or 2 on the control line and detect to obtain the d-c signals for control purposes.

For radio transmission over long distances signals of types 3*c* or 4*a* are normally used as they give the most reliable results. For short radio circuits, as for instance local coverage for broadcast facsimile service, 3*c*, 4*b*, or 4*c* can be used on existing voice transmitters.

Signals of types 3*a* and 3*b* are unreliable except for very short distances and have generally been supplanted by 3*c* if an a-m radio transmitter is used.

TYPES OF SCANNER AMPLIFIERS. It can be seen by the general usage of the various signals that the two important types of amplifier systems will be either for amplitude-modulating a subcarrier or frequency-modulating a subcarrier. Where d-c signals are required it is customary to use either one of these and then detect after amplifying to the desired level.

SUBCARRIER AMPLITUDE MODULATION METHODS. There are three general methods of obtaining signals of this type. First, from the standpoint of the length of time it has been in use, is scanning with chopped light. If the light reaching the phototube is made to flicker, either by modulating the light itself or by using a mechanical shutter or chopper, the output voltage developed by the phototube will not be a direct current but a pulsating voltage which may readily be amplified by an ordinary a-c amplifier.

The minimum frequency of chopping will be determined by the fundamental keying frequency of the scanning process; the chopper frequency will be the carrier frequency and must be high enough to carry the shortest "dot." In practice the chopper frequency is usually made between 2 and 3 times the fundamental keying frequency, with $2^1/_2$ a good average. In the previous example, with a keying frequency of 750 cycles per second, a carrier or chopper frequency of about 1800 cycles would be used. The total bandwidth transmitted would therefore be 1800 ± 750, or 1050 to 2550 cycles. This bandwidth is narrow enough to be carried on regular voice telephone circuits and is so used for many news picture transmissions.

When an ordinary incandescent lamp is the light source, the chopper can be either a rotating disk with holes or slots, or a ribbon or reed vibrating in a magnetic field. When a glow-discharge lamp is the light source, such as used in some types of recorders, the light can be modulated directly without mechanical shutters. The same lamp can thus serve for scanning or for photographic recording on the same machine.

Two other methods of obtaining a-m signals are shown in Figs. 7 and 8. In the first the carrier is fed to the special phototube in a balanced bridge circuit, and a balance for minimum output signal is obtained by means of the variable resistor and capacitor with the phototube dark. As light from the subject copy increases, the tone output of the phototube increases and a true modulation results. A simple audio amplifier to build up the modulated signals to the required level follows the phototube circuit shown.

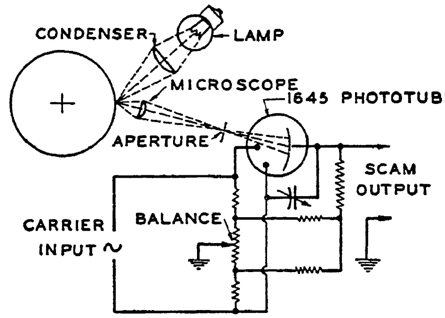

FIG. 7. Subcarrier Amplitude-modulated (SCAM) Signals Obtained by Balanced Phototube Circuit

In Fig. 8, the carrier is fed at 180° phase difference to the two screens of a pair of screen-grid tubes. The plates are connected together so the outputs of the two tubes oppose each other. By proper balancing of grid biases the output tone may be balanced to zero with the phototube dark. As light to the phototube increases, the bridge is unbalanced and the difference in output of the two tubes is obtained. With this circuit it is also possible to balance for minimum signal with maximum light for white on the phototube, and the output tone will then be a maximum for black. Thus either positive or negative modulation may be obtained by shift of the balance adjustments.

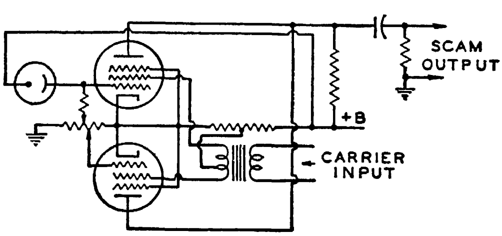

FIG. 8. Subcarrier Amplitude-modulated (SCAM) Signals Obtained by Balanced Modulator

In either of these circuits the frequency of the introduced carrier must be high enough to carry the maximum keying frequency, as explained previously with the light chopper systems.

SUBCARRIER F-M METHODS. In this type of signal black is transmitted at one frequency, white at some different frequency either higher or lower than that for black, and intervening shades of gray at proportionate frequencies between these two limits. A more complicated relationship exists between carrier, keying frequency, frequency swing, and bandwidth required than with the a-m subcarrier. This is, of course, a true frequency modulation and follows the same rules on sidebands as frequency modulation on a radio carrier. (See Section 8 on frequency modulation.) However, it has been found that, with a unity ratio of maximum keying frequency to the total frequency swing from black to white, the usable bandwidth will be confined to about the same overall limits as the a-m subcarrier with both upper and lower sidebands. Again, as with SCAM, the lowest carrier frequency must be high enough to carry the shortest dot, so the low end of the carrier swing should be at least 2 times the keying frequency. For the example with a keying frequency of 750 cycles, the carrier may swing from 1500 to 2250 cycles in going from white to black, and the total band spread (for all side frequencies greater than 10 per cent) will be from 1125 to 2625 cycles. The mid frequency for middle gray will be 1875 cycles, and only the first side frequency of $\pm$ 750 cycles need be carried.

This is only a deviation ratio of 0.5 at the highest keying frequency, but for all other picture frequencies the ratio is higher and for solid white backgrounds is practically infinite. The signal-to-noise improvement over SCAM averages at least 12db for the usual subject matter transmitted. Still greater improvement in signal-to-noise ratio would result from increased swing, but at an increase in bandwidth that is not justified in most facsimile services.

Two methods of obtaining this type of signal are in use. The first, shown in Fig. 9, consists essentially of a beat oscillator with one of the oscillators being shifted over a small percentage of its frequency by a reactance tube. As the light to the phototube increases, the frequency of the variable oscillator will be lowered. The two oscillators are set at sufficiently high frequencies so that the reactance tube can readily swing the required number of cycles without changing amplitude. For the swing of 1500 cycles on white to 2250 cycles on black the fixed oscillator could be set at 100,000 cycles and the variable one swung over the range from 102,250, with the phototube dark, to 101,500 cycles with the phototube receiving maximum light for white.

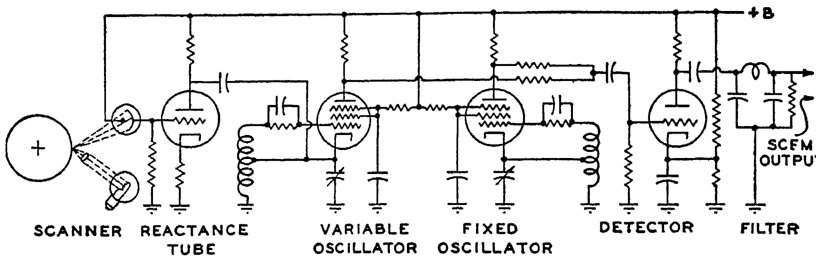

FIG. 9. Use of Reactance Tube and Beat Oscillator to Obtain Subcarrier Frequency-modulated (SCFM) Scanner Signals

A second method of obtaining SCFM signals directly, without heterodyning to obtain the low frequencies, is shown in Fig. 10. A resistance-capacitance oscillator of the 180° phase shift type is varied in frequency directly by using a tube control system as a variable resistor in one mesh of the phase shifting ladder network. When the control tube has zero input (phototube dark) the bias is adjusted to set the low-frequency end of the swing. As light to the phototube increases, the tube resistances decrease and the frequency of the oscillator is raised. Input volume from the phototube is adjusted so that the high-frequency end of the swing is just reached for white. When the proper network and tube constants are chosen, a linear range as high as 2 to 1 in frequency may be obtained with little change in amplitude.

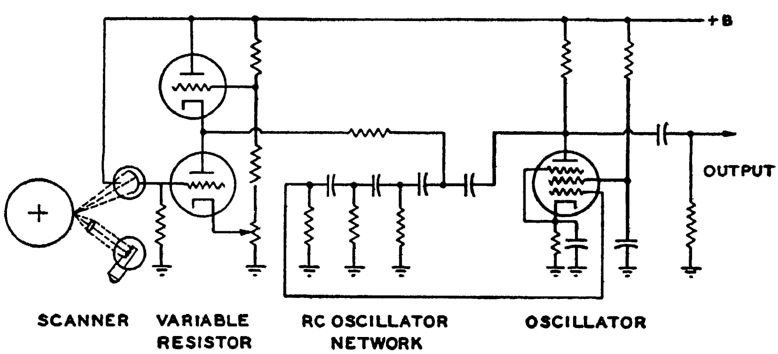

FIG. 10. Use of Tube Control on RC Oscillator to Obtain Subcarrier Frequency-modulated (SCFM) Scanner Signals

This circuit, when connected as shown, will give positive modulation, that is, an increase in frequency for an increase in light. To obtain negative modulation a reversing tube may be connected between the control grid and phototube, or the phototube may be reversed and connected anode to grid, and cathode to a negative supply potential below ground.

The changes in frequency with this circuit are very nearly instantaneous, because there is little stored energy in the network. At the same time, the frequency stability is adequate for the purpose.

It is sometimes necessary to use an existing scanning amplifier system having a-m output and still transmit signals of the SCFM type. A converter is then used in which the SCAM signals are rectified and filtered to obtain the original facsimile signals, and these are then applied to the control grid of an SCFM generator of either of the above types.

RECORDING SYSTEMS

A perfect facsimile recorder will build up a copy of the signals exactly as received, adding or subtracting nothing, and thus deliver a recording limited in detail only by the scanner and intervening transmitting circuit. The finished picture will be almost identical in appearance to the original copy.

Of the many recording methods, the four most generally used will be described here: photographic recording; wet electrolytic recording; dry electrolytic recording; and carbon-paper recording. Each of these systems has advantages possessed by none of the others and, therefore, will have particular uses to which it is the best adapted.

The length of the scanning line and the number of scanning lines per inch are generally the same as for the scanner, but this agreement is not necessary. The recorder copy may be made smaller or larger than the original by properly choosing the proportions of scanning-line length to line advance. The product of the total length of the scanning line and the number of lines per inch is called the index of cooperation; if this value is held constant, any size recording may be made with all dimensions correctly proportioned to those of the original copy. Thus, if the scanner has a total line length of 9 in. and is transmitting at 100 lines per inch, the index of cooperation would be 9 x 100 = 900. If it is desired to receive this picture on a recorder having a scanning-line length of only 4.5 in., the line advance would be made 200 lines per inch, and the received copy would be exactly one-half size.

Other than this index of cooperation, the other essential factor is the number of lines transmitted per minute. This is (often) termed "strokes," and the "per minute," which should be added, is understood. Thus the numbers 40–900 would signify a facsimile picture having an index of cooperation of 900 and transmitted at the rate of 40 strokes per minute.

4. PHOTOGRAPHIC RECORDING

In recording photographically, the sensitized paper or film is generally wrapped on the surface of a drum and is scanned by a small spot of light. The light spot is varied in intensity or size to record the different values of picture density. It may be varied in several ways—electrically, mechanically, or by means of polarization. In the electrically varied light, a neon or other gas discharge lamp is modulated in intensity by the signals. With the mechanical system, the light is steady, and varied either in intensity or size of spot by means of a vibrating shutter or diaphragm. In the polarized system, the Kerr cell is interposed between the light source and the picture drum, and the light is polarized before reaching the cell. The angle of polarization of the cell is changed by the picture signals, allowing more or less light to reach the picture.

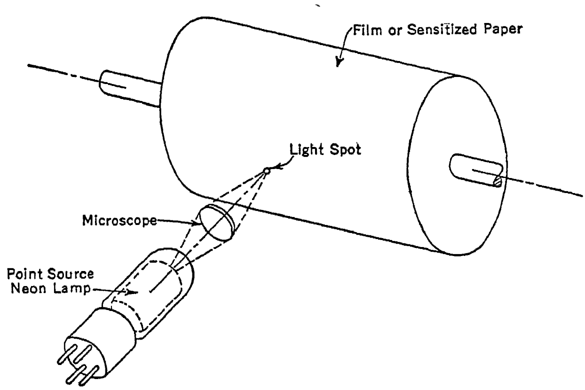

FIG. 1. Photographic Recorder, Using a Neon Lamp

The first method is more generally used in this country, and a simple recorder of this type is shown in Fig. 1. Here the lamp is of the "point-source" type. An intense illumination is produced in a small aperture within the lamp itself, and an image of this aperture is projected onto the surface of the drum by a lens system. The spacings of the lamp and lens system are so arranged that the aperture image is exactly the width of a scanning line. If several values of line advance are to be used with the same optical system, a variable diaphragm is introduced to regulate the size of the image to the proper value for the line width desired.

The relative motions of the optical system and drum may be any of those used in the simple drum scanner. Usually the drum is rotated while the optical system is gradually advanced along its surface.

The second method of photographic recording involves "valving" the amount of light reaching the paper from a steady light source, usually a tungsten-filament lamp. This can be done by placing an oscillograph mirror and aperture in the light path, the position of the mirror being varied electrically to change the area of the aperture exposed. As the amount of light will be directly proportional to area, a smooth variation of light with signal is obtained. Another method consists of placing a thin ribbon in the light path, just closing an aperture. As the ribbon is twisted by the incoming signals, light is allowed to pass through the aperture on both sides of the ribbon. This system produces a "variable width line" type of recording similar in appearance to a zinc etching, or, if the aperture is placed at 90° to the scanning direction, it will produce lines of constant width but variable density.

In the third method of using polarized light, a Kerr cell is utilized to change the light intensity. The optical system consists of two Nicol prisms placed between the light source and the aperture. These prisms are polarized in the same plane and therefore pass light through the system. The Kerr cell is interposed between the prisms, and applying signals to its polarizing plates will change its light-polarizing properties. The amount of light leaving the system is therefore controlled, and a true modulation of the light may be obtained. This system has been used for a number of years in Europe.

The photographic system is far the most accurate in its ability to reproduce completely the signals received and therefore is used in almost all commercial picture circuits. It has one serious disadvantage, however, in that the received picture must be developed before the results are known. The machine must be loaded and operated in the dark. In a fast service this developing is quite a handicap, and the fact that the picture cannot be seen until developed allows possible errors in the setting of the equipment to go unnoticed until the full time of transmission and developing has elapsed.

Most picture circuits are operated at speeds of 6 to 10 square inches per minute, this low speed usually being due to circuit limitations. With adequate light and sensitive films, the photographic recorder is capable of speeds far in excess of this value.

5. WET ELECTROLYTIC RECORDING

Electrolytic recording is similar to photographic recording in chemical action but has the advantage of being visible at once, or almost at once. It may or may not require some form of processing to make the recording permanent, depending on the chemicals used.

The principle of operation is that certain chemicals turn very dark when an electric current is passed through them. If a paper is saturated with such a chemical and scanned by a stylus contact, it may be darkened by current at each signal for black and thus build up the facsimile picture.

The common solutions are organic dyes, though silver or iron salts have sometimes been used as in photography or blueprinting. Some of these solutions react very rapidly but require high current density to bring about a dense enough black; others react with much less current but require some form of washing or fixing to prevent fading.

One recording solution, which gives a dense black permanent recording, used a special steel printer bar that is gradually worn away in the recording process. This chemical process is capable of speeds up to 50 square inches per minute. The chemistry of the color formation is given in U. S. patent 2,358,839. Another type of recording solution, which uses a platinum bar that does not take part in the chemistry of recording, is given in U. S. patent 2,306,471. The dye formed in this case may be any one of several of the azo dye family, and is usually of a deep purple color. Speeds up to 160 square inches per minute have been obtained with this type of solution.

A machine using a stylus would be a simple drum scanner with a dragging contact point on the surface of the paper. Another form of electrolytic recorder requires a continuous roll of supply paper and prints one picture after another without reloading. One form of this continuous type of recorder is shown in Fig. 2.

Here the scanning is done by a combination of a printer bar and a helix on opposite sides of the paper. The raised helix rotates at the same speed as the scanner drum, thus making one complete turn in the length of a scanning line. The point of intersection of this helix and bar will therefore travel across the paper once for each scanning line. Current for printing is passed between the helix and bar, through the paper. The bar is sprung slightly and allowed to drag over the damp paper surface to secure good contact.

In this machine the paper must be moist to conduct the printer current and allow the chemical reaction to take place. For the particular machine described, the paper is impregnated with the chemicals and kept at the proper moisture content by storing in sealed cans. The recorder itself is of moisture-tight construction so that the moisture in the paper is retained until after printing.

In another form of electrolytic recorder a dry untreated paper is threaded through a trough containing the recording chemicals before being fed between the helix and printer bar. After printing it passes over a hot ironing roll to dry and smooth out the recording.

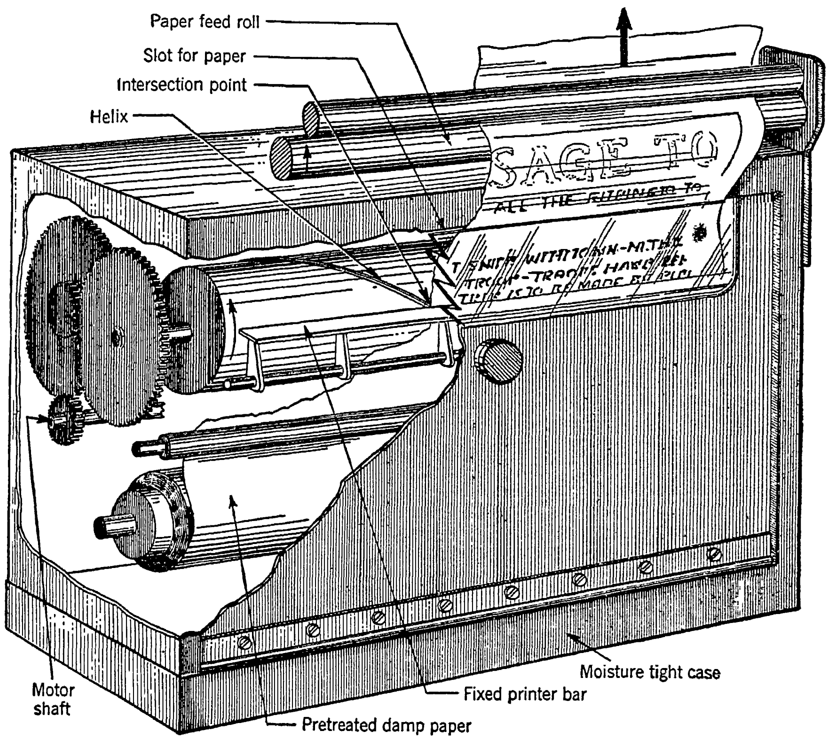

FIG. 2. Recorder Using Wet Electrolytic Paper

The advantages of this type of recorder are its simplicity, its visible recording feature, and the extremely high speeds of which it is capable. Recording speeds as high as 80 or 90 square inches per minute at 120 lines per inch definition are easily attained, allowing a full-sized page of 8 $^1/_2$ by 11 inches to be recorded in 1 minute. Though the handling of wet paper in the machine is awkward, this disadvantage is outweighed in many applications by the speed of recording.

6. DRY ELECTROLYTIC RECORDING

Several dry electrolytic recording papers have been developed for message service facsimile recording: they are much easier to handle than the wet electrolytic papers. though not capable of as high a recording speed. The best known of these, trade-named Teledeltos, has a light gray coating on a dense black paper base that has high electrical conductivity. When current is passed from a small stylus through the paper the metallic coating is burned away, leaving the black paper underneath exposed. The facsimile recording is built up by scanning with a stylus and partially or completely burning the coating where gray or black are to appear. See Fig. 3.

The advantages of this type of recording are that a permanent copy is produced with no processing, the dry paper is easy to handle, and the recorder, with only a stylus and drum,

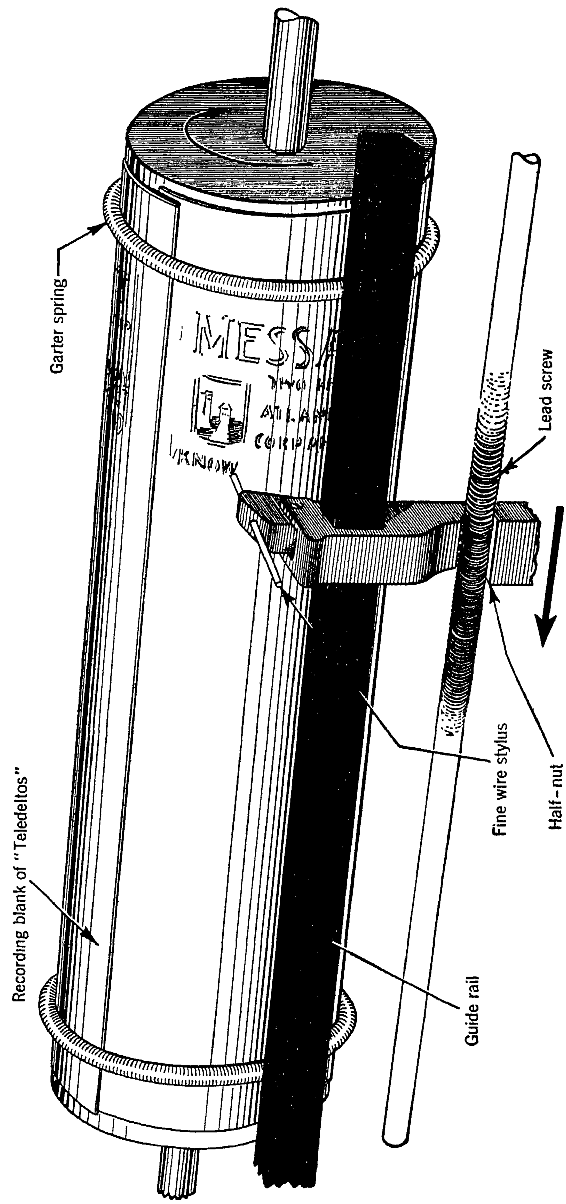

FIG. 3. Recorder Using Dry (Teledeltos) Paper

is mechanically simple. The disadvantages are that the contrast range of the finished copy is reduced by the gray background, and the halftone scale is not as linear as the photographic or electrolytic recorders. These do not greatly affect its value for message service where the subject matter is almost entirely made up of typing or handwriting.

7. CARBON-PAPER RECORDING

The first carbon recorder consisted of a stylus dragging over carbon and white papers wrapped on a drum. The stylus was moved down to give pressure for black, and lifted for white. This is a very simple form of recorder, but it has the disadvantage of the photographic recorder in that the picture is not visible until the drum is stopped and the carbon paper removed. It has the advantages of cheapness and simplicity, and the picture requires no processing to be permanent.

A later form of carbon recorder, illustrated in cross-section in Fig. 4, overcomes the disadvantage of invisible recording. Here the scanning is accomplished with a helix and printer bar, as in the continuous electrolytic recorder. Carbon and white paper are fed between the bar and helix, and after this are separated so that the surface of the white

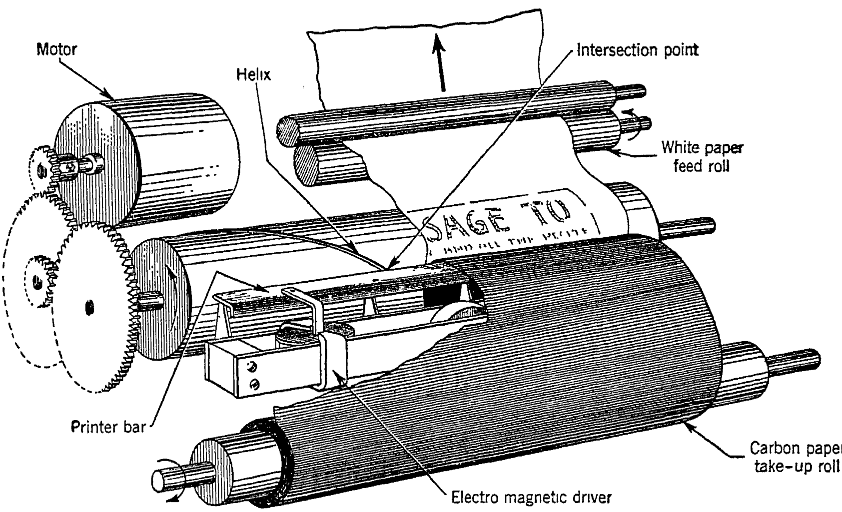

FIG. 4. Continuous-feed Carbon Recorder

paper is visible only a few seconds after the printing process. The bar is not allowed to drag the paper but is normally held away from it by an electromagnetic drive unit.

A signal for black depresses the bar, and a black dot is made by the pressure at the intersection of the bar and helix. The carbon paper is drawn over guides and wound up on a take-up spindle. The white paper is fed by a knurled feed roll with a series of rubber idlers held against it, similar to the paper feed of a typewriter.

Only one electromagnetic driver is shown for the printer bar. However, if wide paper is used, more than one driver may be necessary and the separate units will be equally spaced along the bar.

This method of recording is very simple, uses cheap paper, and prints a very good copy at speeds up to 10 square inches per minute. It is quite reliable, and the complete copy, with no processing necessary, is visible only a few seconds after recording. Its limitations are also pronounced. The printer bar is necessarily heavier than a stylus, and therefore the speed of recording is limited. Almost any carbon paper that may be used here will be soft enough to smudge a little when rubbed in the fingers, the same as a carbon copy from a typewriter. More mechanical accuracy is required in building this printing bar than in the electrolytic recorder, as the bar and helix must be parallel to within a few thousandths of an inch. The depressive motion of the bar is quite small, and, therefore, a little discrepancy in lining up the bar and helix will result in failure of part of the paper to be printed to a full black. Damping of the bar to eliminate "bouncing" and echo printing is somewhat of a problem, but it can be solved by over-powering the printing mechanism and absorbing the excess power in a damping arrangement on the bar itself.

One advantage mentioned separately here for emphasis is that this type of recorder may be used to print more than one copy at a time. If the printer bar action is made sufficiently powerful, several rolls of white and carbon paper may be threaded into the machine and a number of copies of the facsimile made at the same time. As many as 8 separate copies of a message have been made experimentally. Also the carbon paper may be of the "hectograph" type and extra copies of the recording may then be made by the usual duplication process of hectographing.

8. COMPARISON OF RECORDING METHODS

The recording method chosen for some particular service will depend on the quality of the copy required, speed of transmission, cost of the recording paper, ease of operation, and many other factors. In a news picture service, quality of the finished recording is most important, for the pictures are used as masters to make printing plates. Photographic recording is therefore used for all these pictures, the other factors being considered of less importance. Operating speeds are maintained as high as the wire lines or radio circuits will permit, generally 9 or 10 square inches per minute with 100 lines per inch detail.

For message services, speed of transmission is the most important, with simplified equipment able to run unattended as a next requirement. With somewhat limited bandwidths available over wire lines, the high speed of the wet electrolytic process cannot be attained, and the dry electrolytic process with its simpler recorder structure more readily fits the requirements. Operating speeds up to 30 or 40 square inches per minute can be maintained with this type of recording, if the transmission band of the line will permit. The more usual speed over most lines available for this type of service is 16 to 20 square inches per minute.

The requirements for broadcast facsimile of flash news services are primarily for medium speed, direct printing, and a minimum paper cost. Though the wet electrolytic recorder does not use the cheapest paper, it meets the other requirements on speed and direct printing. The copy appearance is pleasing, and the detail is adequate even at higher speeds than those now contemplated. Such broadcast services will probably be most effective at speeds of around 30 square inches per minute. Less than this is too slow, and higher speeds will tend to increase apparatus and paper costs too greatly.

Carbon recording uses the cheapest paper and can run unattended for long periods of time. However, it is the slowest of the recording methods, owing to the mechanical motion required of the printer bar. Its highest operating speed at present is about 10 square inches per minute, inadequate for most services but sufficient in some special instances where speed is less important.

9. RECORDING AMPLIFIERS

The signals received for facsimile recording will usually be in the form of an a-m or f-m tone. This may be either the original SCAM or SCFM tone transmitted over line or radio by the scanner, or it may be one obtained by heterodyning in a radio transmission of direct frequency modulation. If of the SCAM type, the signals will be applied directly to one of the recording amplifiers described later. If of the SCFM type the signals must first be changed into an equivalent SCAM signal by limiting and then passing the constant-amplitude signal through a slope demodulating filter.

Such a converter unit is shown in Fig. 5. The incoming SCFM signal presumably will have spurious amplitude modulation superimposed by fading if received by radio or

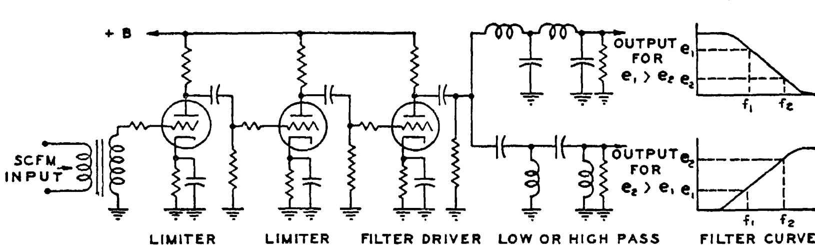

FIG. 5. Limiter Amplifier and Slope Demodulating Filters for SCFM-type Signals

changes in line transmission characteristics if received by wire line. Therefore it is first passed through a limiter amplifier of several stages, so that the limiter output signal will be of constant amplitude over wide changes in input level. This constant-amplitude signal then goes through either a low- or a high-pass filter, or both if pushpull output is desired.

These filters are designed to have slow, straight cut off slopes so that the amplitude of the output signals will vary linearly with frequency.

In the circuit shown the two end frequencies of the SCFM swing are labeled f_1 and f_2 for the white and black frequencies. If demodulated in the upper filter the output will be greatest for f_1 and least for f_2, while the output of the lower filter is the opposite. For undistorted demodulation these filter slopes must be linear beyond the band from f_1 to f_2 by

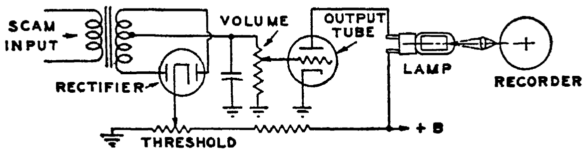

FIG. 6. Printer Amplifier for Maximum Output Current with Minimum Signal Amplitude

the amount of the side frequency spread of the SCFM wave. For the previous example of a swing of 1500 cycles for white to 2250 cycles for black, and band spread from 1125 to 2625 cycles, the filter slope must be linear over the entire range from 1125 to 2625 cycles.

The output of either slope filter will be the equivalent of an SCAM signal in amplitude envelope and can be used in the printer amplifier in the same manner.

Four simplified diagrams of printer amplifiers to actuate the various types of recorders are shown in Figs. 6, 7, 8, and 9. The first two are suitable for photographic recorders using a glow discharge lamp to expose the film or paper. In each the SCAM signal is rectified and

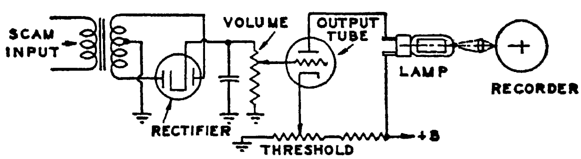

FIG. 7. Printer Amplifier for Maximum Output Current with Maximum Signal Amplitude

filtered by a capacitor across the volume control to obtain the facsimile signals. The output tube is then either driven to lower output current as signal amplitude increases, as in Fig. 6, or to higher output current as amplitude increases, as in Fig. 7. The particular one used will depend on the direction of modulation of the signal, and whether the drum is loaded with film to make a negative or with photographic paper to make a positive copy.

For recorders using a pushpull magnetically driven printer, or driver units of a carbon recorder, these two types of amplifiers may be combined, as in Fig. 8. As signal amplitude increases, the upper output tube will be driven to lower current and the lower tube to higher

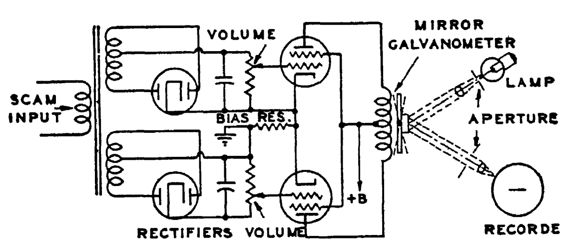

FIG. 8. Push-pull Printer Amplifier for Magnetically Driven Printer Systems

current. When properly adjusted true pushpull output is obtained, and the sum of the two output tube currents will be constant. This constant-sum current can be used as shown in the cathode return bias resistor to furnish the threshold bias required by the lower output tube.

For electrolytic recorders of either the wet or dry type it is a good safety measure to run the helix or recorder drum at ground potential. To accomplish this an amplifier such as in Fig. 9 may be used. A pushpull power amplifier at cut-off bias amplifies the SCAM signals to a power level sufficient for printing. This a-c signal is applied directly between the ground drum and stylus for dry electrolytic recording, but it must be rectified and applied between helix and bar in the proper polarity for most wet electrolytic printing processes. In some of these the color forms on the anode side, in which case the bar is made positive with respect to the helix; in others the color forms on the cathode side of the paper, and so the bar is made negative.

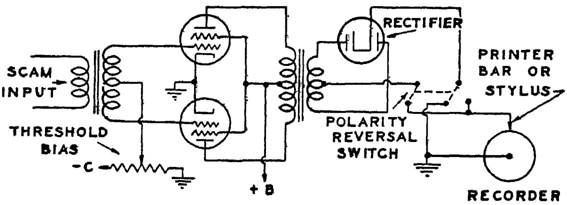

FIG. 9. Printer Amplifier for Either Polarity of Electrolytic-type Recording. With non-polarity sensitive papers, such as Teledeltos, the a-c output is used without rectification.

SYNCHRONIZING AND PHASING

10. SYNCHRONIZING

In every facsimile system, it is necessary that the recorder follow the scanner over the paper in order to produce an undistorted recording. The principle of synchronizing may be better understood by referring to Fig. 1. For clarity the picture elements are shown much larger in proportion than they really are. As the scanner starts the picture on element 1, the recorder also starts on its element 1. As succeeding scanning lines are drawn, the recorder must follow exactly, or the copy will be distorted by a misplacing of the elements.

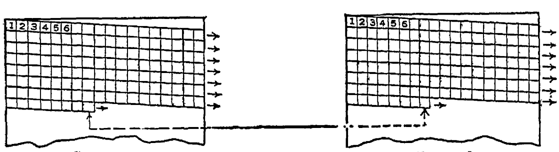

FIG. 1. Synchronism of a Facsimile System

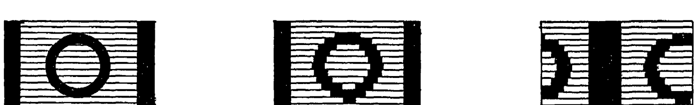
Besides having the synchronizing correct, the recorder must be in "phase" with the scanner, as illustrated in Fig. 2. Even though the two drums are rotating at exactly the same speed, if they are not in phase the border of the picture will be misplaced. The recorder drum must start each scanning line at the same time the scanner is starting that scanning line, or, as shown in Fig. 2*C*, the border will be somewhere between the two edges of the paper instead of being exactly divided. Phasing and synchronizing become the same problem only if the phasing line of the picture, or border, controls the speed of the recorder. Where the synchronizing frequency is independent of the "phasing line," or of a much higher frequency than that of the phasing line, the two problems are separate and must be treated separately. This is generally the case in most commercial systems in use today.



A. Original in scanner *B.* Recorder in phase *C.* Recorder out of phase

FIG. 2. Phasing of a Facsimile Recorder

Before going into the means of synchronizing and phasing, the effect of imperfect synchronizing should be shown, to illustrate the problem better. Figure 3 shows the effect of an error in synchronizing on a unidirectional scanning system and on a back-and-forth scanner. The error illustrated here is that the recorder is running faster than the scanner by a very small percentage. In scanning the vertical line in *A*, the recorder gets farther along its scanning line each time, moving the recorded line farther and farther to the right.

The result, in a unidirectional system, is shown in *B*. In a back-and-forth scanning system, the result is much more pronounced, alternate lines moving apart, as in *C*. The result, for the recorder being too slow, would appear the same with this method of scanning, while with the unidirectional system the line would have slanted down to the left instead of down to the right.

The accuracy of the synchronizing may vary with the particular system. In commercial work, the necessary accuracy is very high. In a system scanning at 60 strokes, 100 lines per inch, and each line of 9-in. length, the total length of scanning line per vertical inch of paper is 900 in. In a picture of 10-in. length, this total scanning line length will then be 9000 in. A good copy will be made if the total drift in the border of the picture is not over $1/4$ in. in this 10-in. length of picture. Thus, the synchronizing system must hold an accuracy of $1/4$ part in 9000, or 1 part in 36,000. It must hold this rate for the whole transmitting time of nearly 17 minutes. Actually most commercial systems have synchronizing equipment accurate to 1 part in 100,000 or better.

Fig. 3. Recorder Not Perfectly Synchronized

TUNING-FORK FREQUENCY STANDARD. In short-distance facsimile transmission, as for instance local coverage of a broadcast facsimile service, the same a-c power supply is often available for both scanner and recorders. Synchronism is then simplified by driving both scanner and recorders with ordinary synchronous motors connected to the common supply. In long-distance transmission, or across the sea, this is not possible, and synchronism is generally maintained by controlling the motors of both scanner and recorder by accurate frequency standards. Such frequency standards usually take the form of very accurate tuning forks that will hold a constant frequency to within 1 part in 100,000 or better. Crystal standards could also be used, but, as the control frequency for the motor is usually low, less dividing of frequency is required with a fork.

To hold the required accuracy, the fork is usually held at a fixed temperature by thermostat control, or a temperature-compensated bimetallic type of fork is used. Figure 4 shows one method of driving a tuning fork by using it as a resonant coupling circuit in a vacuum-tube oscillator. By changing the driving power supplied to the fork, a vernier control on its frequency is obtained. The fork frequency may be amplified by tubes or thyratron inverters to a power level sufficient to drive a synchronous motor directly, or it may be used in other ways to control motor speed.

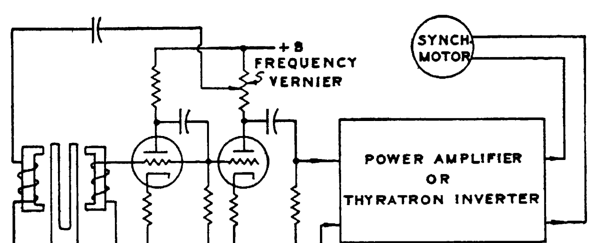

Fig. 4. Fork Control of Synchronous Motor

In one application, an 1800-cycle tuning fork is used both to supply carrier tone for an SCAM signal and is also amplified to a power of about 10 watts to drive an 1800-cycle synchronous motor. The synchronous motor is brought up to speed by a d-c motor, as it is not self starting. In applications where a standard 60-cycle synchronous motor is used, the fork frequency can be made 60 cycles, or divided down to 60 cycles from some higher frequency.

MAGNETIC BRAKE SYNCHRONIZING. Another type of control circuit is shown in Fig. 5. An induction motor, or other type of motor having good speed regulation, is used to drive the recorder or scanner and is controlled to an exact speed by means of a magnetic brake. A tone generator of the phonic wheel type is mounted on the motor shaft, having the correct number of poles to generate a frequency equal to the fork frequency at the correct motor speed. A phase comparison between this generated frequency and the fork control frequency is then used to vary the brake current and make the system lock into synchronism with the fork.

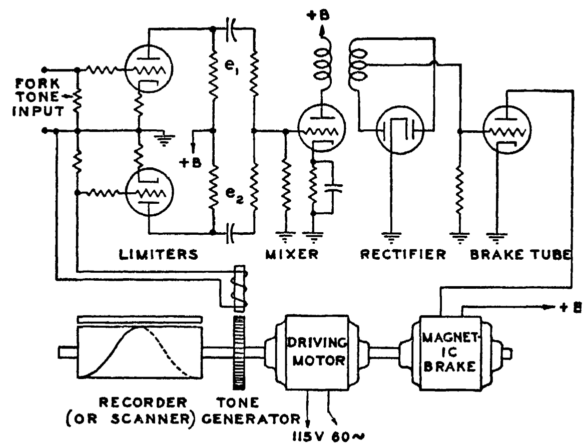

FIG. 5. Magnetic Brake Synchronizing System

A wave analysis of the brake action is shown in Fig. 6. The generated tone and the fork tone are each amplified and limited to give the two square waves e_1 and e_2, as in Fig. 6*a*. These two waves are added together algebraically in the mixer tube to give the waves shown in Fig. 6*b* and are full-wave rectified to give the waves in Fig. 6*c*. The result is then the grid voltage of the tubes supplying the braking current, shown in Fig. 6*d*.

Two conditions are illustrated. The waves on the left side show the motor leading the fork by a small phase angle, and the pulses of brake current are of full amplitude but narrow in time, so that the average brake current is small. If the motor tries to speed up for any reason, such as an increase in line voltage or lightening of the mechanical load, it will advance in phase with respect to the fork. The waves on the right side illustrate how the brake current pulses are increased in time width to give a higher average brake current that tends to slow down the motor. The brake is thus turned full on, or full off, by the square pulses, and the correct average is obtained mechanically rather than by smoothing these pulses in a filter. Hunting is thereby almost completely eliminated. As the two waves are squared up before comparing, the change in ratio of time on to time off is a linear function with phase-angle changes of zero to 180°.

As very effective brake action can be obtained by passing the pulsating direct current through the windings of an ordinary induction motor, a special design of brake is not necessarily required. This system is especially well adapted for very high-speed facsimile where motor powers as high as 1/6 hp are needed and control must be at high frequency to limit phase displacement with changes in load or line voltage.

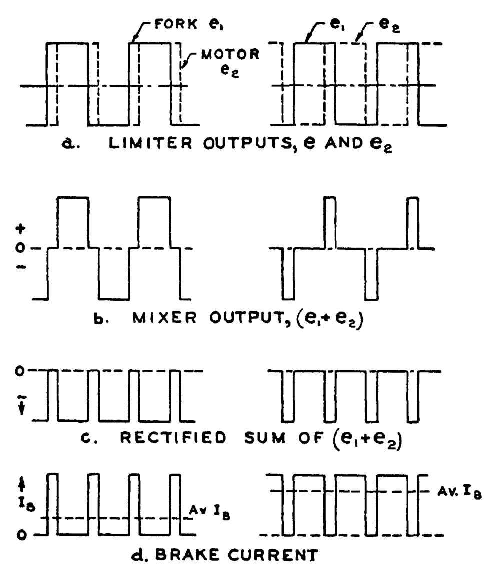

FIG. 6. Brake Operation as Motor Goes from Small Phase Lead on Fork to Large Lead

START-STOP SYNCHRONIZATION. The first methods used for facsimile synchronization were generally of the start-stop type, and, although such a synchronizing system is now practically obsolete for facsimile, it is still used on some forms of automatic tape printers, such as the teletype.

In start-stop systems, the scanner is generally operated at a constant speed and has a "phasing line" of a considerable time length. During this phasing line interval, the recorder will have finished its scanning line and stopped automatically. The scanner sends a pulse at the start of the succeeding scanning line, and a clutch, or similar mechanical apparatus, starts the recorder on the next scanning line. A governor-controlled motor, or some other fairly accurate drive, is used to maintain the recorder at a constant speed for the duration of each scanning line.

The chief merit of this system is that the errors in speed of the recorder are not accumulated, each scanning line starting afresh. The greatest possible discrepancy in synchronizing, therefore, is the error in any one scanning line itself, and this can be made quite small. The disadvantage is that the mechanics of such a system must be quite complicated, and a definite starting pulse must be received or the entire scanning line is lost. The speed of the entire system must, therefore, be quite slow to insure that these two factors do not interfere with the picture. A complicated scanning system cannot be started instantaneously at a high scanning speed, as allowances must be made for the inertia. Fading of the signal, if received by radio, would cause such a system completely to miss whole scanning lines if starting pulses were not received.

For use by line, such a system has advantages, as an ordinary governor will synchronize a motor accurately enough for the purpose, and failure to receive a starting pulse is rare.

OTHER SYNCHRONIZING SYSTEMS. Certain recording systems require no synchronizing at all, and such methods, sometimes used for cable transmission of pictures, involve setting up a certain number of picture elements by machine, or by hand, and sending a tape of this series of elements in numerical order. The recording is then assembled by hand, usually requiring a competent artist to give the picture a lifelike appearance. This method has been used for a number of years with great success over wire and cable. The Bartholemew-McFarlane system or, in shorter terms, the "Bartlane" system is a variation of this method.

The synchronizing frequency of the scanner is sometimes sent over the radio or wire line, and an amplifier is used to build this signal up to a value where it is able to drive or control a synchronous motor on the recorder. Such methods are satisfactory on line transmissions and short radio circuits but cannot be depended on for long radio transmissions.

11. PHASING

The phasing of the recorder to the incoming signals can be accomplished either manually or automatically. The simplest manual method is to throw the recorder out of synchronism and let it drift until some indicator, such as a neon lamp fed by the phase signal pulses, indicates in phase, and then to re-establish synchronism to hold this position.

In a simple automatic system, used on many news photo equipments, the recording drum is driven through a clutch, and a projecting ear on the drum is arranged to engage against a stop-pin having a magnetic release. At the start of the picture the drum is held in start position by this pin, and the clutch slips. When the start phase signal is received the drum is released and, being of low mechanical inertia, starts rotating almost immediately and in phase. The stop-pin is locked out automatically when tripped, so the drum continues to rotate for the duration of the picture transmission time. A phasing system suitable for a continuous recorder is shown in Fig. 7. A phase signal is transmitted at the start of each

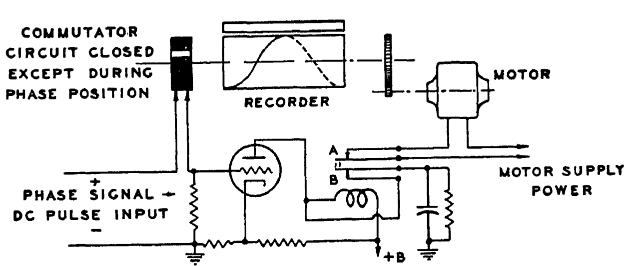

Fig. 7. Automatic Phasing of Continuous Recorder

scanning line, and this signal is selected out of the picture signals by frequency or amplitude discrimination.

It is rectified and passed to the input circuit as a d-c pulse at the start of each line. In series with this input is a commutator that is closed at all times except for a short gap at the correct phase position. When the recorder is running in phase, this gap opens the circuit for a slightly longer time than the duration of the phase pulse, so the tube receives no signal. If the pulse arrives at any other time, it passes through the closed portion of the commutator and causes the tube to draw a pulse of current to operate the relay. This opens the motor circuit momentarily and causes it to drop synchronism. To insure the relays staying open long enough for the motor to lose 1/2 or 1 cycle of synchronism, the contacts *B* of the relay connect the capacitor from relay coil to ground, and the charge current of the capacitor holds the relay in operating position for a fixed length of time. The resistor across this capacitor is too high to pass enough current to hold the relay in, but it bleeds the capacitor to zero charge between pulses. The motor is thus jogged out of synchronism once for each pulse received in an out-of-phase position, and this process continues until the correct phase position is reached, and the commutator again opens the pulse circuit at the correct time.

TRANSMISSION CHARACTERISTICS

12. WIRE LINE TRANSMISSION

Transmission of facsimile signals by either wire line or radio puts more exacting requirements on the circuit than telephone or telegraph transmission. This is largely due to the exact timing of the signals, which requires that delay equalization of a wire line be much more precise than for telephone work. Any appreciable difference in arrival time at the recorder of the high- and low-frequency components of the picture will show as transients and ghosts that exaggerate the outlines of objects in the picture and may even make typing unreadable. Accurate delay equalization is therefore required on all but short lines.

The amount of delay equalizing necessary is also directly affected by the speed of the transmission and by the bandwidth required. For the previous example of a maximum keying speed of 750 cycles, the shortest dot to be transmitted is 1/1500 second, or 0.667 millisecond. Any difference in delay equalization over the band of 1800 $\pm$ 750 cycles, or from 1050 to 2550 cycles, should not exceed a fraction of this 0.667 millisecond or noticeable distortion will result. In this case, the line should be delay-equalized to $\pm$ 0.25 millisecond over the 1050- to 2550-cycle bandwidth. In many long lines used for facsimile, this maximum delay error of $\pm$ 0.25 millisecond, over a band of 1000 to 2600 cycles, is maintained.

If the speed of transmission were doubled, the maximum permissible delay error would be halved and the bandwidth doubled at the same time. The problem of getting good enough lines is therefore increasingly difficult as speed is increased.

This exactness of delay equalization can be compared to regular voice circuits where 10 or even more milliseconds' delay difference does not appreciably affect quality of speech.

Where a-m signals are being used, the line must also be equalized for amplitude over the transmission band, but this is usually an easier problem. Where SCFM signals are used the amplitude characteristic of the line is relatively unimportant, but the delay characteristic must be as good as for SCAM signals.

For short transmissions of less than 100 miles portable scanners are sometimes operated into ordinary coin-box phones and over regular long-distance lines. This practice is satisfactory in some cases, but distortion is much greater than over the specially equalized lines, and picture quality is therefore lower.

13. RADIO TRANSMISSION

Radio transmission is beset with more difficulties than line transmission and, for long distances, is generally slower. Many factors enter in long-distance radio transmissions, such as fading, multipath delays, interference, echos, and other forms of distortion that must be corrected for, or else the speed must be decreased until the particular distortion present is reduced sufficiently to be no longer objectionable.

Rapid changes in transmission distance, due to varying heights of the ionized layers, give the effect of varying delay times on wire lines and are the limiting factor on speed of transmission. Some of the most pronounced effects can be eliminated by suitable directive antennas with limited pick-up angles, to eliminate the next higher order of skip or hop. When such antennas are used, and the proper choice of carrier frequency made for the distance, speeds up to 10 sq in. per minute are generally possible on circuits as long as New York to London, and a speed of 6 sq in. per minute is very reliable.

In earlier radio facsimile systems, dot-halftoning was developed so that a keyed on-off CW type of transmission might be used. Limiting the incoming signal then allowed most of the results of fading to be removed. However, all present long-distance transmissions are made either by using SCFM on regular voice transmitters, or direct frequency modulation, or frequency shift of the radio carrier. The dot-halftone systems have therefore become obsolete, and at the same time speeds have increased from 2 to 3 times that possible with the dot systems. With either of these newer methods limiting can be done either at radio frequency for frequency modulation or at audio frequency for SCFM and fading can be largely removed.

For short distances, or when using ultra-high-frequency relaying, the speed is not so limited, for multipath troubles do not enter, and wide bands may be used.

SPECIALIZED APPLICATIONS

14. DUPLICATORS

Many applications of facsimile have been made that illustrate that it is not limited solely to the transmission of pictures over long distances. The scanner and recorder can be mounted on the same shaft and a duplicator, or copying machine, obtained. Two types of facsimile duplicators are in use, each having definite advantages over other forms of duplicators in certain applications.

In one type of duplicator a wet electrolytic recorder is combined with a rapid-loading type of scanner, such as shown in either Fig. 4, p. 5, or Fig. 5, p. 6. The speed of operation is very high, 85 sq in. per minute, and a full-sized letter page 8 1/2 by 11 in. is copied in slightly over a minute, with 120 lines per inch detail. The wet paper passes over an ironing roll after printing, and a finished dry copy is thus delivered.

As both scanner and recorder are rigidly coupled to the same driving motor, no synchronizing or phasing is required. The amplifier system from phototube to printer becomes very simple, as there is no transmission and reception problem over line or radio.

This type of duplicator is useful where only a few copies each of a large number of originals are required. As reflected light is used the original may be opaque, entirely unsuitable for blueprinting. It thus compares with photo-copying (though the cost of the printing paper is less) but eliminates the necessity of developing and fixing.

MULTIFAX. In *Multifax*, a master mimeograph stencil is cut by facsimile methods so that a large number of copies of the original may be made. Copy containing illustrations and diagrams that would be almost impossible to make up by ordinary means can thus be obtained in quantity, without going through more expensive printing processes.

The scanner and recorder are on the same shaft, as in *Duplifax*, to eliminate the need of synchronizing and phasing. The stencil is clamped on a recording drum and cut by a stylus which is vibrated at high frequency. While vibrating, the stylus is moved towards the drum for black and delivers a large number of blows to the stencil to displace the wax. The stylus is retracted for white so that it just misses touching the stencil. The vibrating stylus has no tendency to drag out or tear the stencil, as it would if pressure only were applied, and so much finer detail can be realized than with hand-cut stencils.

A full letter-sized master stencil can be prepared from the original in 10 or 15 minutes by this method, about the time required for typing a stencil without illustrations. Another advantage is that the original is prepared on white paper, and printed diagrams or illustrations may be pasted in place without being hand drawn on the stencil.

15. TAPE FACSIMILE

Tape facsimile systems are a special adaptation of facsimile in which the recording is printed on a narrow slip similar to that used in news tickers. The scanning may be optical or mechanical, but the recorders for either type of scanning are usually of the helix and printer-bar type, somewhat like a miniature version of the carbon recorder.

Where optical scanning is used, the message is typed, or handwritten, on the transmitting tape, and this original copy then fed through a scanner similar to that shown in Fig. 1. A spot of light is traversed across the width of the tape by the combination of a rotating prism and a fixed system of three cylindrical lenses and one right-angle prism. One stroke across the tape is obtained for each face of the prism that passes. These scanning lines are very short, usually 1/4 to 1/2 in. The phototube signals generated by the reflected light are then used to obtain either SCAM or SCFM signals in the same manner as in any page facsimile scanner amplifier.

For mechanical scanning the transmitter takes a form similar to a tape-teletype machine, in which each letter is represented by a disk similar to an "Omnigraph" disk. Each disk is a commutator and keys a series of signals that will form a facsimile image of that character when printed by the recorder. Operation of this form of tape scanner is then similar

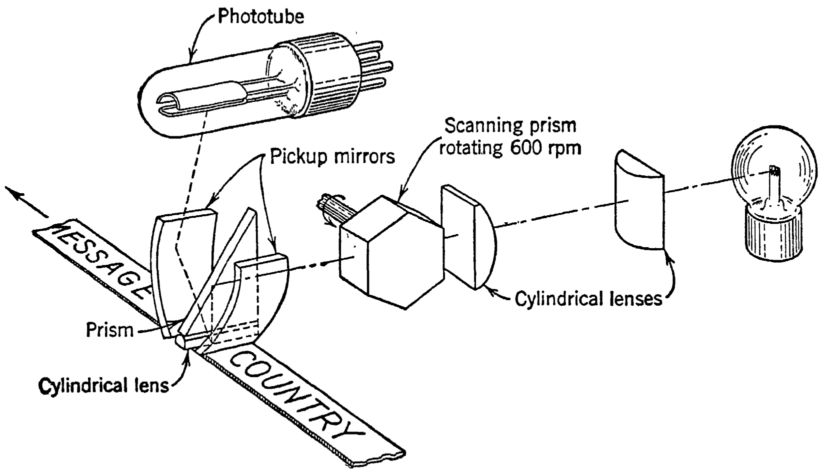

FIG. 1. Tape Facsimile Scanner

to that of a teletype machine, but with the output signals coded for facsimile recording rather than for operating a typewriter type of receiver.

Either type of scanner will operate the tape recorder shown diagrammatically in Fig. 2. The helix is very small for a scanning line as narrow as this, and it can be inked directly by the ink roller shown instead of by using a slip of carbon paper to supply the coloring matter as in the page type of recorders. Otherwise the recorder action is exactly the same as for the page carbon recorder shown in Fig. 4, p. 15. Tape systems are built for message service

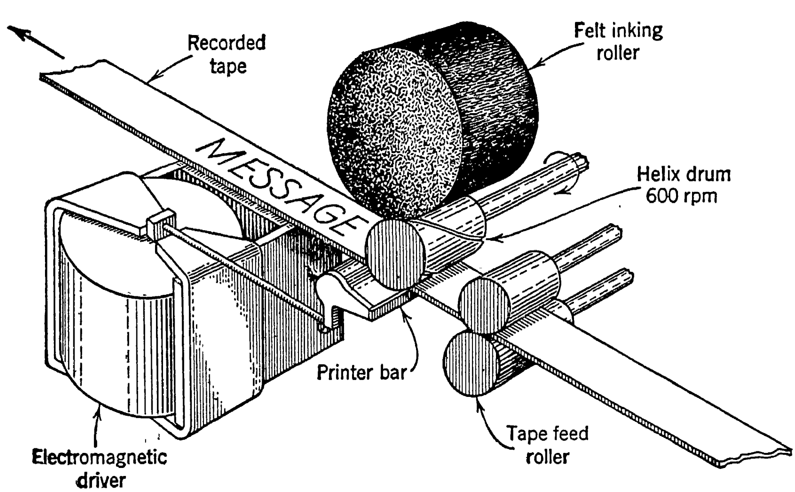

FIG. 2. Tape Facsimile Recorder

and do not need to have the fine detail usually required in a picture system. Whether optical or mechanical scanning is used, the characters transmitted are large block type to reduce keying frequency and to get as large a number of words per minute as possible in a narrow channel.

The scanning-line length is very little greater than the height of a letter, so that there is little waste time in margins. For instance, if $^3/_{16}$-in. block type is used, the scanning line will be about $^1/_4$ in. long. To transmit this type, the shortest dot necessary would be about 0.020 in., and a maximum number of cycles per scanning line would be 6. With the constants of 60 lines per inch and 60 lines per second, 1 in. of tape per second is transmitted with a keying speed of not over 360 cycles per second. This tape speed of 1 in. per sec will represent about 60 words per minute.

While this band of 360 cycles for 60 words per minute is about 8 $^1/_2$ times that required for the commercial automatic 7 unit codes, where 42 cycles (or bauds) per second represents 60 words per minute, this disadvantage is largely offset in instances where signals are poor, or noise high. With tape facsimile, interference can obliterate a letter, but it cannot make it print a wrong one.

TELEVISION

PRINCIPLES AND THEORY

By A. V. Loughren

Television is defined as "the electrical transmission and reception of transient visual images." *

Television technique for monocular, monochrome pictures has developed sufficiently to lead to adoption by the Federal Communications Commission of standards for broadcasting.

1. PHYSIOLOGICAL REQUIREMENTS

The performance required of a television system is determined by physiological requirements which must be met for the performance to be acceptable. Section 14 discusses these in detail. They vary from individual to individual, but generally acceptable design values for the several quantities have been arrived at based on extensive tests. These requirements include:

Resolution. An observer with good eyesight is able to resolve successive contrasting objects individually subtending as little as 1 minute of arc. A square subtending 1 minute of arc on a side corresponds to a solid angle of approximately 10^{-7} steradian. (References 1, 2, 3.)

Field of View. A normal eye is capable instantaneously of critically observing a field of the order of 0.001 steradian. Since the eye direction can be quickly and readily changed, a much greater field than this is available within a very short interval of time. For sustained viewing of images the viewing distance of four to eight times the picture height chosen by most observers produces an image field of the order of 0.02 to 0.07 steradian. Such a field is 200,000 to 700,000 times the minimum resolvable solid angle (reference 3).

Sharpness. Sharpness is the subjective quantity corresponding to the objective quantity "resolution." Figure 1 shows the relation between sharpness and resolution; it in-

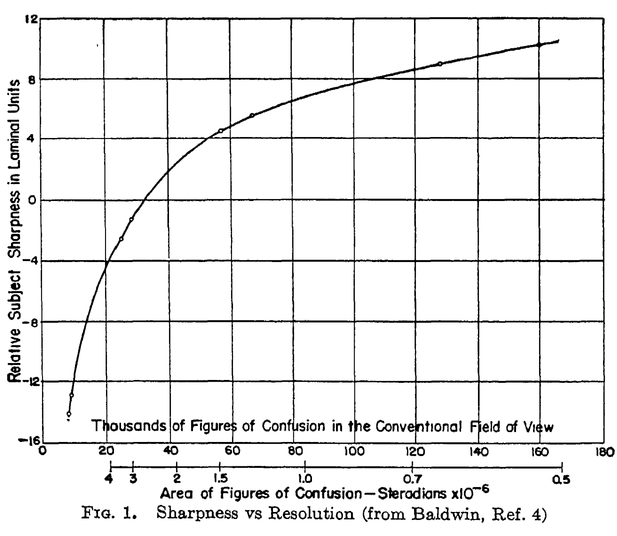

FIG. 1. Sharpness vs Resolution (from Baldwin, Ref. 4)

dicates that increasing the resolution by making the size of the figure of confusion less than 1.5×10^{-6} steradian increases the sharpness only slightly (reference 4).

---

* RMA.

Brightness. Because of its essentially logarithmic response and its ability to control admitted light by means of the iris opening, the human eye is capable of observing objects whose brightnesses lie within the range from 4×10^{-5} to 4000 ft-lamberts. It is found, however, that satisfactory viewing requires restriction of this range. Under conditions of low ambient illumination, highlight brightnesses as low as 1 ft-lambert are found acceptable; however, under conditions of normal artificial and natural lighting indoors, highlight brightnesses as great as 200 ft-lamberts are desirable. Values of 10 to 100 ft-lamberts are suitable for design purposes.

Contrast. The total contrast range instantaneously perceptible to the eye is believed to be about 40,000 : 1. However, reproductions exhibit contrast ranges from 10 : 1 for rather unsatisfactory images to 200 : 1 for the best photographic transparencies. Television pictures having a contrast range of 30 : 1 have been judged reasonably satisfactory.

Color. See Section 14 and references 5 and 25.

Depth. See Section 14.

Moving Objects. Ideally, reproduction of a picture of a moving object requires that each elementary area of the picture change synchronously with the corresponding changes in the original scene caused by the motion of the object. It is known, however, that the resolution of the eye for moving objects is much poorer than for stationary objects. It is consequently permissible to reproduce the picture at finite intervals rather than continuously. For most purposes the interval of $^1/_{24}$ sec is short enough to leave with the observer the illusion that motion is continuous rather than discontinuous.

Shape and Size of Picture. A rectangular shape with the width equal to four-thirds of the height has been found generally acceptable. This ratio is defined as the aspect ratio.

The minimum acceptable size for reproduced pictures is believed to lie in the range between 4 by 5.33 in. and 7 $^1/_2$ by 10 in. Smaller pictures produce fatigue within a short time unless special devices are worn by the viewer. The maximum acceptable picture size is determined primarily by the viewing distance available. For household use pictures up to 15 by 20 in. are suitable, while for use in halls and theaters much larger ones are appropriate.

2. SUBDIVISION OF PICTURE; EFFECT OF SCANNING RATES

Methods of transmitting and reproducing a television picture fall into two classes. Both classes depend on the subdivision of the scene into a sufficiently large number of elementary areas. In one class of system a separate transmission channel is provided continuously for each element. The large number of elements required for a satisfactory picture has shown systems of this class to be impracticable. In the other class, which all present practical systems use, the elements are connected to a single transmission channel successively in an ordered sequence common to both transmitter and receiver. This process is called *scanning*.

SCANNING. An area to be scanned is subdivided into elements each of which is connected to the transmission channel periodically in some regular sequence. In its simplest form the operation consists in starting at the upper left-hand corner of the picture, traversing successively the row of elements along the top of the picture from left to right, following with a similar traverse one element width lower, and continuing this process until the bottom of the scanned area is reached. A single traverse across the picture in one direction is called a scanning line. The complete scanning pattern is referred to as a raster. This process is shown diagrammatically, for a picture containing only a few scanning lines, in Fig. 2. The electrical frequency components produced by thus scanning a fixed image may be shown to consist of: (1) a d-c component; (2) components at the vertical scanning frequency and its harmonics; (3) components at the horizontal scanning frequency and its harmonics; (4) components at sum and difference frequencies of the above. Physically the d-c component represents the average brightness of the image. The components at the vertical frequency and its harmonics represent bands extending horizontally across the picture. The components at the line frequency and its harmonics represent vertical bands. The components at sum and difference frequencies represent inclined bands. If the picture changes with time, side bands are added to some or all of these components (references 6 and 29).

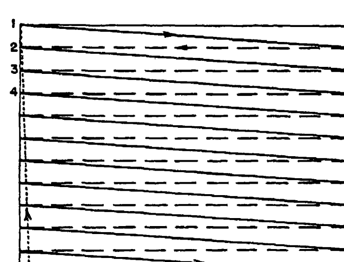

FIG. 2. Simple Raster

Vertical Resolution. The scanning spot in the usual case is not rectangular nor does it exhibit uniform effectiveness over its area. As a typical example of this, Fig. 3 shows the distribution of light intensity over the scanning spot of a cathode-ray tube. If the spot moves rapidly in one direction, forming a line, its effective distribution in the other direction assumes some such form as that shown in Fig. 4 at A. This figure also illustrates, at B, the condition under which a flat field of illumination is produced by the overlap of successive lines, and at C a line-to-line spacing which fails to produce a flat field. Similar relations exist with respect to the scanning spot in the photosensitive device at the transmitter.

The photo device at the transmitter should be adjusted to satisfy the flat-field criterion. Failure to do this results in a type of distortion known as "beads," which is not susceptible of any subsequent correction.

Vertical width of confusion, defined as the average width in the reproduced image of a very narrow line appearing before the transmitter, positioned at a slight angle with respect to the scanning lines, is equal to $\sqrt{2}$ times the scanning-line pitch (reference 7).

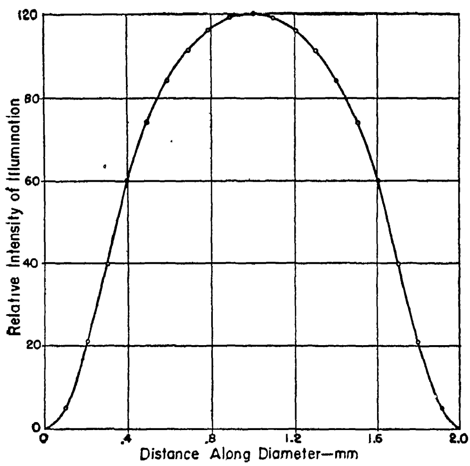

FIG. 3. Distribution of Intensity across Scanning Spot (After Zworykin, *Proc. I.R.E.*, Dec., 1933)

Horizontal Resolution. If the scanning spot of a pick-up device moves horizontally across a vertical line of negligible width, the resulting electrical impulse describes the horizontal characteristic of the spot. Typical forms of this impulse are shown in Fig. 5. The width of a rectangle having the same maximum height, and including the same area as the spot characteristic (as shown dotted in Fig. 5*b*), is an approximate measure of the duration of the impulse. Since the spot is traveling at a fixed velocity, the abscissa in Fig. 5 represents not only time but also distance. It may, for analysis, be transformed into steady-state amplitude and phase characteristics as functions of frequency (for example, by means of the Fourier integral theorem). The effective band width may be expressed approximately by the width of a rectangular area having the same maximum height and same included area as the frequency characteristic. It may be shown that to a useful approximation the effective spot width in seconds (or microseconds) is related to the effective band width in cycles (or megacycles) by the equation:

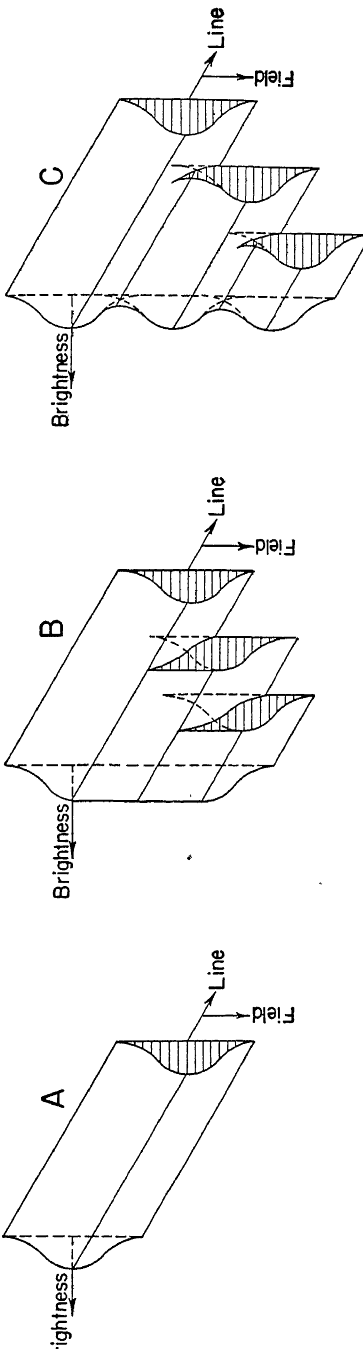
$$t = \frac{1}{2f_c} \tag{1}$$

where t is the time-duration of the equivalent rectangular electrical transient and f_c is the cutoff frequency of the equivalent rectangular frequency characteristic. A signal generated by a scanning spot moving across a narrow line as just described, transmitted electrically and reproduced by a reproducing device, will have its frequency spectrum modified both by the electrical circuits and by the equivalent transmission characteristic of the spot of the reproducing device. These several characteristics may be multiplied together to produce the overall transmission characteristic of the system. The corresponding effective horizontal width of confusion is then obtained by applying to this characteristic the inverse transformation by means of the Fourier integral theorem. As an approximation, the effects of several sources of limitation on the frequency band width, connected in cascade, on the effective overall band width, and on the duration of the shortest reproducible impulse are given by the equations

$$f_c = \frac{1}{\sqrt{\dfrac{1}{f_{c1}^2} + \dfrac{1}{f_{c2}^2} + \cdots}} \tag{2}$$

and

$$t = \sqrt{t_1^2 + t_2^2 + \cdots} \tag{3}$$



A. Single Line.

B. Several Lines Overlapping to Produce a Flat Field.

C. Several Lines Spaced to Produce a Wavy Field.

FIG. 4. Lateral Distribution of Scanning Line Brightness

So long as the frequency characteristic or the transient impulse form reasonably well approximates the error function

$$y = e^{-x^2}$$

the relations given above are close approximations (references 7 and 8).

The scanning spot is usually symmetrical and thus exhibits no phase distortion. The electrical circuits, however, are potential sources of phase distortion. Phase distortion affecting low-frequency components of the reproduced picture tends to alter the vertical or lateral shading of the picture. Phase distortion affecting high-frequency components tends to give the picture a "bas relief" effect in which edges of objects in the image may be preceded or followed by bright or dark outlines. Sharp cutoff in the amplitude characteristic produces "overshoots" superficially similar to high-frequency phase distortion. The two effects differ in that if a symmetrical object is scanned the distortion due to sharp amplitude cutoff will be itself symmetrical, whereas that due to phase distortion will be opposite in its character on the two sides of the image (reference 9).

FLICKER. Flicker is not inherent in television. It is a consequence of the use of scanning in conjunction with picture display devices in which energy is supplied to a given elementary area of the display device for only a minute fraction of the total time. The use of such display devices with the scanning sequence of Fig. 2. at a picture repetition rate of 25 or 30 per sec, produces severe flicker at brightnesses even below 1 ft-lambert. Restriction of the maximum brightness to this level is not acceptable.

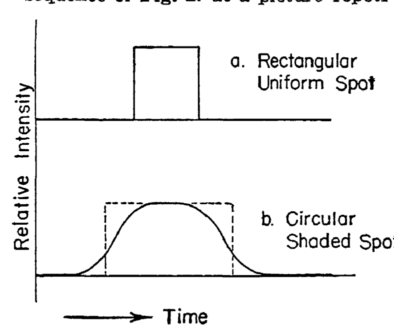


FIG. 5. Electrical Impulse Produced by Scanning a Narrow Vertical Line

A major improvement is obtained by interlaced scanning. In this form of scanning, shown in Fig. 6, the vertical component of velocity of the scanning spot is doubled as compared to that of Fig. 2 so that while the spot crosses the picture from left to right it falls an interval equal to *twice* the distance between scanning lines. If, therefore, the spot starts at the top center to trace line 1, after completing line 1 it goes to the left-hand side of the picture and starts line 3, continuing in this manner until it reaches the bottom right side of the picture. At this point the vertical retrace takes place and the spot returns to the top left of the picture and starts to scan line 2, followed by lines 4, 6, etc., until the lower center of the picture is reached. (For purposes of illustration the vertical retrace time is assumed to be very small.) This method of operation has the consequence that for an observer at such a distance that he just fails to resolve individual scanning lines the effective flicker frequency has been doubled; thus, very much greater brightness is permissible without any increase in the picture repetition rate. This advantage is only slightly impaired when the observer's distance is such that he can commence to resolve individual scanning lines. The analogy between the practice of interlacing and the motion-picture practice of interrupting the light at a rate greater than the frame frequency should be noted.

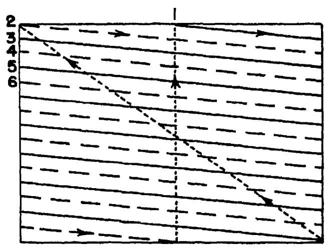

FIG. 6. Interlaced Scanning

In interlaced scanning the time required by a single vertical traverse of the picture is no longer equal to the time required to scan a complete picture. A single vertical scan is called a field; a complete picture is called a frame. The customary variety of interlace thus has two fields per frame. Higher orders of interlace have been proposed but have not found widespread use.

It is desirable that the scanning processes, both horizontal and vertical, repeat exactly from cycle to cycle. If the number of lines to a complete frame is an odd number, and a frame consists of two fields, correct interlace and uniformity of repetition of the scanning operation go hand in hand. This arrangement is called "odd-line interlace."

3. RESOLUTION AND FLICKER REQUIREMENTS; BAND WIDTH

In article 2 it was noted that the vertical width of confusion was equal to $\sqrt{2}$ times the scanning-line pitch; hence

$$W_v = \frac{V\sqrt{2}}{n} \tag{4}$$

where V is the picture height and n the number of useful scanning lines per picture. It was also noted that the horizontal width of confusion, in seconds, was

$$t = \frac{1}{2f_c} \tag{1}$$

Since

$$W_h = tv \tag{5}$$

where v is the horizontal spot velocity, it follows from eq. (1) that

$$W_h = \frac{v}{2f_c} \tag{6}$$

It is desirable that the horizontal and vertical widths of confusion be approximately equal. Thus

$$\frac{V\sqrt{2}}{n} = \frac{v}{2f_c} \tag{7}$$

whence

$$f_c = \frac{nv}{2\sqrt{2}V} \tag{8}$$

The number of useful lines in the complete picture, n, will be less than the total number of line-periods in the picture time-interval, n', by a factor a (usually 0.90 to 0.93) introduced to provide time for the vertical return of the spot. The line-repetition rate, or line-scanning frequency, in cycles per second, is the product of the picture-repetition frequency N and the total number of lines per picture, n'.

If no time were allowed for horizontal return of the scanning spot from the right to the left of the raster, the horizontal velocity would have the value

$$v = WNn' \tag{9}$$

where W is the picture width. Retrace time must be provided, thus reducing the useful portion of the line-period from unity to a fraction b, usually 0.82 to 0.85. The actual velocity is then

$$v = \frac{WNn'}{b} \tag{10}$$

Substituting this value in eq. (8)

$$f_c = \frac{nn'NW}{2\sqrt{2}bV} = \frac{an'^2N}{2\sqrt{2}b} \times \frac{W}{V} \tag{11}$$

and, since W/V, the aspect ratio, is $^4/_3$,

$$f_c = \frac{2a}{3\sqrt{2}b}\, n'^2N \tag{12}$$

If the picture is viewed from a distance equal to four times its height, the angular width of confusion is found from eq. (4) to be

$$W_a = \frac{\sqrt{2}}{4an'} \quad \text{radian} \tag{13}$$

while the corresponding square solid angle is

$$S = \frac{1}{8a^2n'^2} \quad \text{steradian} \tag{14}$$

In article 1 it was stated that the figure of confusion should not exceed 1.5×10^{-6} steradian. However, the method of defining the boundaries of the figure, in the study there referred to (reference 4), differed from that of article 2 sufficiently to require introduction of the factor 1/1.9 when this figure is applied to the preceding analysis. Using the resulting value of 0.8×10^{-6} steradian, and choosing the value 0.90 for a, eq. (14) yields the value

$$n' = 439 \text{ lines per picture}$$

The American television standards have been set at 525 lines per picture, thus more than meeting the resolution requirement in the vertical direction.

The vertical repetition rate must be at least 25 and preferably 30 per second for the complete picture in order to minimize flicker, even with interlaced scanning. It is advantageous to make the rate an integral submultiple of the power supply frequency, to eliminate disturbance of interlace by stray fields; a vertical rate of 30 per second is therefore chosen. The corresponding line frequency is 30 times 525, or 15,750 cycles per second.

The effective cutoff frequency, as defined in article 2, is obtained by substituting in eq. (12) the values $a = 0.90$, $b = 0.84$, $n' = 525$, $N = 30$. Thus

$$f_c = 0.505n'^2N = 4.18 \text{ Mc}$$

With a frequency band including components up to 4 or 4.5 Mc, the gradual cutoff required to avoid severe "overshoots" (and usually obtained automatically as a consequence of scanning spot distributions) results in an effective band width which rarely exceeds 3 Mc (reference 7). The condition of equal vertical and horizontal widths of confusion (eq. [7]) is thus not usually obtained; moderate departures from this condition are known to be of only minor importance (reference 4).

4. PICK-UP DEVICES

Early work on television employed mechanical scanning of the object or scene to be televised. The optical system focused an image on a plane at which a disk provided with apertures spaced about its periphery was interposed. A single rotation of the disk produced one complete scan of the image. The photoresponsive device located behind the disk responded instantaneously to the light transmitted by the apertures as they successively traversed the image. In a modification of this arrangement the scanning process was applied to the light which illuminated the object. This modification reduced the total amount of light incident on the subject, and the accompanying heat, very considerably.

Analysis of these mechanical scanning methods shows that the light incident upon the photoresponsive device is inversely proportional to the number of picture elements, and that, for an acceptable number of elements in the picture, it is not practicable to increase the scene lighting and the pick-up lens size sufficiently to produce a useful signal-to-noise ratio (reference 26). The limitation inherent in mechanical pick-up systems encouraged the development of photo responsive devices capable of storing light energy over the entire scanning period, thus permitting an improvement of several orders of magnitude in the signal-to-noise ratio. These devices are described in Section 15.

5. PICTURE DISPLAY DEVICES

Early picture display devices employed a light source of instantaneously controllable intensity (such as a crater-type glow-discharge lamp or a high-intensity arc whose light output was modulated by a Kerr cell) in conjunction with a mechanical scanning device similar to that described in connection with the preceding article. With arrangements of this sort each picture element is illuminated for a time interval corresponding to its own duration.

The average illumination of a picture element at the viewing screen is equal to the illumination intensity during the picture element divided by the ratio of frame duration to picture element duration. A typical value for this ratio is 300,000. In consequence of this factor, and the limited intrinsic brightnesses of convenient light sources, mechanical scanning systems as heretofore proposed have been largely supplanted by electronic scanning using cathode-ray tubes (reference 2).

In a modification of a mechanically scanned television reproducer, Scophony developed a method of storing the light-modulation information in a liquid cell in such fashion that an individual picture element could be illuminated for a period many times the element's own duration. Practical difficulties have prevented widespread use of this arrangement (references 10, 11, 12, and 13).

In a cathode-ray tube the instantaneous power concentration in the scanning spot may reach values of 10 to 1000 kw per sq in. Efficiencies of fluorescent materials in converting from electrical to luminous energy lie in the range of 5 to 10 per cent. On this basis, average highlight brightnesses of a few thousand foot-lamberts are possible. The cathode-ray tube has, therefore, become the accepted television picture-reproducing device. Cathode-ray tubes are described more fully in Section 15.

Electronic control of the opacity or alternatively the light-reflection coefficient of a surface has been employed for certain special purposes. In one form the effect of an injected electron in producing opacity in a transparent alkali halide crystal is employed. In another arrangement a layer of flakelike particles such as graphite, suspended in a fluid, is used; in the absence of electric field the particles exhibit random orientation and thus prevent light transmission, but an applied electric field makes the orientation orderly and permits light transmission in the direction of the field (references 14, 15, and 16).

SCANNING CIRCUITS FOR CATHODE-RAY DEVICES. The electron beam of the cathode-ray tube may be deflected by either electric or magnetic field. Both fields involve the storage of energy in the deflection space within the tube and incidentally in the external circuits.

Wave forms for a deflecting field are shown in Fig. 7. Curve *A* shows an ideal form. Curve *B* shows a departure from the ideal form introduced to permit a finite retrace time and thus avoid the necessity for handling unreasonably excessive currents or voltages in the deflection circuits during the retrace intervals. Curve *C* shows a typical practical curve in which the form of variation is modified from that of curve *B* to eliminate the discontinuities of slope exhibited by curve *B* and thus reduce the number of harmonics which must be faithfully transmitted to the deflecting circuit.

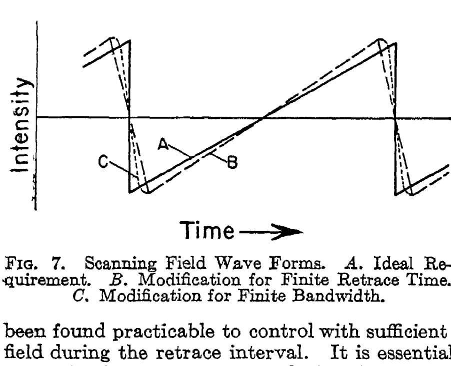

FIG. 7. Scanning Field Wave Forms. *A*. Ideal Requirement. *B*. Modification for Finite Retrace Time. *C*. Modification for Finite Bandwidth.

For faithful reproduction it is essential that the scanning wave have the same form in both the pick-up device and the reproducing device. It has not been found practicable to control with sufficient accuracy the wave form of the deflecting field during the retrace interval. It is essential, therefore, that no attempt be made to transmit picture information during this interval. Means are customarily provided for preventing the appearance of the reproducing screen from being affected by signal potentials during the retrace.

SCANNING CIRCUITS FOR ELECTROSTATIC DEFLECTION. Figure 8 shows a typical circuit for producing electrostatic deflection voltages. Oscillator tube *V*-1 is here shown as a blocking oscillator. Other forms such as multivibrators and thyratrons may also be used. The oscillator acts periodically to discharge capacitor C_1. The capacitor is then charged through R_1 until the voltage at the oscillator anode rises to a point where, in conjunction with any voltage which may be applied on the grid, oscillation is again produced, thus again discharging C_1. The voltage variation with time on C_1 during the trace portion of the period is, of course, exponential. It is essential, therefore, that the amplitude at this point be kept small enough to preserve a good approximation to

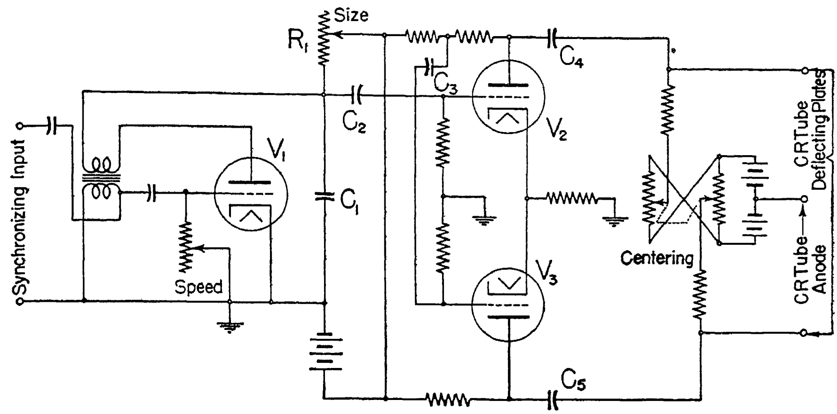

FIG. 8. Electrostatic Deflection Circuit

linearity. The amplifier tube V_2 and phase inverter tube V_3 amplify the voltage appearing across C_1 to the required level and provide the usually necessary outputs of opposite polarities. In choosing the values of components care must be taken that the capacitors C_2, C_3, C_4, and C_5 do not introduce excessive phase shift for the fundamental frequency component. A total shift of 3° is a useful upper limit. By care in the choice of component values the circuit may be made to work down to frequencies much lower than the normal television field frequency of 60 cycles; it may also be used readily at frequencies at least ten times higher than the normal line-scanning frequency of 15.7 kc.

A simpler circuit which is useful for scanning frequencies of the same order as television line frequencies is shown in Fig. 9. In this circuit capacitors C_1 and C_2 are charged from

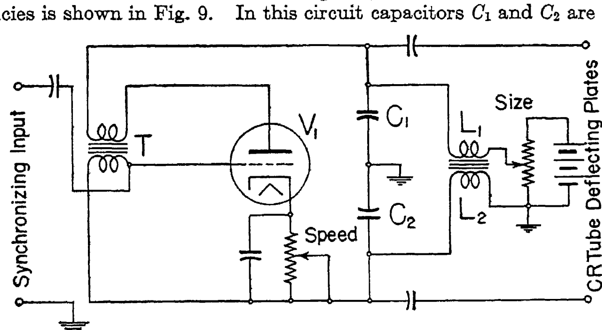

FIG. 9. Electrostatic Deflection Circuit

the power supply during the trace period through the reactor L_1, L_2. While this charging current is oscillatory, the choice of a resonant frequency less than one-tenth the scanning frequency for the circuit consisting of the two reactor windings and two capacitors in series results in the use of only the linear central portion of the oscillatory cycle. When the voltage appearing across C_1 and C_2 is great enough, tube V_1 goes into oscillation drawing a heavy current and discharging the pair of capacitors. If the equivalent series resistance of V_1 is sufficiently low, this discharge will be oscillatory and will last for one-half cycle at a frequency determined by the apparent inductance of the primary of transformer T and the capacitance of capacitors C_1 and C_2. (Insufficient leakage inductance in T makes the retrace time unnecessarily short and the peak current and dissipation in

V_1 excessive.) The potential difference between the opposite ends of C_1 and C_2 reverses during this discharge and rises to a negative value which may be a considerable fraction of the voltage on the capacitors before V_1 began to conduct. With the cessation of conduction in V_1, C_1 and C_2 are again charged through L_1, L_2, and the cycle repeats.

CIRCUITS FOR MAGNETIC SCANNING. In the magnetic scanning cycle the current in the coil by which the magnetic field is produced is zero at the midpoint of the scanning trace. During the latter half of the trace the current is built up under control of a vacuum tube to the value required to produce the full deflection. The flow of current through the vacuum tube is then interrupted, and the scanning current continues to flow in the coil, charging the distributed capacitance which is in shunt with the coil until the current vanishes. The distributed capacitance is now charged to a high potential; it discharges back into the coil, producing a current of opposite polarity to that which previously flowed. When the potential energy stored in the distributed capacitance has been transferred completely back to the coil, the next scanning-line trace starts; the flow of coil current is permitted to continue through a vacuum tube in order to cause the current to decrease linearly to zero value at the midpoint of the trace. In this cycle energy is supplied to the circuit during the latter half of each trace, a half-period of free oscillation takes place during the retrace, and the energy is then dissipated during the first half of the succeeding trace. These relations are shown on an ideal basis in Fig. 10. It is necessary, of course, that the resonant half-period of the free oscillation not exceed the permissible retrace time.

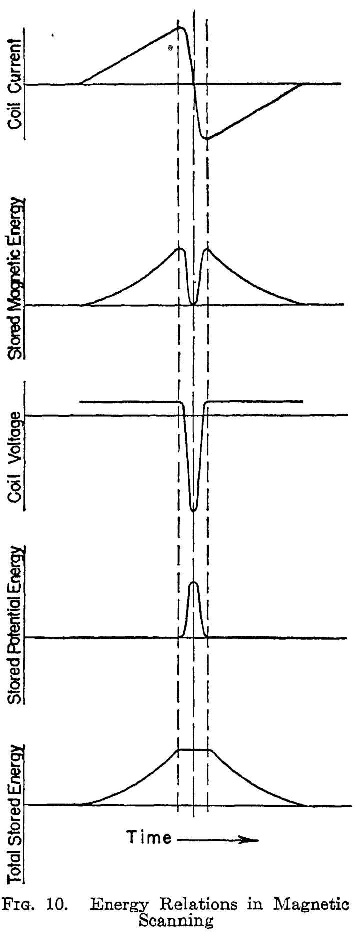

FIG. 10. Energy Relations in Magnetic Scanning

The energy required in the magnetic field (within the tube) to deflect a cathode-ray tube fully is a function of accelerating voltage and deflection angle primarily. Typical tubes require amounts of energy between 30 and 300 microjoules. These amounts of energy must be provided and dissipated during each scanning cycle. Thus, for a type 10BP4 cathode-ray tube requiring about 300 microjoules for horizontal deflection and a horizontal deflection frequency of 15,750 the power which must be delivered by the scanning circuit within the tube is 4.8 watts.

A typical line-frequency magnetic scanning circuit is shown in Fig. 11.

A step-down transformer is interposed between the energy supply tube V_1 and the scanning coil or yoke Y, to decrease the effective distributed capacitance of the circuit, thus assisting to obtain suitably short retrace time. The wave-form diagrams of the figure, which are corrected for the effect of the transformer ratio, show the current gradually increasing in tube V_1 during the trace and terminating abruptly at retrace. During this same period the current in tube V_2 rises abruptly to a maximum value and decreases smoothly during the rest of the trace. The analogy between these two current wave forms and the corresponding forms in a class AB amplifier should be noted. Tube V_3 provides the feedback connection for self-oscillation.

The circuit is arranged to make use of the energy returned by the yoke Y during the first half of the trace. This energy is stored in capacitor C_1; the voltage thus developed across C_1 is used to augment the anode supply voltage for tube V_1. This is called the "bootstrap" connection.

It is usually necessary, for line-frequency scanning, to use a relatively low inductance in the yoke. The current is therefore relatively high and may reach peak values of 0.1 to 1.0 amp. Relatively large direct currents (0.01 to 0.20 amp) are consequently required to correct any incidental decentering of the raster. The circuit of Fig. 11 is therefore designed to permit the full B supply current of the receiver to flow through the centering control.

Overall efficiency of the circuit of Fig. 11 may reach a value of 15 per cent. Delivery of 5 watts to the magnetic field within the tube thus requires at least 30 watts of d-c power (reference 80).

The power required for the relatively slow vertical scanning is very much smaller than that for horizontal scanning. A typical circuit is described in article 32 of this section.

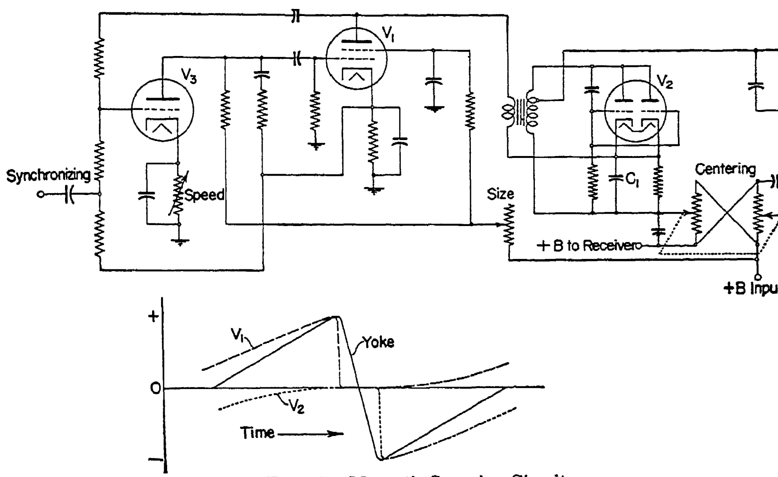

FIG. 11. Magnetic Scanning Circuit

KEYSTONE CORRECTION. When the electron beam in its undeflected position does not strike its target at a right angle the shape of the raster produced by uniform deflecting fields will be a keystone. Circuit arrangements which modulate one of the scanning generators by a signal derived from the other are required to produce a rectangular raster under these conditions. Application for these is found in the Iconoscope type of camera tube and in certain forms of picture tubes (reference 81).

6. SYNCHRONIZING

In television practice the picture information is generated in an orderly sequence. The picture display device must display this information in the same sequence if the original picture is to be reproduced. It is necessary, therefore, that information to synchronize the scanning operations of the display device be furnished with the picture information and that this information be subject to delays in transmission identical to those experienced by the picture information. Synchronizing signals are, therefore, included with the picture signals.

There are two ways in which scanning devices may be synchronized. In the simpler of these the synchronizing signal has essentially a pulse form and is applied to the scanning device in such fashion as to terminate the scanning trace and initiate the retrace. This action takes place at a speed limited only by the transient response of the scanning oscillator itself. This method of operation has the advantage of simplicity but the disadvantage that the scanning cycle may be mistimed and the picture consequently distorted by either: (1) a noise impulse tripping the oscillator prematurely; (2) loss of a synchronizing pulse due to a temporary blocking of the signal channel by noise, or (3) the combination of random noise components with the synchronizing pulse to produce random phase variation of the leading edge of the pulse.

The alternative synchronizing method is to apply the synchronizing signal and a signal derived from the scanning device to a phase comparison circuit whose output voltage controls the frequency of the scanning device. If the synchronizing pulses are uniformly spaced and the scanning device is itself stable in frequency, the phase control may be made slow acting, thus effectively decreasing the band width of the synchronizing signal channel and reducing its susceptibility to noise interference by several orders of magnitude (reference 17).

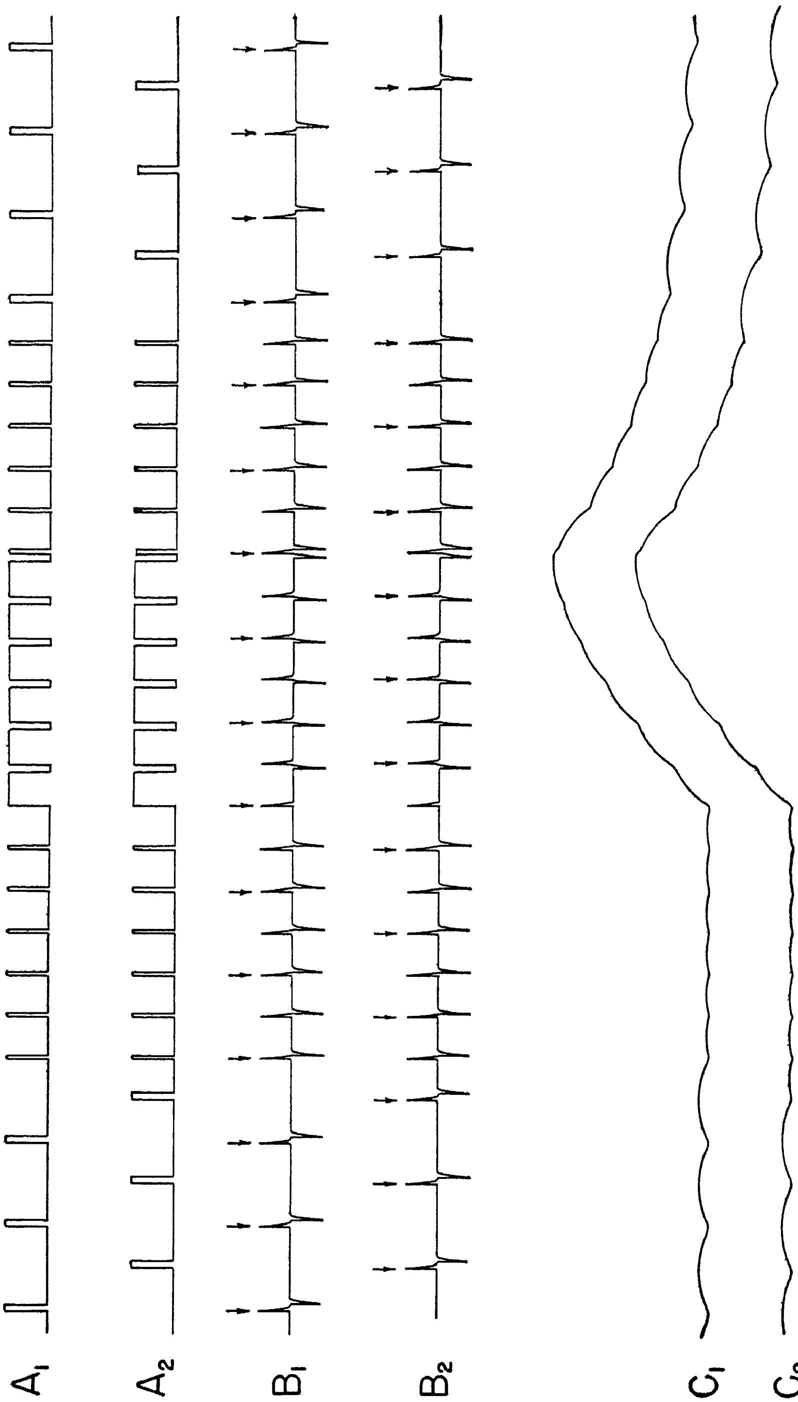

FIG. 12. Synchronizing Signal Wave Forms. *A*. Composite. *B*. Effect of Differentiating. *C*. Effect of Integrating.

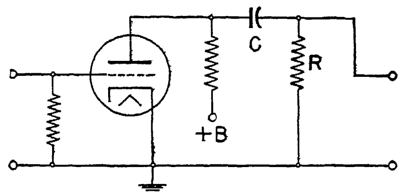
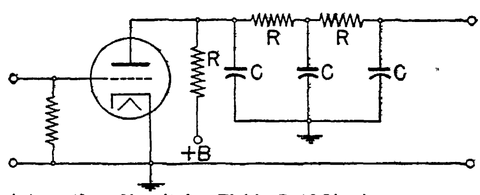
Separate synchronizing signals are required for the two directions of scanning. With interlaced scanning it is essential that these signals be readily separable one from the other in a receiver. The form of composite synchronizing signal which has been adopted to meet these requirements is shown in Fig. 12. In line A_1 of Fig. 12 the last three line-synchronizing pulses preceding the vertical retrace interval appear at the left, followed by six equalizing pulses, six field synchronizing or "broad" pulses, and six more equalizing pulses. Transmission of normal line pulses is then resumed, to continue until the next field retrace interval, shown at A_2. The traces A_1 and A_2 are separated in time by *exactly* one field period; in consequence of the use of "odd-line interlace," the line pulses in A_1 and A_2 are one-half line period out of phase. The line-frequency signals may be separated from the composite signal by differentiation, as shown at B_1, B_2; the arrows here represent the times at which the line oscillator should "fire"; at each of these, a synchronizing signal is provided. The field frequency signals may be separated by integration, with the results shown at C_1, C_2. It is a characteristic of an integrating circuit that it "remembers." For this reason the interval immediately preceding the vertical synchronizing signal contains horizontal synchronizing signals at twice the normal repetition rate. By this means the time intervals immediately preceding the vertical synchronizing pulses in the two fields are made identical. The line synchronizing pulses are reduced to half their normal duration during this period so that their integrated value will be no greater than that of line pulses of normal duration and normal repetition rate. These equalizing pulses also appear for a short interval following the vertical synchronizing signal to insure that during the entire interval in which the vertical scanning device is sensitive to synchronizing signals those signals will be alike in both fields.



Differentiating Circuit for Line; RC = 2 μsec.



Integrating Circuit for Field; R=100k ohms, C=0.005 μf.

FIG. 13. Synchronizing Signal Selection

The diagrams of Fig. 13 illustrate differentiating and integrating circuits to perform the separations shown in Fig. 12.

7. THE VIDEO SIGNAL

The video signal is generated by a pick-up tube as described in Section 15. The output of this device usually requires amplification to raise it to usable level and may, in addition, require processing to remove from the signal certain spurious components which are not properly a part of the signal. Its direct component must either be transmitted faithfully with the same gain as other components or be reinserted by either manual or automatic means after amplification has taken place.

Figure 14 shows a test pattern used for testing television systems and the oscillogram of a single scanning line of that pattern. The oscillogram was taken at a point in the transmission system where all spurious components had been eliminated. The correspondence between elements of the picture and elements of the oscillogram is shown.

TRANSMISSION OF THE D-C COMPONENT. It is theoretically possible to transmit and amplify the d-c component along with the other components of the video signal. In practice, however, this is frequently found to be inconvenient. A satisfactory alternative, known as "d-c reinsertion," may be followed once the black level of the signal has been established. In this alternative practice the recurring black intervals are used to provide an a-c carrier of the d-c component. This practice is illustrated in its simplest form in the two-stage amplifier of Fig. 15. The blocking capacitor C_1 prevents transmission of the d-c component from the anode circuit of V_1 to the grid of V_2. The video signal is applied to the grid of V_1 with positive polarity, that is, with an increase in object brightness represented by a change of signal potential in the positive direction. The black level, therefore, represents the most negative portion of the signal. The signal polarity is reversed in the anode circuit of V_1 so that at this point the black level is the most positive portion of the signal. The diode V_3 is connected to conduct on the positive portion of

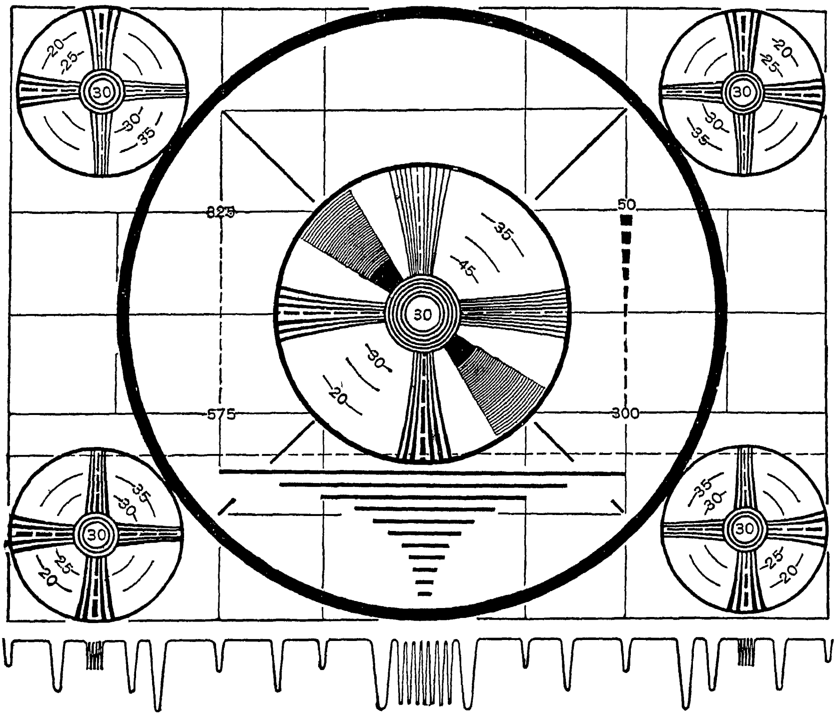


Fig. 14. Television Test Pattern and Sample Line Wave Form. Test pattern (copyrighted by Radio Corp. of America). Wave form of single line as shown.

the signal reaching it. (The grid-to-cathode conductance of V_2 shows a similar characteristic.) Current flowing through the diode in response to the black intervals of the signal establishes such a charge on C_1 as to reduce the flow of current through the diode to a value just sufficient to make up for the leakage from the condenser through R_1. If the effective resistance of the charging path (including the series resistance of the diode and the resistance of R_2) is small, the amount by which the diode anode is positive with respect to its

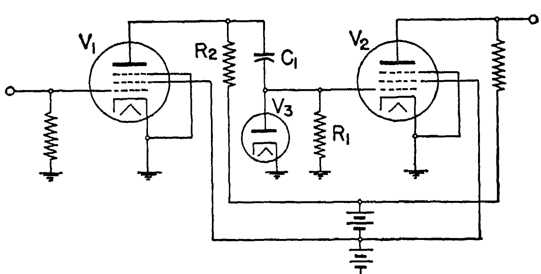

Fig. 15. D-c Reinsertion Circuit

cathode, during the black intervals, will be a negligible fraction of the total signal potential. The black intervals of the signal will, therefore, be held at substantially the potential of the diode cathode, and the gray and white portions will extend negatively from this potential in their appropriate amounts.

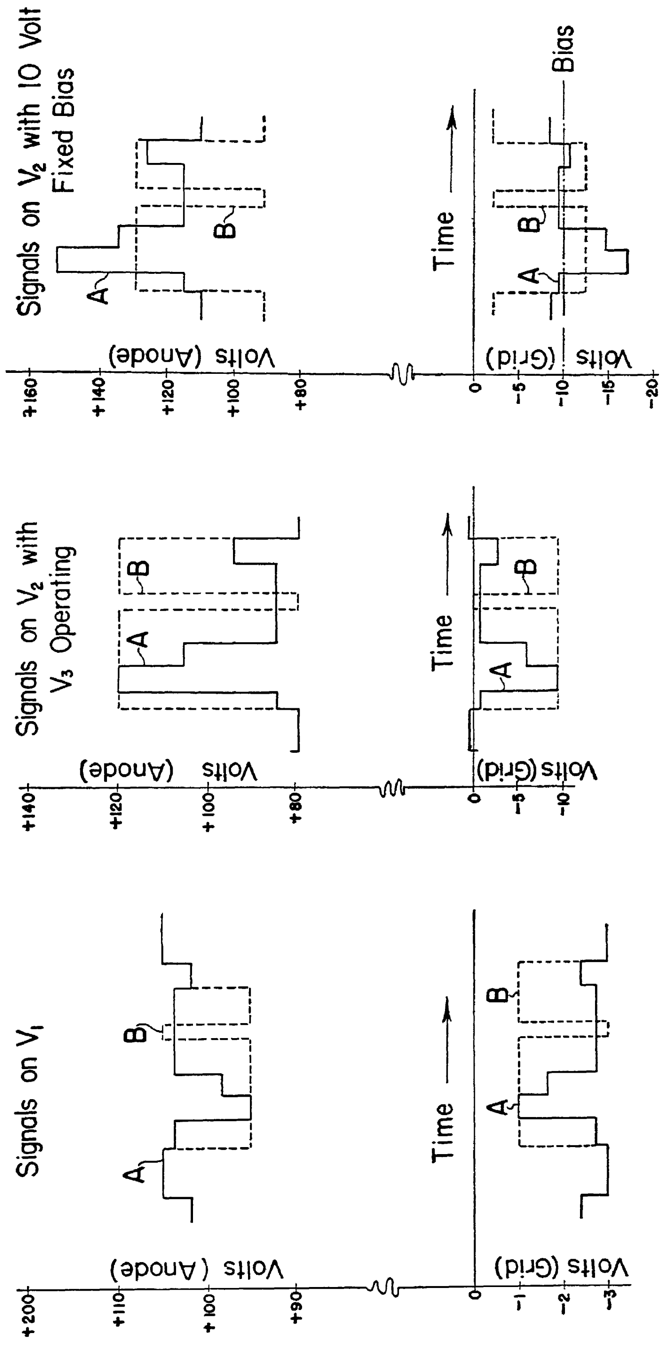

FIG. 16. D-c Reinsertion

Figure 16 shows the performance of the circuit of Fig. 15 with two different signals. Signal A has a little white, but mostly dark gray and black, while signal B is all white except for a brief black interval. The effectiveness of the reinsertion action is shown by the substantial agreement in black levels for both signals, at the grid and also at the anode of V_2. The curves shown for the performance at V_2 when the diode is replaced by a fixed bias show the much greater range of voltages which tube V_2 must handle without distortion, if d-c reinsertion is not practiced.

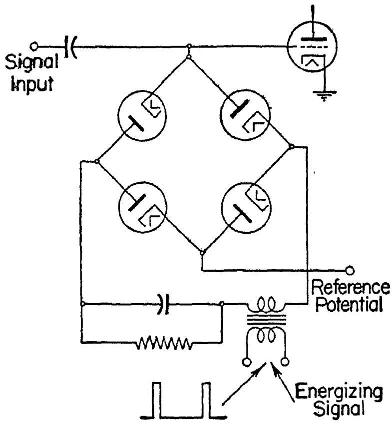

FIG. 17. Clamp Circuit

Because of the high impedance of diodes at the low currents they are called upon to handle in the circuit of Fig. 15, the accuracy with which the black level is maintained is somewhat imperfect. When more accurate performance is required, a more elaborate arrangement known as a clamp circuit may be used in place of the diode V_3 and resistor R_1 of Fig. 15. In a clamp circuit, an external source applies power to a network of diodes, producing considerable currents and low diode impedances. The network is balanced so that any deviation of the signal potential from the potential of a reference point during the flow of current from the external source is corrected by a small unbalance in the currents in the branches of the circuit. Figure 17 shows one form of clamp circuit. Clamp circuits differ from the circuit Fig. 15 in that (*a*) they are capable of conduction in both directions; (*b*) in consequence of this they must be energized only during appropriate time intervals. See also reference 27 and 84.

8. THE COMPOSITE SIGNAL

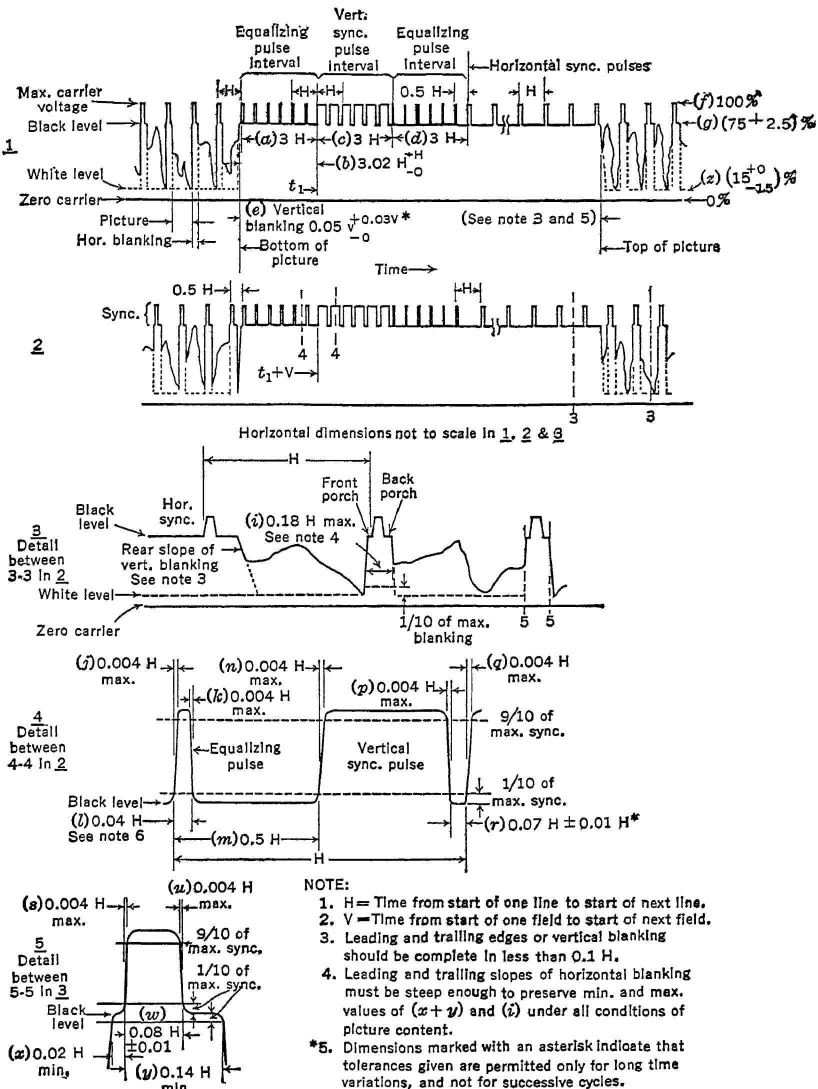
In the design of television systems provision must be made for the transmission of these four signals: (*a*) video signal; (*b*) horizontal synchronizing signal; (*c*) vertical synchronizing signal; and (*d*) sound signal.

The system may be designed to transmit all four of these from separate transmitters. Alternatively, two or more may be combined and transmitted by a single transmitter. The combination of the picture signal and the two synchronizing signals in a single transmission has been recognized as particularly suitable, since it simplifies both receiving and transmitting apparatus and also removes some sources of non-uniform transmission delay between these components.

The construction of a composite signal containing these three individual signals requires the synchronizing and picture signals to occupy different ranges of amplitude, since these two classes of signals cannot be distinguished from one another by a frequency separation. They must also occupy different time intervals. These requirements are satisfied by assigning a range of potentials beyond black (and, therefore, called infra-black) to the synchronizing signals and by inserting synchronizing signals in the time intervals provided for scanning retrace. Figure 18 shows at 3 an oscillogram of two lines of a composite signal showing line synchronizing pulses properly located in the retrace intervals. The position of the leading edge of the pulse in the retrace interval is set a short time after the beginning of the interval so that even receiver circuits of somewhat restricted band width (and hence slow transient response) will have time to reach black level before the synchronizing pulse begins, regardless of whether the picture edge is white or black. Failure to provide this interval results in phase modulation of the scanning by the picture content. This interval (sometimes called the "front porch") is made no greater than required by the foregoing consideration, since any extra waiting at this point is at the expense of either decreased time available for scanning retrace or decreased time available for picture.

The placement of the field signal conforms to the practice already described for the line signal. The field signal is located in the same region of amplitude as the line signal and is placed to occur during the vertical retrace region.

The portion of the transmission amplitude range not occupied by synchronizing signals is reserved for the picture information.



NOTE:

1. H = Time from start of one line to start of next line.
2. V = Time from start of one field to start of next field.
3. Leading and trailing edges of vertical blanking should be complete in less than 0.1 H.
4. Leading and trailing slopes of horizontal blanking must be steep enough to preserve min. and max. values of $(x + y)$ and (i) under all conditions of picture content.
*5. Dimensions marked with an asterisk indicate that tolerances given are permitted only for long time variations, and not for successive cycles.
6. Equalizing pulse area shall be between 0.45 and 0.5 of the area of a horizontal sync. pulse.
7. Refer to text for further explanations and tolerances.

FIG. 18. FCC Standard Television Synchronizing Wave Form

9. THE RADIO-FREQUENCY SIGNAL

The composite signal of Fig. 18 may be applied to an r-f carrier as either amplitude, phase, or frequency modulation. In television broadcasting, multipath transmission is frequently observed; picture distortions caused by multipath transmission when phase or frequency modulation is used are so serious that these methods of modulation have not seemed practicable. Television broadcasting, therefore, makes use of amplitude modulation.

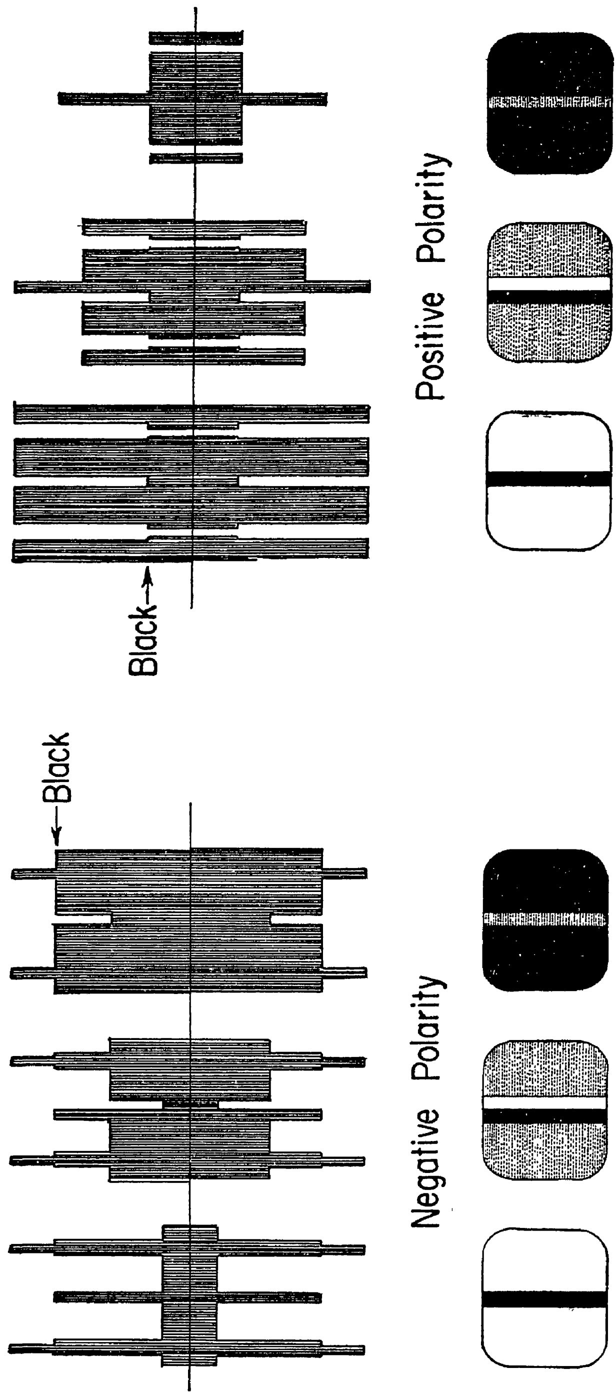


Fig. 19. Modulation Envelope Wave Forms

POLARITY OF MODULATION. Polarity of modulation may be either positive (that is, with an increase of image brightness represented by an increase of radiated signal) or negative. Figure 19 illustrates these two forms, showing individual scanning line signals for three distributions of picture content. A positive modulation polarity signal includes at all times the synchronizing level (zero carrier) and the black level. It does not indicate the level of peak white unless elements of this intensity are present in the picture. Negative modulation polarity, on the other hand, includes at all times the synchronizing level (maximum carrier intensity), the black level, and peak white (zero carrier).

Automatic gain control circuits for receivers require the presence in the received signal of some characteristic which is independent of modulation. In sound transmissions, the average value of the carrier has the required characteristic, but in television signals, the average value is dependent on average picture brightness. White level, black level, or synchronizing level must be used instead. Preferably, the peaks of the signal envelope should be used, so that a simple peak detector may serve as the source of automatic gain control information. It is found, therefore, that negative modulation polarity simplifies very much the provision of automatic gain control in receivers.

The effects of impulse noise interference on signals of the two polarities are quite different. With positive modulation impulse noise usually produces bright spots in the reproduced picture and has little effect on synchronizing signals. With negative modulation impulse noise produces primarily black spots on the picture (which are on the whole less disturbing than the bright spots produced with positive modulation) but has a greater tendency to interfere with synchronizing signals. Since it is found possible to minimize the effect of impulse noise on synchronizing sufficiently by careful circuit design in the receiver and since automatic gain control is believed desirable, American standards for television have chosen negative modulation polarity.

BAND WIDTH. As was shown in article 3, the desired band width of television video signals exceeds 4 megacycles. The application of this signal as amplitude modulation to a carrier produces a signal having a total spectrum width which exceeds 8 megacycles. Since radio channels are not available in unlimited quantities and since also the cost of amplifiers is increased as their required band width increases, television broadcast practice is based on vestigial sideband transmission. Curves *A* and *B* of Fig. 20 show the radio-

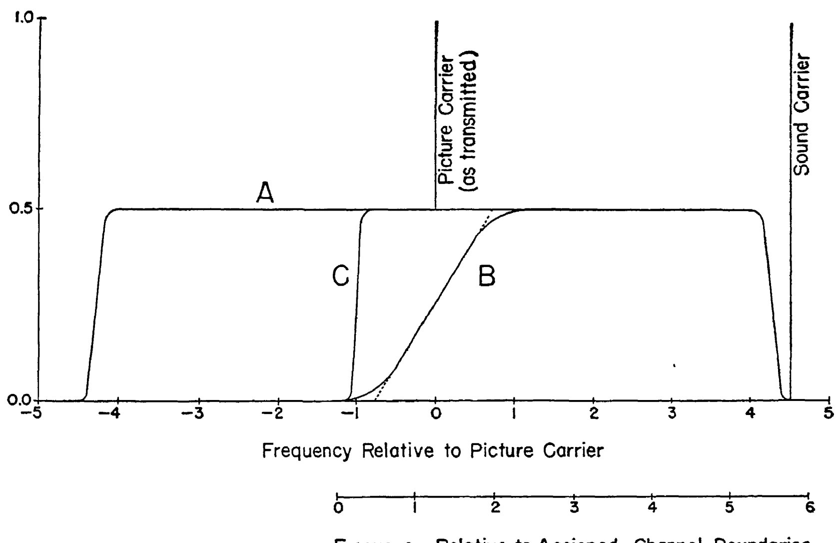

FIG. 20. Radio-frequency Amplitude Characteristics. *A*. Double Side-band Transmission. *B*. Vestigial Side-band Transmission Overall Characteristic. *C*. Vestigial Side-band Transmission; Transmitter Only.

frequency amplitude characteristics for double sideband transmission and for vestigial sideband transmission (references 19 to 24).

The overall transmission characteristic for vestigial sideband transmission requires that the signal originally produced with a carrier and symmetrical sidebands must be attenuated selectively. The practice which has been standardized is to provide a receiver characteristic having the same form as the desired system overall characteristic. The corresponding transmitter characteristic must, therefore, exhibit negligible attenuation at all frequencies which are effectively transmitted by the receiver. It has therefore been standardized as shown in Fig. 20 as curve *C*.

SOUND TRANSMISSION. The sound accompanying a television picture is transmitted on a separate carrier whose frequency is located, with respect to the picture carrier and its sidebands, as shown in Fig. 20. The sound carrier is frequency modulated with maximum deviation of 25 kilocycles. The pre-emphasis practice standardized for frequency-modulated sound broadcasting is also used for television sound.

FREQUENCY ALLOCATION. Because of the wide frequency channels required for television, allocation of channels below 50 megacycles would interfere with so many existing services as to be impracticable. Television allocations for commercial use, therefore, lie in the range between 54 and 216 megacycles, as shown in the table. Allocations at higher frequencies have been made for experimental and relay use.

Channel	Nominal Boundaries	Picture Carrier	Sound Carrier
2	54– 60	55.25	59.75
3	60– 66	61.25	65.75
4	66– 72	67.25	71.75
5	76– 82	77.25	81.75
6	82– 88	83.25	87.75
7	174–180	175.25	179.75
8	180–186	181.25	185.75
9	186–192	187.25	191.75
10	192–198	193.25	197.75
11	198–204	199.25	203.75
12	204–210	205.25	209.75
13	210–216	211.25	215.75

POLARIZATION OF RADIATED SIGNAL. A simple horizontally polarized dipole antenna has a horizontal directive pattern which is sometimes useful in minimizing effects of multiple transmission paths. Since in other respects there is little net advantage either way between horizontal and vertical polarization, horizontal polarization has been standardized.

10. STANDARDS

The Federal Communications Commission has established the following Standards of Good Engineering Practice for television broadcasting:

1. The width of the television broadcast channel shall be 6 megacycles per second.
2. The visual carrier shall be located 4.5 megacycles lower in frequency than the aural center frequency.
3. The aural center frequency shall be located 0.25 megacycle lower than the upper frequency limit of the channel.
4. The visual transmission amplitude characteristic shall be as shown in Appendix II [curve *C* of Fig. 20].
5. The number of scanning lines per frame period shall be 525, interlaced 2:1.
6. The frame frequency shall be 30 per second, and the field frequency shall be 60 per second.
7. The aspect ratio of the transmitted television picture shall be 4 units horizontally to 3 units vertically.
8. During active scanning intervals, the scene shall be scanned from left to right horizontally and from top to bottom vertically, at uniform velocities.
9. A carrier shall be modulated within a single television channel for both picture and synchronizing signals, the two signals comprising different modulation ranges in amplitude (see Appendices I and II) [Figs. 18 and 20].
10. A decrease in initial light intensity shall cause an increase in radiated power (negative transmission).
11. The black level shall be represented by a definite carrier level, independent of light and shade in the picture.
12. The pedestal level (normal black level) shall be transmitted at 75 per cent (with a tolerance of plus or minus 2.5 per cent) of the peak carrier amplitude.
13. The maximum white level shall be 15 per cent or less of the peak carrier amplitude.
14. The signals radiated shall have horizontal polarization.
15. A radiated power of the aural transmitter not less than 50 per cent or more than 150 per cent of the peak radiated power of the video transmitter shall be employed.

16.* *Variation of Output.* The peak-to-peak variation of transmitter output within one frame of video signal due to all causes, including hum, noise, and low-frequency response, measured at both synchronizing peak and pedestal level, shall not exceed 5 per cent of the average synchronizing peak signal amplitude.

17.* *Black Level.* The black level should be made as nearly equal to the pedestal level as the state of the art will permit. If they are made essentially equal, satisfactory operation will result and improved techniques will later lead to the establishment of the tolerance if necessary.

18.* *Brightness Characteristics.* The transmitter output shall vary in substantially inverse logarithmic relation to the brightness of the subject. No tolerances are set at this time.

See also reference 28 for an extended discussion of standards.

TELEVISION BROADCASTING

By T. J. Buzalski, A. L. Hammerschmidt, and F. J. Somers

A modern television broadcasting plant provides facilities for the pick-up and broadcast of entertainment, news, and cultural and educational subject matter in both sight and sound. The purpose of such a plant is to provide an adequate and satisfactory public service, and this requires a flexible and well-coordinated installation. A functional subdivision of equipment and facilities is the following:

(*a*) Studio and control facilities (picture and sound).
(*b*) Field pick-up and relay facilities (picture and sound).
(*c*) Visual and aural broadcast transmitters.

Typical studio and control facilities consist of one or more live-talent studios, a film pick-up studio, a video effects studio, one or more announcers' booths, and a master control room having switching and monitoring facilities for feeding the various studio outputs or remote pick-up outputs to the transmitter, as required. The master timing or synchronizing generator, various picture line amplifiers, power supply rectifiers, and other equipment common to the studio facilities system are usually grouped in a main equipment room for maximum efficiency and ease of maintenance.

Field pick-up facilities include portable television cameras with their associated control, monitoring, and synchronizing equipment and portable sound equipment. Either radio relay circuits, coaxial cables, or equalized telephone lines are used to transmit the picture signals back to the master control room of the broadcast station proper. The sound portion of the program is generally transmitted back by wire line, though radio circuits are used where wire facilities are not available. Field pick-ups also encompass the use of mobile equipment where the television cameras, along with their synchronizing, control, and monitoring equipment, are mounted in a moving boat, aircraft, or other means of locomotion.

The need for maximum height of the transmitting antenna to provide line-of-sight reception for as many receivers as possible usually requires that the visual and aural transmitters be located remote from the television studios. The visual link between the master control switching point and the transmitter may be a radio relay circuit, a coaxial cable, or an equalized telephone line. The aural link between the master control point and the transmitter is usually a wire line.

In order to coordinate operations and to assure program continuity, the television plant must be provided with an adequate and flexible intercommunication and order wire system separate and apart from the sound program pick-up, control, and transmission equipment.

11. LENS APERTURE REQUIRED

The lens speed required for a given camera pick-up tube and scene illumination is best determined by experiment under operating conditions or from data supplied by the tube manufacturer. If it is desired to compute the lens speed which will provide a sufficiently bright image to meet the requirements of a given pick-up tube, the following formulas (see reference 33) are applicable:

$$F \text{ (focal length of lens)} = \frac{W}{2} \cot \frac{\alpha}{2} \text{ inches} \tag{1}$$

$$f \text{ (numerical aperture)} = \frac{0.064W\sqrt{TBs}}{\sqrt{10^6 I_n N}} \tag{2}$$

* These items are subject to change but are considered the best practice under the present state of the art. They will not be enforced pending a further determination thereof.

where W = the width in inches of the pick-up tube sensitive surface.
α = the desired horizontal angle of view in degrees.
s = the pick-up tube sensitivity in signal microamperes per lumen.
B = the surface brightness of the scene in candles per square foot.
T = the light transmission factor of the lens (usually between 40 and 60 per cent).
N = the required peak picture signal-to-rms noise ratio.
$\bar{I}_n$ = the equivalent rms noise current (amperes) at the input of the amplifier used with the pick-up tube.

The noise generated in pick-up tubes without electron multipliers is small compared with that originating in the first tube of the video-preamplifier. Noise currents generated in the first video amplifier stage result from two significant components: thermal agitation noise in the input circuit and current fluctuations in the plate circuit of the first video amplifier tube. An expression combining these components for the computation of the equivalent rms noise current ($\bar{I}_n$) follows (see reference 33):

$$\bar{I}_n = 2\sqrt{\frac{kTfm}{R}\left(1 + \frac{RR_t(2\pi fmC)^2}{3}\right)} \tag{3}$$

where $\bar{I}_n$ = equivalent rms noise current in amperes.
k = Boltzmann constant (1.37×10^{-23} joule per °K).
T = absolute temperature (300° K).
fm = pass band of amplifier in cycles per second.
R = input resistor of amplifier in ohms.
R_t = equivalent grid resistance of input tube for noise in ohms at 300° K (for first video amplifier tube).
C = total shunt capacity (pick-up tube, stray capacity, and video amplifier input capacity).

In a non-storage pick-up tube where the photoelectrons are amplified by an electron multiplier incorporated in the pick-up tube, the predominant noise originates at the photocathode. (See reference 34.) The equivalent rms noise current in this case is given by the following expression:

$$\bar{I}_n = \sqrt{2ei_0fm} \text{ amperes} \tag{4}$$

where i_0 = current for one picture element.
e = electron charge = 1.59×10^{-19} coulomb.
fm = pass band of equipment (cycles per second).

It should be pointed out that the sensitivity s of a pick-up tube in signal microamperes per lumen is not necessarily a constant. In some types of tubes s is a function of the incident light. This is illustrated by the curve of Fig. 1, which shows s for a sample Icono-

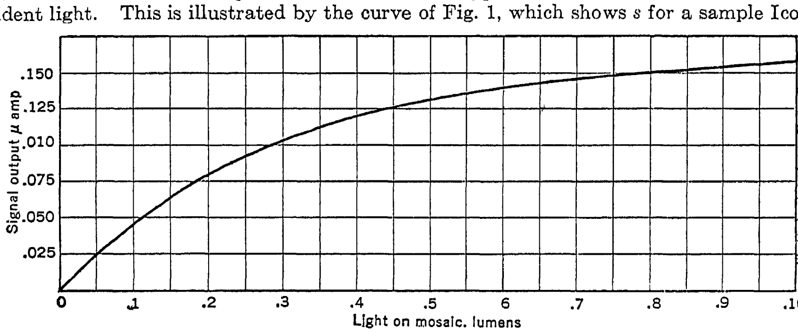

FIG. 1. Signal Output vs Illumination Characteristic of a Typical Iconoscope

scope (reference 56). Another type of tube having a non-linear sensitivity curve is the Image Orthicon (reference 30). The signal output vs. illumination curves of the Orthicon and the Image Dissector are essentially straight lines.

12. STUDIO CAMERA DESIGN

Aside from the pick-up lens, view finder (references 31 and 32), and other optical requirements, the electrical and mechanical design of the studio camera must be given careful consideration. Experience has shown that the following principles should be followed in the design:

(a) In order to keep the camera as small, light, and mobile as possible, the number of tubes and components housed in the camera proper should be kept to the minimum. As much auxiliary equipment as possible should be mounted on permanent racks in or near the control room.

(b) All electrical camera controls and adjustments which may require attention during a broadcast should be located at or within easy reach of the control-room console.

(c) The mechanical layout of the camera should facilitate rapid servicing in case of failure. Such features as replaceable plug-in type video preamplifiers will simplify maintenance of the camera.

A variety of different types of camera tubes have been used for television studio pick-up. Before 1946 the Iconoscope camera found the widest acceptance among television broadcasters. Subsequently the Image Orthicon (reference 30) with its greater light sensitivity has been found to have practical advantages for studio use. Since space does not permit a detailed discussion of all camera types, the Iconscope has been chosen in the following example since it embodies many features that are common to present television cameras.

In a typical Iconoscope studio camera design, the following items are included in the camera housing proper:

(a) Video preamplifier (five tubes) including a high-peaker stage and a cathode follower to feed a 75-ohm coaxial line.

(b) Beam blanking amplifier (double triode).

(c) Horizontal and vertical deflection coils in a yoke assembly arranged to be fed from an external source via coaxial cables.

(d) Bias lighting arrangement for improving the collection of secondary electrons from the mosaic.

(e) Filament transformer (110-volt alternating current to 6.3-volt alternating current 60 cycles).

This particular design of camera used an optical view finder and was mounted on a movable pedestal equipped with a pushbutton-controlled motor-driven elevating arrangement, a suitable tilting and panning head being provided for mounting the camera.

A typical flexible cable for connecting the camera to the rack equipment has conductors and insulation as shown in Table 1. As indicated in the table, this cable has been designed as an all-purpose cable which can be used with a variety of camera and pick-up tube types. Conductors 26 and 27 are coaxial cables, conductor group 28, 29 is a shielded balanced twisted pair video cable. Conductors 3 and 4 are used to feed high voltage to the pick-up tube. Video cable shields should be run separately from the common power supply circuit ground to avoid possible interference pick-up due to common ground return impedance.

For camera cable lengths of 100 to 150 ft maximum, it is practical to locate the deflection wave generators in the control-room racks, provided sufficiently low-impedance deflection coils are used in the camera deflection yoke. For longer cable lengths, it is advisable to locate the deflection amplifiers in the camera proper or in the camera pedestal, feeding the horizontal and vertical driving pulses or sawtooth waves out to the camera from the racks via terminated 75-ohm coaxial cables or terminated balanced pair twinax cables.

Some types of camera tubes are easily damaged if the deflection circuits fail during operation. This is true of Iconoscopes. Orthicons may also be damaged if the mosaic is illuminated when the deflection failure occurs. It is, therefore, necessary to provide protective devices to bias off the scanning beam automatically when deflection fails. Relays actuated by rectified deflection currents have proved satisfactory for this purpose.

The video output of the camera may be fed to the control room from the camera either by a coaxial line or by a balanced twisted pair transmission line with an external grounded shield. The latter is preferred to give better discrimination against hum pick-up in long cables.

The camera preamplifier design usually provides for a peak-to-peak video output from the camera of between 0.1 and 1.0 volt. The higher levels are preferred to provide discrimination against possible interference pick-up in the cable.

VIDEO PREAMPLIFIER DESIGN. The scene brightness, the speed of the lens, the sensitivity of the pick-up tube, and the value of pick-up tube signal load resistor being known, the low-frequency gain required of the preamplifier to bring the signal up to the desired level to feed the 75-ohm cable can readily be calculated. (By low-frequency gain is meant the gain for video frequencies below 50 or 100 kc.) The high-frequency gain required of the amplifier, assuming that the general practice of feeding a "flat" signal to the line is followed, is dependent on the frequency and phase distortion introduced at the input of the preamplifier by the network used to couple the output of the pick-up tube to the grid of the first stage of the preamplifier. Use of a high value of load resistor (30,000 to 100,000 ohms) compared to the value which would be chosen for flat response (1000 to

3000 ohms) offers advantages in discrimination against low-frequency noise and microphonic disturbances in the first preamplifier stage, because it results in a relatively greater level of low-frequency signal being applied to the first grid than if a flat system is used. On the other hand, tubes having a self-contained electron signal multiplier such as the Image Dissector or the Image Orthicon can provide a relatively large signal output current so that a relatively low value of signal load resistor can deliver sufficient signal voltage, in many cases, to override noise and microphonic disturbances generated in the first thermionic amplifier stage.

When a high value of signal load resistor is used, it is the practice to compensate for the frequency and phase distortion introduced by incorporating a "high-peaker" stage in the video preamplifier. Figure 2 is a block diagram illustrating one form of high-peaking.

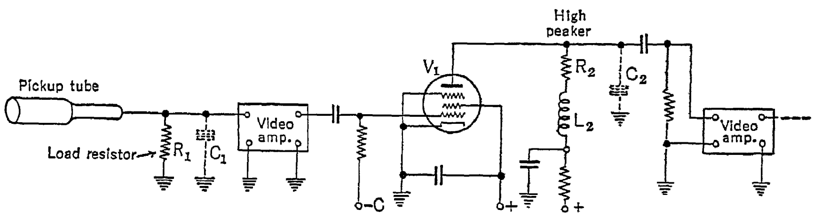

FIG. 2. High Peaker Stage Employing Resistance and Inductance in the Plate Circuit

The load impedance Z_1 for the pick-up tube consists of R_1 and C_1 in parallel, C_1 being the combined output capacitance of the pick-up tube, stray and wiring capacitances, and the input capacitance of the first video amplifier stage. The video amplifier stages following the input circuit are designed for uniform response over the required band width. These feed a high-peaker stage V_1 having an effective plate load impedance Z_2 at high frequencies consisting of R_2 and L_2 in series (neglecting C_2). Since the internal impedance of both the pick-up tube and V_1 will be relatively high (they may be considered as constant-current generators) and since the amplifier between the pick-up tube and V_1 is designed for uniform response, the overall response of the system is proportional to the product Z_1Z_2. If the values of Z_1 and Z_2 are chosen so that $Z_1Z_2 = A^2 =$ constant (inverse networks), an

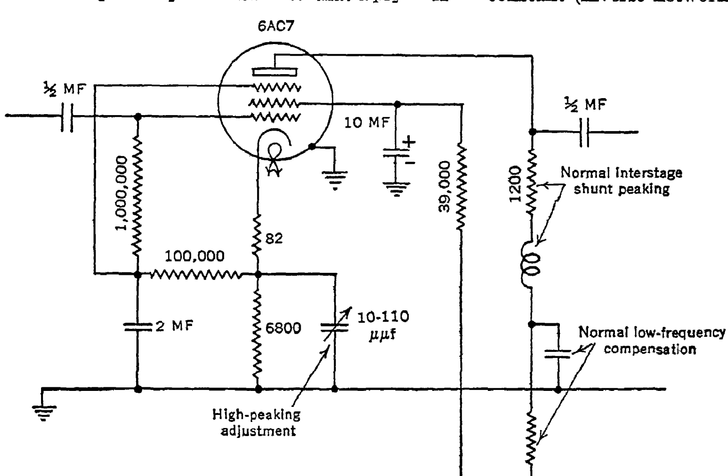

FIG. 3. High Peaker Stage Utilizing Variable Cathode By-pass

overall flat response will be obtained for frequencies below the point where the resonance of C_2 with L_2 begins to have important effect. This condition is fulfilled when $R_1C_1 = L_2/R_2$. It has been found that, if L_2 is chosen such that the resonance of C_2 with L_2 occurs at a frequency about 1.5 or more times higher than the top video frequency for which the balance of the amplifier is designed, the effect of C_2 can be neglected.

Obviously, by adding a series coil to the input circuit, a pair of inverse networks could be provided which would exactly compensate for the distortion including the effect of C_2.

From a practical standpoint, however, the simpler arrangement of Fig. 2 has been found to give satisfactory results. Two other high-peaker circuits which are simple and yet can be designed to give satisfactory compensation over a reasonably wide band are illustrated in Figs. 3 and 4. A variety of other circuits and compensation methods can also be used.

The low-frequency compensation of the preamplifier generally follows standard practice, the amplifier being designed to pass without appreciable distortion a 60-cycle square wave applied to the input terminals. In some designs of Iconoscope preamplifiers, an additional network consisting of 150,000 to 300,000 ohms shunted by 0.001 to 0.005 μf is placed in series with the low-potential end of the signal load resistor to obtain improved operation

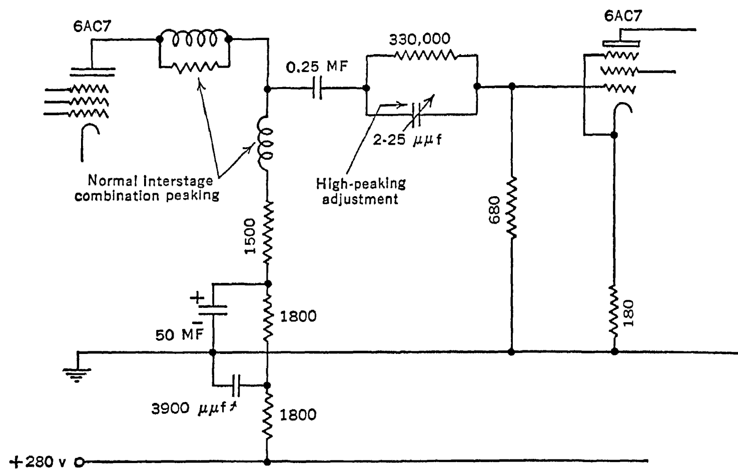

FIG. 4. High Peaker with Variable Series Capacitor

at low and medium frequencies. When this is done, an appropriate network must be inserted in one of the later stages of the amplifying system to compensate for this low-frequency pre-emphasis.

13. STUDIO EQUIPMENT

CONTROL ROOM. In a typical studio control room for Iconoscope cameras, the rack equipment for each camera chain consists of the following:

(*a*) Horizontal deflection sawtooth wave generator, with the output modulated by sawtooth waves of vertical frequency for keystoning. The amplitude of the sawtooth wave, as well as the amount of keystoning, is adjustable. An output transformer feeds the low-impedance deflection coils in the camera via a 75-ohm coaxial cable. An impedance step-up transformer located in the camera is sometimes used to feed the deflection coils.

(*b*) Vertical deflection sawtooth wave generator with an output transformer feeding a 75-ohm coaxial line which connects to the camera vertical deflection coils. An impedance step-up transformer located in the camera is sometimes used to feed the deflection coils.

(*c*) Regulated power supplies for deflection amplifiers, video amplifiers, and the Iconoscope.

(*d*) Studio amplifier. This amplifier provides video outputs for feeding monitoring circuits and the master control room. The output circuits feed 75-ohm coaxial lines at a signal voltage level between 0.5 volt and 1.0 volt peak to peak, depending on the standard level adopted for a given plant. The output of the studio amplifier contains picture blanking signals but not synchronizing signals. An excess of picture blanking signals is introduced in one of the later stages of the studio amplifier followed by an adjustable clipper or pedestal (brightness) control. The amplifier is provided with a video gain control.

(*e*) Shading amplifier. Certain types of camera tubes, including the Iconoscope, generate a spurious signal output in addition to the signals representative of picture information. The effect on the television picture of uncompensated spurious signals is to produce shaded areas not present in the original scene.

It has been found in practice that the effect of spurious signals can readily be compensated by the addition of a few simple wave forms of appropriate amplitude and polarity to the camera video output. Since the shading wave forms and amplitudes required vary with scene illumination, it is the practice to provide individual manual adjustment of shading waveforms for each Iconoscope camera. Pick-up tubes which do not always require shading signals are the Image Dissector, the RCA type 1840 Orthicon, and the Image Orthicon.

The following shading wave forms, adjustable in amplitude and polarity, are provided for each camera chain: (1) horizontal sawtooth; (2) vertical sawtooth; (3) horizontal parabola (adjustable clipping); (4) vertical parabola (adjustable clipping); (5) vertical sine wave with adjustable phase (the inclusion of vertical sine wave is optional).

When a studio is equipped with more than one Iconoscope camera, it is usually economical to provide a shading generator having a low-impedance pushpull output bus for each shading wave form. Relatively high-impedance center-tapped potentiometers can then be connected in parallel with these buses to feed a shading isolation and mixing amplifier, associated with each camera chain.

Shading signals should be added to the video signal in a low-level stage of the video system prior to the introduction of picture blanking. Introduction of shading into a low-level stage (it is sometimes fed into an early stage of the preamplifier in the camera) tends to prevent overload of the higher-level stages due to uncompensated tilt in the video signal wave form.

The following operating controls should be located on the studio console for each camera chain: (1) Iconoscope beam current; (2) Iconoscope focus; (3) video gain (contrast); (4) pedestal (brightness); (5) all shading controls.

The following controls which generally require attention only during initial warm-up of the equipment need not be mounted on the console but should be within easy reach of the video operator: (1) vertical deflection amplitude; (2) vertical deflection centering; (3) keystone adjustment; (4) horizontal deflection amplitude; (5) horizontal deflection centering; (6) bias light adjustment.

Though the example given above deals with Iconoscope cameras, the same general principles and layout apply for other types of pick-up tubes, except, of course, that different arrangements of operating controls and adjustments are necessary. The need for shading signals is generally associated with Iconoscopes alone, but availability of at least sawtooth and parabola wave forms is often advantageous when using other types of camera tubes which nominally do not require it. Thus a tube with somewhat non-uniform sensitivity over different parts of its photoelement may produce a satisfactory picture if shading signals are available.

AMPLIFIER DESIGN. In the usual equipment layout, the studio amplifier performs the following functions:

1. Provides for the insertion of shading wave forms if they have not previously been added in the preamplifier.
2. Provides for the addition of picture blanking signals of adjustable amplitude to the video signal.
3. Provides for variable gain control (automatic gain control is sometimes used) of the video signal.
4. May include one or more of the following corrective features: (*a*) gamma correction; (*b*) aperture distortion correction; (*c*) correction for phase distortion.
5. The studio amplifier usually provides at least two independent outputs of combined video and blanking signals at levels of 0.5 volt to 1.0 volt peak to peak at 75-ohm impedance. One of these outputs normally feeds the master control and switching point where the studio output may be switched to the transmitter. The other output feeds the local studio picture monitoring circuits.

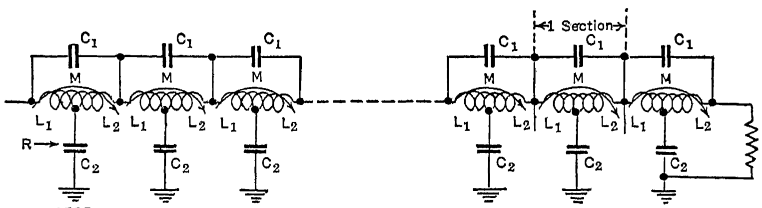
The video coupling networks used in the studio amplifier follow the conventional designs. Shading signals are generally added via a tube whose plate or cathode feeds an impedance common to a plate or cathode of one of the video stages. Blanking signals are generally added through a tube whose plate feeds an impedance common to the plate of one of the later video amplifying stages. An excess of picture blanking signal is added, being clipped off by a variable clipping arrangement in the following video stage. Care should be exercised in the design to provide an exceptionally linear clipping arrangement to avoid crowding of signal voltages corresponding to the darker portions of the picture.

MONITORING AND SWITCHING FACILITIES. Studio monitoring facilities generally consist of a picture monitor showing the outgoing picture plus one picture preview monitor for each camera in operation in the studio. The outgoing picture or "on the air" monitor should preferably be fed through a return feed from the master control point and should be synchronized from the synchronizing signals which have been added to the video and blanking components at the master control point. The preview monitors are generally of the "driven type," i.e., locked-in by the horizontal and vertical driving pulses utilized to operate the camera deflection circuits. When this is done, the preview monitors may be switched from one camera output to another without loss of synchronization. Also, since the camera outputs normally do not provide synchronizing signals, the use of driving impulses gives more stable results than blanking signals for preview monitor synchronization. The on-the-air monitor should be synchronized from pulses contained in the composite input signal, however, because it is often necessary to connect it to view pictures supplied from other sources in the normal course of operations.

One satisfactory method of switching the video monitors is to provide them with high-impedance inputs (via cathode followers in some designs) so that one or more can be switched to the 75-ohm monitoring output bus of any one of the studio amplifiers. Monitor switching may be accomplished by mechanical switches, by switching relays, or by electronic means. A relay switching system controlled by a set of pushbuttons and indicator lamps mounted on the control console is sometimes used.

In addition to picture monitoring facilities, wave-form monitors have to be provided as a continuous check on the shading and voltage level of the signal generated by each camera chain as well as that being fed out of the studio. A pushbutton-controlled switching system for the wave-form monitors is desirable.

TIME DELAY NETWORKS. In the usual television studio plant having more than one studio or signal source, it is the practice to add the synchronizing signals to the video



$L_1 = L_2 = \frac{0.158R}{f}$ = self-inductance of each coil.

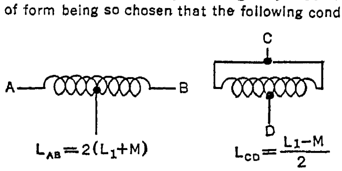
$M = \frac{0.050R}{f}$ = mutual inductance of L_1 and L_2. (Coils are wound so that the fields are series aiding, thus giving an effective negative mutual inductance).

$C_1 = \frac{0.029}{Rf}$

$C_2 = \frac{0.315}{Rf}$

f = top frequency required to reproduce original pulse.
R = design impedance.
Approximate delay per section $= \frac{0.316}{f}$ seconds.

The L_1, L_2, M assembly is a single-layer coil with a center tap, the wire size spacing between turns and diameter of form being so chosen that the following conditions are satisfied.



A center tapped coil satisfying these conditions is the equivalent of two coils each of self-inductance L_1 and of negative mutual inductance M

FIG. 5. Delay Network Employing Negative Mutual Inductance

and blanking signals at one point in the system, usually the master switching or control point. This is done for the following reasons: (1) failure of the studio output does not disturb the transmitter or throw receivers out of synchronization; (2) synchronizing signal level fed to the transmitter can be made independent of variations in studio output level; (3) insertion of synchronizing signals in the system at a single point just prior to the studio-transmitter link is the most practical way to maintain synchronizing signals at the exact level required by the transmitter.

Since the cables connecting the various studios with the master control position are usually of different lengths, electrical networks are employed to delay the signals arriving via shorter cables so that the proper "front porch" margin between the starting time of the horizontal picture blanking pulses and the starting time of the horizontal synchronizing pulses will be maintained when synchronizing signals are added. The delay networks usually consist of a number of sections of artificial line utilizing lumped constants. Though it would be possible to insert the delay networks in the studio video outputs, it is generally preferable to insert them in the coaxial lines feeding the studio with the camera driving, camera blanking, and picture blanking signals. This is more economical as less perfect delay networks can be used and the effects of any slight transmission line reflections due to incorrect termination can readily be removed by clipper stages in the studio deflection and blanking amplifiers.

DESIGN OF DELAY NETWORKS. Studio delay networks may be designed in a number of forms. A common type is an artificial line with $Z_0 = 75$ ohms in the form of a ladder network with a number of series coils and shunt capacitors. This type of artificial line may be treated as a low-pass filter with the cut-off chosen somewhat higher than the top operating frequency. As in usual filter practice, this type of network is best terminated by a double M-derived network at its output. A design using negative mutual inductance which gives excellent performance is shown in Fig. 5. The top operating frequency may be chosen on the basis of the number of harmonics of line-scanning frequency required to reproduce a pulse of a given steepness. The order n of the highest harmonic required is $n = 100/p$, where p is the time of rise of the wave expressed in percentage of the fundamental period (reference 35).

Continuous lengths of transmission line can be used in lieu of lumped delay networks. If a continuous length of line is used for time delay, it should have reasonably low attenuation and uniform time delay over the required frequency band.

14. GAMMA (TRANSFER CHARACTERISTIC)

The term gamma (γ), has been used to define the slope of the curve of the logarithm of image brightness vs. the logarithm of object brightness (reference 36). Unless otherwise specified, the slope γ refers to the central linear portion of the curve, between the extremities of the brightness values considered.

Though the term gamma is a useful concept when making comparisons with photography, the trend is away from it in connection with television systems. As a matter of fact, the term must be applied with caution since it often leads to erroneous conclusions. The reason for this is twofold. First, gamma, being a numeric and referring only to the central portion of the characteristic, tells nothing about the effect of the shape of the toe and knee of the curve; second, the concept is difficult to apply in many portions of the television system where a reference to picture black is not directly available. Therefore, the term gamma, if used at all, should be restricted to comparisons of original scene brightnesses and final image brightnesses in an overall sense.

"Transfer characteristic" (reference 28) is the name that has been given to the logarithmic plot of light input vs. signal voltage output of a television transducer. Thus, the Iconoscope performance curve of Fig. 1, plotted to logarithmic coordinates, could be called the "signal current vs. illumination transfer characteristic" of an Iconoscope.

GAMMA CORRECTION. It can be shown that the overall signal-to-noise ratio of a television pick-up, transmitting, and receiving system is improved by transmitting a logarithmic light vs. voltage characteristic. Though the exact shape of the curve has not been standardized (1949), it appears to be accepted that the light vs voltage characteristic of the Iconoscope (see Fig. 1) is close to the ideal shape. The reproducer normally has the opposite curvature to Fig. 1. This is conveniently obtained by providing a picture tube with the required light output vs. grid voltage transfer characteristic.

When a pick-up tube such as an Image Dissector or an RCA type 1840 Orthicon, having linear voltage output vs. illumination transfer characteristic, is used, it is necessary to incorporate a non-linear element in the amplifying system to achieve the desired logarithmic curvature. An amplifier designed for this purpose is called a gamma-correction amplifier.

A wide variety of circuits may be used for gamma correction. The following design principles apply: (*a*) Black level must be established at the input to correction stage so that the correction can be applied independent of the excursions of the *AC* axis of the video signal with respect to black level. (*b*) The correction should be applied prior to the video stage in which picture blanking pedestals are inserted. (*c*) The correction amplifier should be designed so that the amount of correction applied is variable between no correction at all and the maximum value. The maximum value is limited by the minimum signal-to-noise ratio that can be tolerated. A difference in video gain between the signals corresponding to the dark portions and the light portions of the picture of 10 : 1 or even 100 : 1 is often desirable. A gain difference of 10 times is the most that can be used in many cases, however, owing to signal-to-noise ratio limitations. The amount of correction to be applied for a given scene is subject to artistic as well as technical requirements. (*d*) For a television system capable of reproducing only a relatively narrow contrast range, the exact shape of the gamma-correction curve is relatively unimportant as far as the eye is concerned when viewing the overall result.

A common type of gamma-correction amplifier utilizing tubes of different characteristics in parallel is shown in Fig. 6. Another system having a diode connected across the cathode resistor of a video stage is shown in Fig. 7.

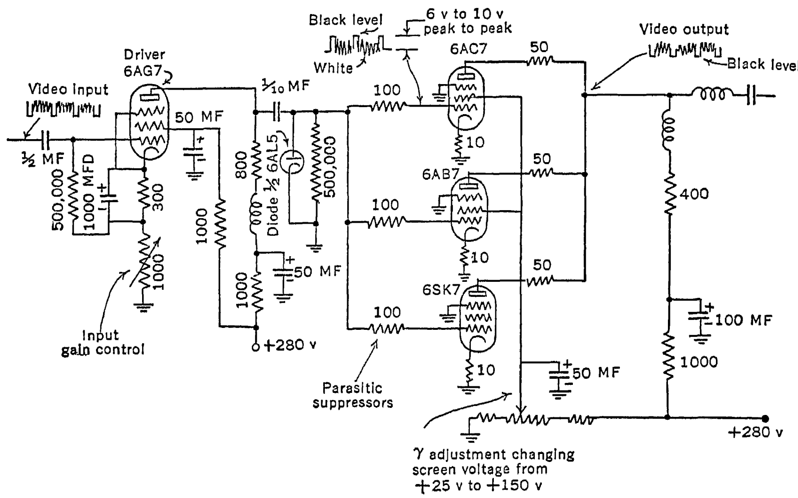


FIG. 6. Gamma Correction Stage Using Tubes in Parallel

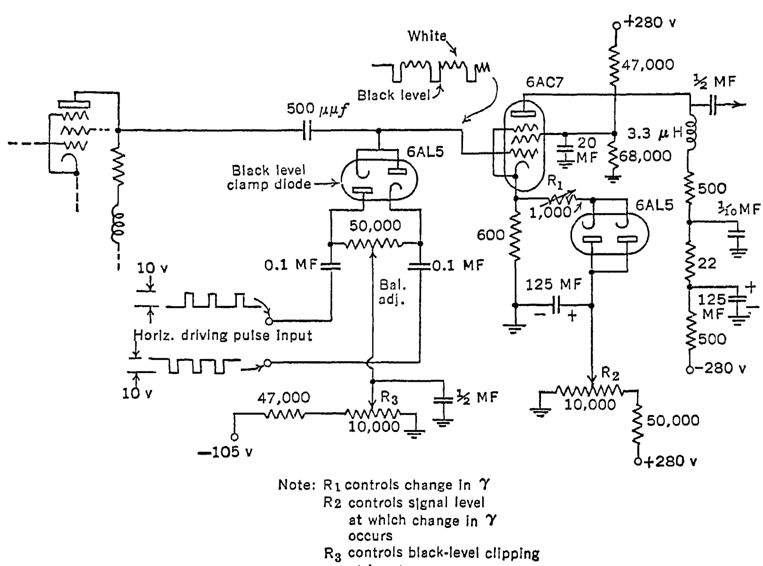

FIG. 7. Gamma Correction Stage with Variable Cathode Degeneration

15. APERTURE CORRECTION

When the size of the pick-up or reproducer scanning spot is appreciable compared to a picture element, aperture distortion takes place. For a mechanical scanning system or an equivalent system in which the dimensions of the scanning spot are accurately known, the amplitude vs. frequency distortion caused by the finite size of the aperture may be accurately calculated (reference 6). For cathode-ray systems the effects of aperture distortion are best determined by test. In a pick-up tube using cathode-ray beam scanning, for example, the effects of aperture distortion may be measured by determining the signal output obtained by scanning different patterns of uniformly illuminated alternate black and white lines of various pitches. A measured signal output vs. picture element size curve having been obtained for a given type pick-up tube, an amplitude correction equalizing network may be designed to compensate for the aperture distortion (reference 2). The complete aperture correction equalizer should include a phase equalizer to compensate for any phase distortion introduced by the amplitude correction network. Apertures of irregular shape may also introduce phase distortion. The aperture correction network, if designed for a characteristic impedance of 75 ohms, may be connected between the studio amplifier output and the coaxial line feeding the master control position.

The amount of aperture correction that can be applied in a given case is limited by the extent to which a corresponding reduction in the signal-to-noise ratio of the studio output can be tolerated. As a practical matter, it is found that the inherent resolution capabilities of most types of television pick-up tubes is great enough so that a special network for aperture correction is unnecessary. Adjustment of the high-peaker stage (see article 12) for the sharpest picture may often include some inadvertent correction for aperture-distortion effects.

16. FILM PICK-UP

To assure program continuity and flexibility the following may be considered the minimum equipment requirements for the television film pick-up studio: (1) two television film pick-up cameras with associated control, monitoring, and amplifying equipment; (2) two 35-mm sound-motion-picture projectors; (3) two 16-mm sound-motion-picture projectors; (4) two 35-mm slide projectors; (5) sound control and monitoring facilities.

The amplifying, control, and monitoring equipment for the film pick-up studio is essentially the same as that for the direct pick-up studio. Additional console controls required are remote projector starting and phasing. Since the synchronizing generator is generally locked-in with the local power mains, synchronous motors are used to operate the film projectors. A convenient method of phasing the projectors is to shift the phase of the synchronizing-generator 60-cycle reference voltage, thereby shifting the phase of camera scanning with respect to the projector. Mechanical phasing methods are also satisfactory.

Both storage and non-storage types of pick-up tubes are suitable for television film pick-up. Since the standard sound film frame rate is 24 per second and the standard television frame rate is 30 per second, the difference is made up by scanning consecutive frames 2 and 3 times respectively at the 60-cycle interlaced field deflection rate.

In the case of non-storage-type pick-up tubes, such as the Image Dissector, the optical image of the film or an appropriate section of it must be projected optically on the photocathode at the time scanning takes place. Intermittent film projection is not considered practical for non-storage tubes since the film pull-down time is limited to approximately 0.00117 second according to present standards. Special projection methods are therefore required. Some of these employ uniform motion of the film in conjunction with optical and electronic means to provide scanning of alternate film frames in the required 2,3 sequence (reference 37).

For storage-type pick-up tubes, such as the Iconoscope, the optical image is flashed on the mosaic during vertical blanking time and the stored "charge-image" scanned off during the normal vertical scanning time (reference 38). The film is moved during the vertical scanning time when the mosaic is dark. For 35-mm film a special intermittent motion designed so that the interval between pull-downs alternates between $^1/_{20}$ and $^1/_{30}$ second may be used to attain the required projection sequence, the maximum film pull-down time available being approximately 0.015 second under 1946 standards. Projectors for 16-mm film can be designed for a pull-down time of 0.007 second or less, in which case a normal equally spaced intermittent may be used. A synchronously driven rotating shutter placed between the projector lens and the pick-up tube is used to flash the picture on the mosaic. Proper phasing between the light flashes and the scanning may be obtained by mechanical or electrical means.

Automatic brightness control (automatic adjustment of the picture blanking clipper bias in the studio amplifier) may be provided for film pick-up by means of an auxiliary photocell to pick up the light from the film a few frames ahead of projection. This photocell output is integrated and applied to the blanking clipper bias circuit.

17. MASTER CONTROL POSITION

In the usual television plant, where there are several signal sources, including remote pick-ups, all switching and the final monitoring of the signal before it is sent to the transmitter are done at a central point called the master control position. The synchronizing generator, the synchronizing signal distribution amplifiers, the video line amplifiers, and the various items of test equipment used in connection with operations are usually located in a main equipment room adjacent to the master control position.

A typical studio master control pulse and video system layout is shown in Fig. 8. The synchronizing generator outputs are fed to the inputs of a number of pulse distribution

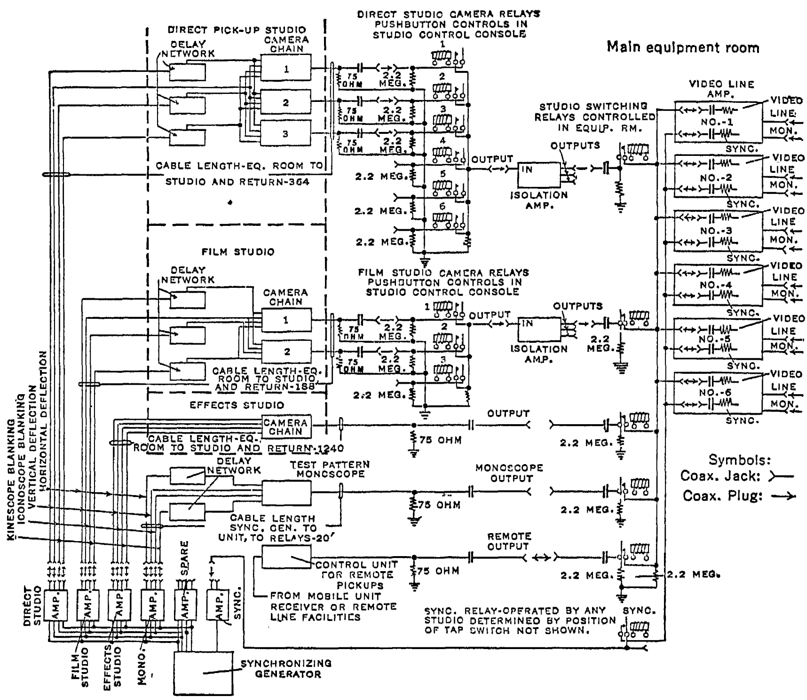

FIG. 8. Block Diagram Showing Pulse Distribution to Studios and Video Switching Circuits at the Master Control Position

amplifiers as shown. A separate pulse distribution amplifier feeds each studio and the monoscope. A separate distribution amplifier is also reserved for synchronizing signals. This system of pulse distribution isolates one studio from another so that an accidental short circuit or failure in a pulse line to one studio cannot affect the others. A spare pulse distribution amplifier is held in readiness in case of failure of one of the amplifiers. It is also good practice to have a spare synchronizing generator in operation at all times and to provide means for quickly switching it into service if the regular generator fails.

As shown in the diagram, delay networks are inserted in the pulse lines to all studios except the one having the longest cable run. The delay networks are adjusted (by adding or removing sections) so that the time of arrival of the blanking signals from each studio at the master control position switching relays will be the same and will be such that the proper front porch delay of synchronizing signals will be maintained when the signals are added. There is generally enough coincidental time delay in the camera vertical deflection system so that no delay networks are required to time the vertical pulses properly. It will be noted that the output of each studio camera is brought to a bank of switching relays associated with that studio and located at the master control position. These relay switching banks in turn feed isolation amplifiers which are arranged to feed banks of relays connecting the studio outputs to the line amplifier inputs. Each line amplifier provides two outputs, one of which can be patched to feed the transmitter and the other can provide a monitoring return-feed to one of the studios.

Normally, only one or two of the amplifiers (regular and spare) will be used for feeding the picture transmitter. The other line amplifiers are patched to provide monitoring feeds for the studio control rooms, announcers' booths, clients' booths, or other points in the television plant where line-fed monitors are used. As indicated, coaxial patch cords in connection with coaxial jacks are provided so that changes in system interconnections can be rapidly effected as dictated by operating requirements. In addition, a number of spare coaxial cables connecting to each studio terminate in a jack-field adjacent to the master control console. This makes it possible to patch up special circuit arrangements as required. Means are also provided for patching up special control circuits. For example, the effects studio output, which may be a picture of a title slide, can be patched into one of the spare camera relays in the relay bank associated with the direct pick-up studio. Thus the video operator in the direct pick-up studio merely presses a camera switching button when he wishes to insert the slide in the outgoing program.

The master control position is equipped with picture and wave-form monitoring facilities, a television receiver used as an off-the-air monitor, and audio monitoring equipment. The master control desk is normally equipped with a pushbutton-controlled monitoring system so that the incoming picture from any of the sources can be checked as required. A wave-form monitor associated with the picture monitor is used for checking signal levels, pulse wave forms, etc. All program switching between the various signal sources and the transmitter is done at the master control position.

A control unit for handling remote pick-ups consisting of a picture monitor, a wave-form monitor, and a variable gain video amplifier is usually provided. The output of this unit feeds into one of the relays in the line amplifier bank as shown. A relay is also provided to open the line amplifier synchronizing signal input when the remote relay closes, as the remote signal normally arrives complete with synchronizing signals. When the remote synchronizing generator is locked-in with the same power supply as the main generator, it is possible to adjust the phase of the two synchronizing signals so that the rapid switch from local to remote pick-up causes no appreciable disturbance of receiver scanning.

Conventional relay interlock systems are used to prevent closing of more than one relay in a particular bank at any time and to drop out one relay when the next is picked up. Magnetic delay circuits can be arranged to delay the drop-out of one relay until just before the next closes.

A wide variety of electronic fading and switching systems may be used in addition to the relay system shown. Fades, lap dissolves, superposition of one image on another, in whole or in part, may be accomplished electronically.

SYNCHRONIZING GENERATOR. Electronic synchronizing signal generators, rather than electromechanical generators, are almost universally used for providing the pulses needed to operate the television plant. The type generally used (reference 27) incorporates an AFC oscillator operating at double line frequency in connection with a frequency divider having an output at field frequency. The output of a discriminator comparing the local 60-cycle power frequency with the output of the frequency divider controls the AFC oscillator. By means of a number of multivibrators, delay networks, and pulse shaping networks, the generator provides the following outputs: (1) synchronizing signals; (2) line-frequency driving pulses; (3) field-frequency driving pulses; (4) camera blanking signals; (5) picture blanking signals. Controls are provided for regulating the duration times or "widths" of the various pulses. The relative starting times of the various pulses are usually controlled by means of an electrical delay network incorporated within the unit. The outputs of the synchronizing generator are normally available at peak-to-peak voltages of 4 to 6 volts at an impedance of 75 ohms.

The general practice has been to use the local 60-cycle power source for locking-in the synchronizing generator. However, some designs incorporate a selector switch for locking the synchronizing generator in either with the local power frequency or with a subharmonic of a crystal oscillator. Operation of the synchronizing generator from a stabilized frequency source independent of the local 60-cycle power mains has many advantages.

18. PULSE MEASUREMENTS

In order to insure that the transmitted blanking and synchronizing pulse wave forms conform to the FCC standards, the television broadcasting plant must be provided with test equipment for measurement of the relative starting times, slopes, and duration times of these pulses.

Space does not permit a discussion of the great variety of measurement techniques that can be or have been successfully used. However, the following have been found to be convenient and are sufficiently accurate for practical purposes (reference 35):

SINE-WAVE SWEEP. A method that allows rapid and accurate checks to be made of pulse slopes, widths, and delay times utilizes an oscilloscope with sine-wave sweep of

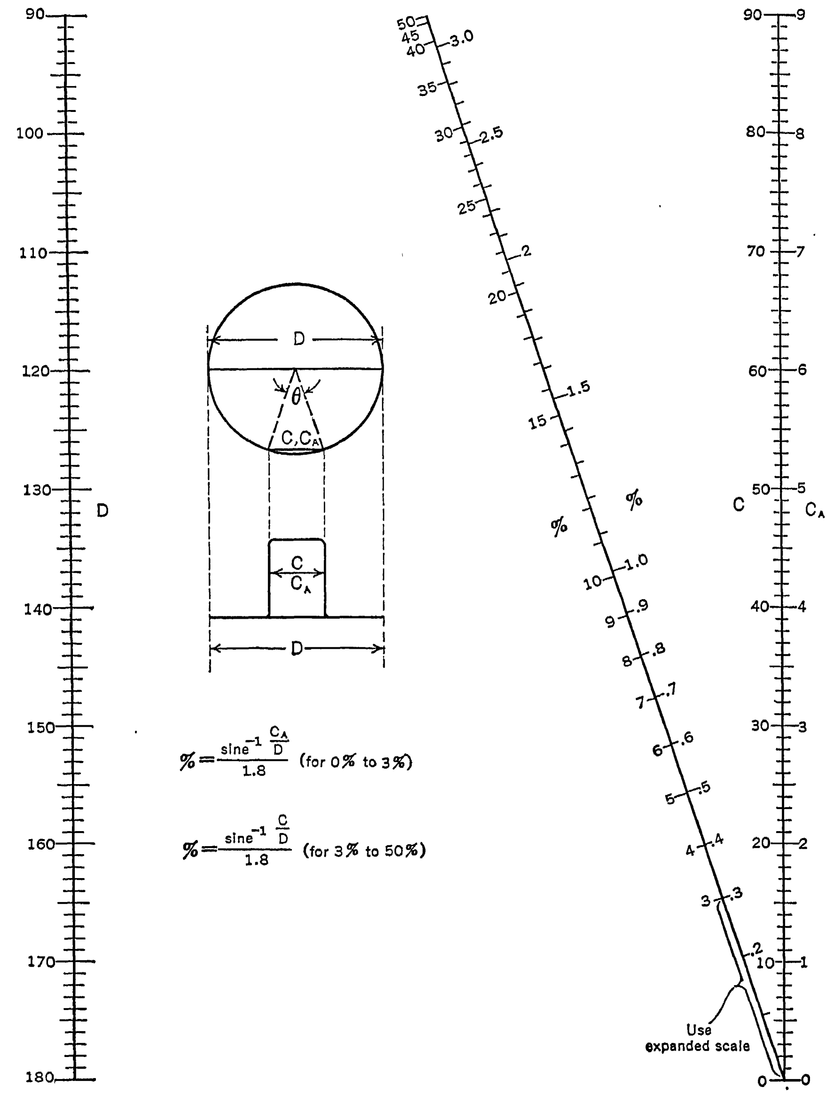

FIG. 9. Alignment Chart for Pulse Width, Scope, and Relative Time Delay Measurements Using Sine Wave Horizontal Sweep

either line or field scanning frequency depending on the character of the pulse to be measured (reference 35). The line-frequency sine wave is obtained by filtering out the fundamental of the horizontal pulses from either the synchronizing signal, the picture or camera blanking signals, or the horizontal driving pulses. For accurate results, the sine wave used for measurement purposes should be well filtered so that the arithmetic sum of all harmonics does not exceed 1 per cent. The local 60-cycle a-c mains, filtered as required, may be used as a source of field-frequency sine wave if the field frequency is locked in with the local power source. The oscilloscope used should have a linear horizontal sweep width of about 100 mm minimum. Pulse widths are measured by shifting the pulse to the center of the screen by means of a sweep phase shifter and measuring the dimensions indicated on Fig. 9 with a transparent millimeter scale at the 10 and 90 per cent amplitude points of the wave.

The width of the pulse in percentage of a sine wave period may then be obtained from the nomographic chart. The expanded scale should be used for widths of less than 3 per cent. Pulse slopes are measured by shifting the pulse edge in question to the center of the screen so that the 10 and 90 per cent amplitude points are symmetrically disposed about the center line of the sweep and scaling C or C_A and D. The C dimension appears magnified compared to linear sweep when sine wave is used, and the accuracy of measurement is thereby enhanced. Pulse delay times may be measured with respect to a specific time (such as the starting time of horizontal blanking) by shifting the phase of the sweep until the starting time of horizontal blanking and the starting time of the pulse in question appear symmetrically disposed about the center line of the horizontal sweep. C and D may then be scaled off and the relative delay in percentage of a horizontal scanning period read from the chart. The delay time of a network may be similarly measured by comparing the difference in position on the sweep of an input and output test pulse.

A variation of the sine-wave method uses an accurate phase shifter calibrated in percentage of a scanning period. This does away with chart and millimeter scales, and the linearity of horizontal sweep of the oscilloscope is no longer a factor as slopes and widths may be read off by shifting the wave known amounts with respect to a fine vertical line drawn down the center of the oscilloscope screen.

PULSE CROSS METHOD. The number of vertical synchronizing signal sections, the number of equalizing impulses before and after the vertical synchronizing impulse, and the approximate widths of the synchronizing and blanking signals may be determined by the pulse cross method (reference 35). These determinations are accomplished by locking in the picture monitor with horizontal and vertical pulses which have been delayed half a period and reversing the polarity of the composite video input signal. The pulse and blanking signals then appear as a white cross in the center of the picture tube screen. The items mentioned above may then be determined by measurement and observation of this pattern. The vertical deflection amplitude should be expanded by about 3 : 1 while making this test. A simple switching arrangement can be arranged to shift the picture monitor from normal to pulse cross operation rapidly during operation.

19. OVERALL VIDEO SYSTEM RESPONSE

In the usual television plant the picture signals pass through a relatively large number of amplifier stages in cascade in traveling from the camera to the transmitter. The transient response of the overall system must therefore be given careful consideration. A small phase or amplitude distortion in each individual stage has a cumulative effect when a large number of stages is operated in cascade (reference 39). The overall effect of such distortion when not compensated is to cause transients of an oscillatory nature to occur whenever the scanning spot encounters an abrupt change in scene brightness.

Mathematical analysis of the overall transient characteristics of a practical system is not only difficult but is complicated by the fact that all stages will not ordinarily use identical forms of high-frequency compensation or peaking. A practical engineering approach to the problem which yields a satisfactory solution is the following: (*a*) When laying out the plant, an accurate estimate can be made of the number of stages likely to be connected in cascade. This estimate can be used in conjunction with published data (reference 39) to decide on reasonable values of design parameters for high-frequency compensation of individual stages. (*b*) The design parameters for high-frequency video compensation having been chosen, the time delay distortion, due to a number of stages in cascade, can be calculated. If the difference in transmission time between medium frequencies (100 to 200 kc) and high frequencies (5 Mc) for the number of stages in cascade begins to approach an appreciable fraction of the time of one picture element, then it is advisable either to choose other design parameters giving smaller time delay distortion per stage or to employ a properly designed phase compensation network. (*c*) It is advisable to choose video amplifier design parameters such that the overall video amplitude response will be uniform within ±1 db. This can be accomplished by choosing a top video frequency (for design purposes) somewhat higher than the nominal top frequency handled by the transmitter. Thus, the studio equipment amplifiers might be designed and compensated for a top frequency of 6 Mc to assure uniform overall amplitude characteristics up to the 4.5-Mc nominal top frequency dictated by present standards. When this is done, however, care should be taken that there are no appreciable peaks in the amplitude response beyond 4.5 Mc. A gradual decay in amplitude response beyond 4.5 Mc rather than an abrupt change is desirable. (*d*) The low-frequency compensation of the video system (60 cycles to 100 kc) should follow conventional principles, considering the number of amplifier stages in cascade. (*e*) Having observed the above design precautions and provided a system having uniform amplitude response (within ± 1 db) from 60 cycles to 4.5 or more megacycles, the overall transient characteristics of the system should be investigated experimentally by square-wave techniques. The low-frequency transient response may be investigated by means of 60-cycle square waves. The high-frequency transient response may be investigated using steep-sided square waves of a fundamental frequency of 100 kc (reference 42). The 100-kc square wave should be of sufficient steepness to represent harmonics of 100 kc beyond the cut-off frequency of the system. The equivalent phase and amplitude characteristics of the system may be obtained from the square-wave response wave shape either by mathematical analysis or by means of special charts (reference 40). Appropriate phase and amplitude correction networks may be designed on the basis of square-wave test data.

Standards should be set as to the maximum allowable amount of overshoot and following transients that can be tolerated in the square-wave response characteristics of a television broadcast system. In any specific case, however, one can form an opinion as to whether objectionable transient effects exist by observing the television image, preferably an image of a resolution test pattern having a number of sharply defined boundaries of high difference in contrast. An overshoot or oscillatory transient differing by 2 per cent from the final steady-state value of a square wave will normally be noticeable in the image.

20. TELEVISION FIELD PICK-UP EQUIPMENT

From the electrical standpoint, television field pick-up equipment is quite similar to studio equipment, the major circuit functions being identical. Mechanically, however, the equipment is usually segregated into small, light-weight units of suitcase style so that it may be readily transported (reference 44).

A block diagram of a typical complement of field pick-up equipment for two cameras is given in Fig. 10.

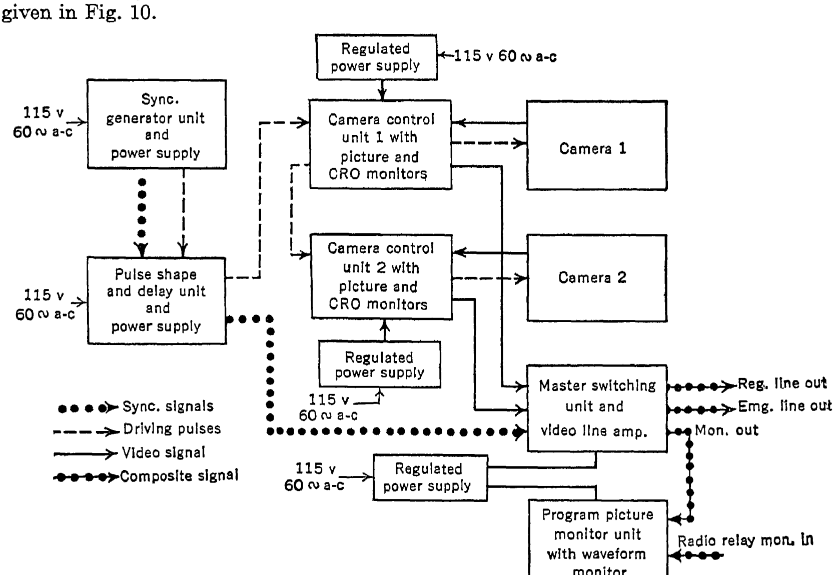

FIG. 10. Block Diagram of a Typical Complement of Portable Field Equipment for Two-camera Operation

21. RELAY OF TELEVISION SIGNAL

Television network facilities may be classified as "intercity" and "local." Under the first category are included long-distance coaxial carrier cables and radio relay multilink circuits. The latter class includes existing telephone pairs and special shielded television pairs, video coaxial cables, and short-haul microwave radio pick-up links.

INTERCITY TELEVISION FACILITIES. Coaxial cables (references 45 and 46). The long-distance coaxial cables consist of several coaxials enclosed in a lead sheath along with ordinary paper-insulated telephone pairs. A 3/8-in. longitudinal seam coaxial is common, although 0.27-in. coaxials have also been used. Figure 11 pictures a coaxial unit open at the end to show the construction. See also Section 10.

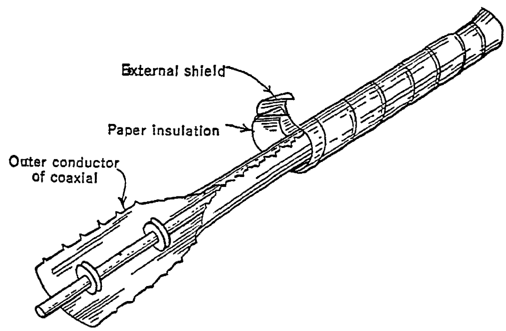

FIG. 11. Typical Construction of a Coaxial Cable Using a Minimum Amount of Solid Dielectric

Figure 12 shows the characteristic impedance, the phase delay, and the attenuation of 3/8-in. coaxials. The useful frequency range for television purposes on such a system depends upon the type and spacing of the repeaters. The present coaxial system employs repeaters at approximately 8-mile intervals and transmits television with a 311-kc carrier up to about 3.1 Mc, giving a 2.8-Mc video band. These lines must be carefully equalized for gain and delay characteristics. Figure 13 shows overall characteristics obtained (1946) on the New York–Washington coaxial system.

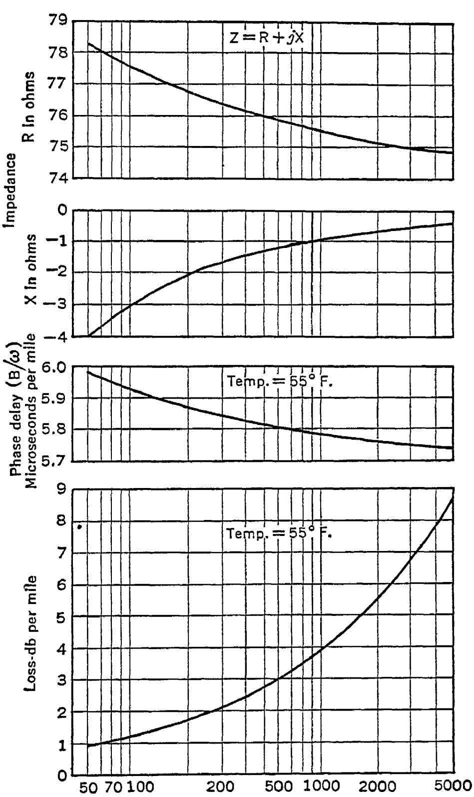

FIG. 12. Transmission Characteristics of a Coaxial Cable Constructed as in Fig. 11 (outside diameter, 3/8 inch)

Transmission of television signals over local video facilities is direct; i.e., the entire band of frequencies produced by the television camera from a few cycles per second to high frequencies is transmitted directly over the line. On long-distance coaxial facilities, however, a carrier method of transmission is used to avoid the effects of low-frequency interference. By using a relatively low carrier frequency and vestigial sideband transmission, the band-width requirements of the repeaters are not materially increased over a noncarrier system. Figure 14 illustrates a typical carrier transmission system for a 2.8-Mc pass band in which a dual modulation and demodulation process is utilized.

Only the frequencies above about 200 kc are used to transmit the television signal over the line, although the space below 200 kc may be used for the accompanying sound-program channel. The main reason for not using very low frequencies is that such coaxial systems would be noisy and difficult to equalize. In the frequency range used, coaxial systems are extremely quiet and relatively easy to equalize. For very long distances, the cost and complexity of the terminal apparatus are small compared to those of the rest of the circuit, but for short video facilities they might be objectionable.

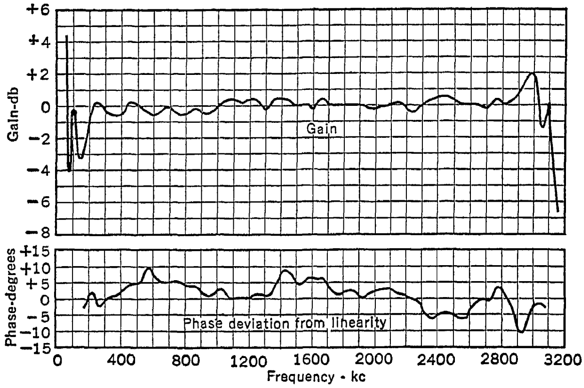

FIG. 13. Overall Characteristics of the New York–Washington Coaxial Circuit (1946)

Microwave Radio Relay (reference 47). Multilink radio relay systems also provide an important network facility for the transmission of television programs. No general rules can be given governing the choice between coaxial cable and radio relay, however, as each specific installation must be carefully studied from a number of standpoints. Among the factors governing such a choice, economic considerations will usually be paramount. Such questions as relative operating and maintenance costs and network reliability must

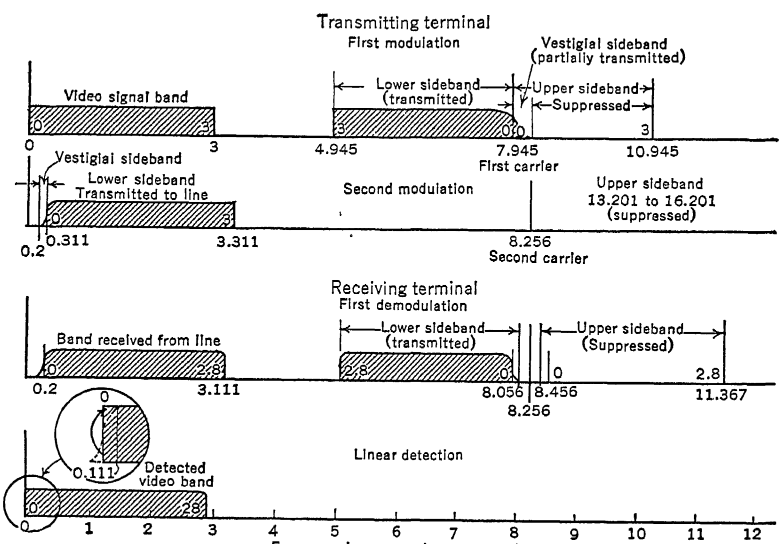

FIG. 14. Diagram of a Typical Dual Modulation and Demodulation Process Used for Transmission of a 2.8 Megacycle Video Band over a Long Coaxial Cable

also be considered for each installation. Figure 15 indicates the repeater gains required for both methods of transmission assuming a useful band width of 5 Mc. It will be noted that, except for extremely large-diameter coaxial cable, fewer repeaters are necessary for the radio relay system. This figure also illustrates the reduction in repeater gain which may be effected by employing the higher frequencies in the microwave region when a given size antenna reflector is used.

LOCAL TELEVISION CIRCUIT FACILITIES. Various local television transmission facilities may include ordinary telephone pairs, specially designed shielded pairs, coaxial cables, or microwave radio systems. Intracity wire transmission of television is accomplished at video frequencies thus avoiding the use of carrier terminals for the short distances encountered.

Telephone Pairs (references 45 and 46). Typical transmission characteristics of telephone pairs are shown in Fig. 16. Because of the large attenuation of the higher video frequencies, it is necessary to install suitable amplifiers at spacings of an average length of 1 mile, though this interval may be increased somewhat when the larger gages are employed.

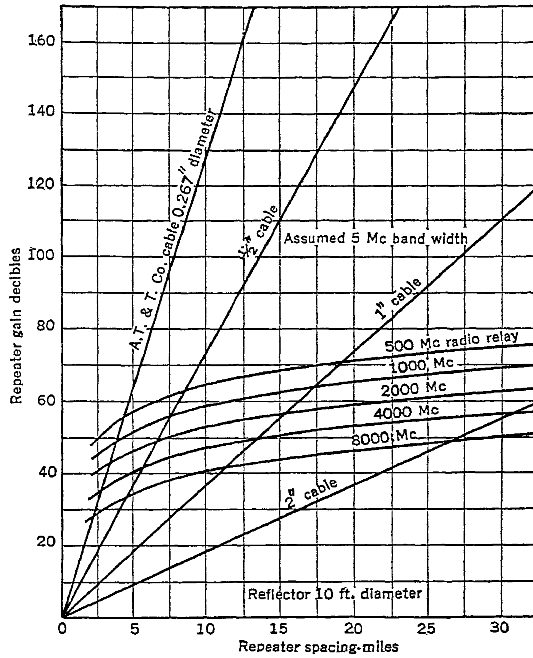

FIG. 15. Comparative Repeater Spacings and Gains for Coaxial and Microwave Circuits

It is necessary to equalize the attenuation and phase characteristic vs. frequency of the telephone pairs over the video band of frequencies. This is accomplished by means of variable equalizers associated with each video amplifier. Pre-emphasis of the level of the higher video frequencies is usually employed in these transmission circuits to obtain an improved signal-to-noise ratio.

Other factors to be considered in the use of telephone pairs for video transmission are the selection of suitable pairs within the cables and the removal of bridged taps on the pair selected. The selection of pairs within a chosen cable sheath is made with a view toward reducing interference

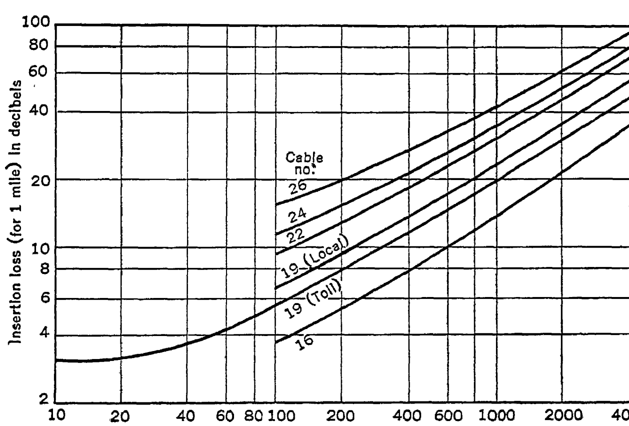

FIG. 16. Insertion Loss of Various Types of Telephone Pairs for Video Frequencies

from adjacent circuits and to avoid cross-talk coupling around the video repeater. All bridged taps are removed to assure minimum impedance irregularities due to these lumped constants along the lines.

Shielded Pairs. Where it is desirable to extend the length of the wire circuit between video repeaters, the use of special shielded pair is indicated. An opened section of such a cable is shown in Fig. 17. The transmission characteristics of such a shielded pair are

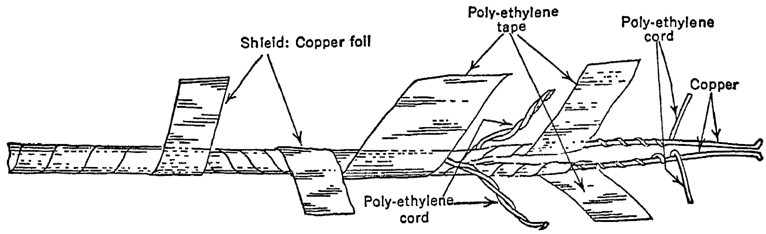

FIG. 17. Low Loss Balanced Shielded Video Transmission Line

given in Fig. 18. With this pair it is possible to extend the video repeater spacing to approximately 3.5 miles.

This type of cable consists of a pair of No. 16 gage wires insulated and spaced by means of polyethylene strings. This core is then enclosed within a cylindrical shield formed with metal tapes. A number of these units may be enclosed in a lead sheath, or the shielded pair unit may be inserted in an ordinary telephone cable replacing a certain number of the usual paper-insulated pairs.

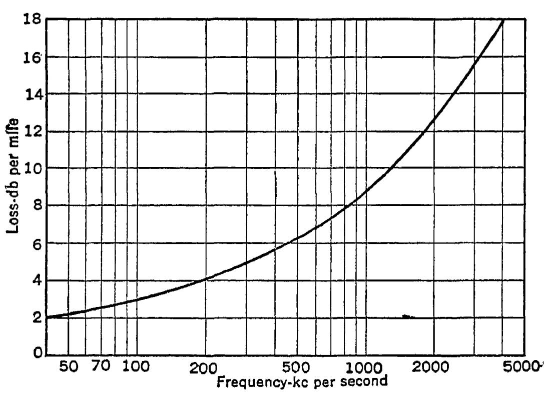

FIG. 18. Attenuation Characteristics of the Line Illustrated in Fig. 17

Coaxial Cable (references 45 and 46). Although of primary importance for network facilities, coaxial cable may be used for intracity circuits of a more permanent nature, such as studio-transmitter link service. For short distances, transmission of the video signals without utilizing a carrier system is practicable. The inherent unbalanced properties of the coaxial cable, however, usually require that special low-frequency balancing circuits be employed. A typical "hum" balancing circuit is shown in Fig. 19. Included in this figure is a simulated generator of low-frequency interference. It will be noted that noise current components flow in opposite directions through the cable terminating resistor R_1 and the hum balancing potentiometer R_2. By adjustment of the balancing potentiometer, a condition can be found such that equal and opposite noise voltages are developed between points a–b and points b–c. The noise is thereby reduced

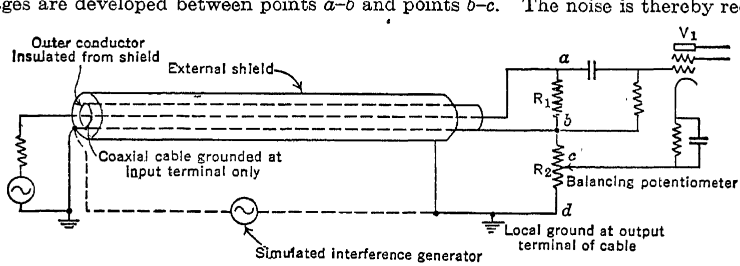

FIG. 19. Hum Balancing System for a Coaxial Cable Having an External Lead Sheath Insulated from the Copper Outer Conductor

at the input of the amplifier so that the signal voltages alone are applied between the grid and cathode of V_1.

Equalization of transmission of coaxial cables is usually accomplished by the use of an equalizing network inserted between the cable and the input of the receiving video amplifier.

In certain applications where coaxial and balanced transmission facilities are to be connected, special amplifier circuits or wide-band video repeating coils are employed to make the transition.

Microwave Radio Relay. Microwave radio relay is also an important local facility for video transmission. Many television field programs, such as parades and special events broadcasts, are not repeated at frequent enough intervals from a given location to justify the expense of wire facility installations. Furthermore, programs originating at distances greater than 20 miles from the studio plant are usually more economically handled by radio relay. Proper evaluation of these and related factors is necessary to determine the choice between radio relay or wire facilities. Radio relay may also be employed for studio-transmitter link service.

The power requirements for a microwave relay system may be approximated by the following formula. Although accurate only for the free-space propagation condition, application of this formula in practice where line of sight exists will yield results of sufficient accuracy to be useful. It should be noted that the maximum total received power due to ground reinforcement can approach, as a limit, four times the received power for free-space propagation as obtained from the formula.

The free-space transmission formula is (reference 48):

$$P_t = \frac{P_r d^2 \lambda^2}{A_r A_t} \tag{5}$$

where P_t = power fed to transmitting antenna at input terminals } Same units
P_r = power available at output terminals of receiving antenna }
A_r = effective area of receiving antenna }
A_t = effective area of transmitting antenna } Same units
d = distance between antennas }
λ = wavelength }

The power necessary at the receiving antenna output terminals depends, among other factors, upon the signal-to-noise ratio requirements of the relay system. The noise level due to thermal agitation at 20 deg cent may be computed from the following expression (reference 47):

$$P_n = (0.8 \times 10^{-20})(B) \tag{6}$$

where P_n = noise power in watts due to thermal agitation.
B = twice the highest modulation frequency in cycles per second.

In practice, the noise level due to all equipment causes will usually be between 10 and 15 db above thermal.

The effective area of an antenna is directly proportional to the power gain. The following tabulations indicate the effective areas of several typical antennas.

Antenna	Effective Area
Isotropic radiator	$\lambda^2/4\pi$
Half-wave dipole	$0.1305\lambda^2$
Parabolic reflector	Two-thirds of the projected area of the paraboloid

Several factors affect the effective area of a paraboloid, the most important being the efficiency of excitation. For example, the effective area is reduced to approximately three-eighths of the projected area when only half of the exciting antenna energy is directed toward the reflector. If transmission lines or wave guides are used in the antenna system, the attenuation due to these components should be taken into consideration when applying the free-space-transmission formula.

22. TRANSMITTER PLANT TERMINAL EQUIPMENT

Terminal equipment located at the television transmitting plant performs the function of raising the signal level delivered by the program source to that required by the transmitter and provides the necessary picture and wave-form monitoring facilities. The equipment is usually installed in a shielded room; it may consist of the following units:

A. An amplifier with means of controlling the composite signal amplitude.

B. An amplifier with independent amplitude control of the synchronizing and picture portions of the composite video signal.

C. Video switching system to select one of several sources of signal.

D. A line amplifier of sufficient output to meet the input level requirements of the video section of the transmitter.

E. Picture and wave-form monitors.

F. Monitor switching system to select circuits to be monitored.

Figure 20 shows a simplified block diagram of the visual portion of a typical television transmitter plant. Equipment required for the television sound channel follows standard frequency-modulation broadcasting practice.

VISUAL CARRIER FREQUENCY GENERATION. The r-f carrier signal for a television transmitter is generally developed by conventional methods. The primary source of radio-frequency energy is usually a highly stabilized quartz-crystal oscillator operated at a relatively low frequency. This low-frequency, low-power signal is multiplied and

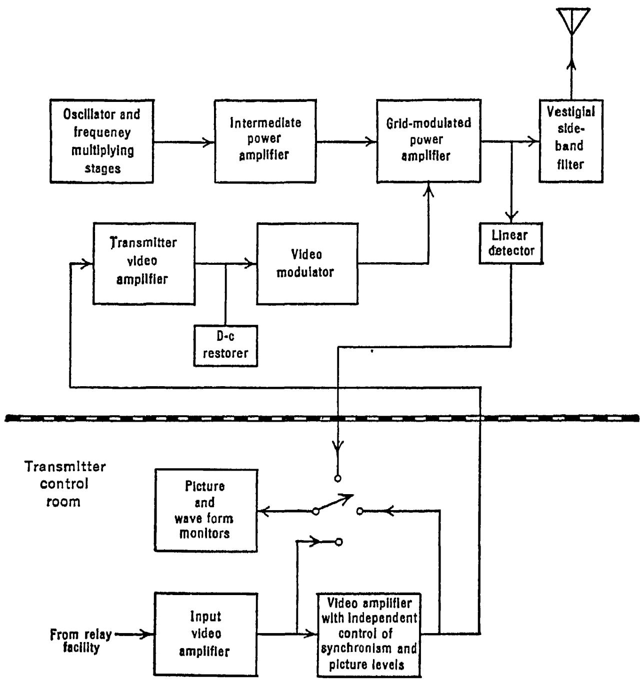

FIG. 20. Picture Transmitter Block Diagram Showing Video Input Equipment

amplified to the frequency and power level required at the modulated amplifier stage of the transmitter.

MODULATION METHOD. A few of the many possible methods of modulating the visual carrier (reference 49) are illustrated in Fig. 21. Of these, grid-bias modulation is almost universally used.

Modulation may be either at low or high r-f level. At low level the grid-bias-modulated r-f amplifier is followed by one or more class B linear r-f amplifier stages having the required band-pass characteristics.

MODULATED AMPLIFIER. The plate and grid (if grid-bias modulation is used) tank circuits of the modulated amplifier as well as all succeeding r-f stages must be capable of passing the generated sideband power without excessive amplitude or phase distortion. This requires tank circuits of relatively low impedance resulting in rather poor operating efficiencies as compared to sound transmitters.

NEUTRALIZATION. The band-pass characteristic of a television transmitter using triode tubes depends not only upon the circuit elements but also upon the effectiveness of neutralization. At low frequencies, where lead inductances may be neglected, a simple capacitance bridge adequately represents the neutralizing circuits. At higher frequencies, however, where lead inductances become appreciable, additional compensation is usually necessary, especially for wide-band operation. Figure 22 indicates the stray inductances often encountered and methods of compensation (reference 50). Stray or undesired coupling between input and output circuits not only disturbs neutralization but also affects the band-pass characteristics of the amplifier.

D-C TRANSMISSION. According to 1946 standards, the tips of the synchronizing signals correspond to maximum carrier envelope amplitude, and this is held as nearly constant as possible during a given transmission. Black level, which corresponds to the base of the synchronizing pulses, is maintained at a fixed percentage of the maximum carrier envelope amplitude within narrow tolerance independent of the values of light and shade in the picture transmitted. In order to achieve this result one or more of the various forms of "d-c restoration" circuits are used in the modulator stages of the transmitter. (See article 7.)

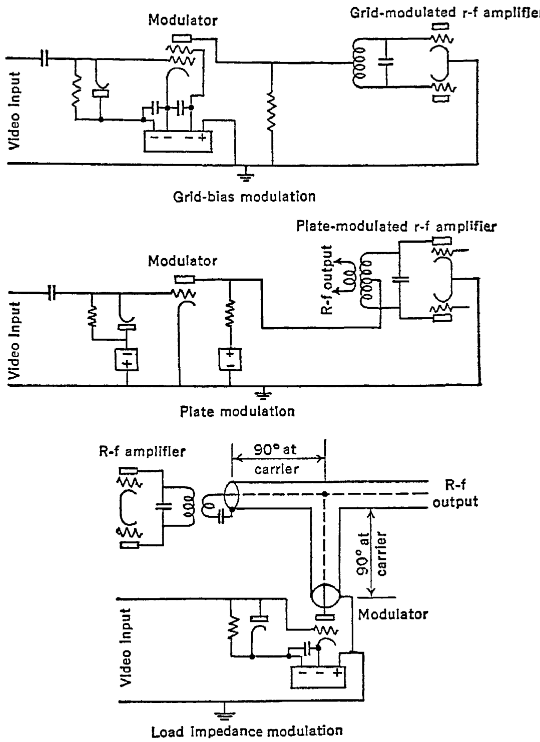

FIG. 21. Video Modulation Methods for Amplitude Modulation

VESTIGIAL SIDEBAND TRANSMISSION. A vestigial sideband system of television transmission (reference 51) is standard for commercial television broadcasting. The higher-frequency sideband components up to but not in excess of carrier plus 4.5 Mc and the lower-frequency sideband components down to carrier frequency −0.75 Mc are transmitted. The remainder of the low sideband energy must be attenuated as rapidly as possible and must reach and retain a low order of magnitude at frequencies lower than carrier frequency −1.25 Mc. Curve C of Fig. 20, article 9, illustrates the standard vestigial sideband transmission characteristic.

Transmitters which are modulated at high power level must be followed by a vestigial sideband filter which absorbs the developed but undesired sideband energy (reference 52). Vestigial sideband filters employ various configurations of elements and are usually constructed in the form of sections of concentric transmission lines of suitable lengths, diameters, and diameter ratios. A single section of one type of vestigial sideband filter is shown schematically in Fig. 23. Generally, two or more sections of this type of filter are used. In addition, "notching" filters are often required to provide additional attenuation at the low-frequency edge of the assigned channel.

Transmitters which are modulated at low power level may achieve the required transmission characteristics by proper design and adjustment of the interstage coupling networks of the following linear amplifiers. In this case, a less pretentious vestigial sideband filter may be necessary at the output of this type of transmitter in order to achieve the required characteristic.

RADIO-FREQUENCY MONITORING. Since the output of a vestigial sideband transmission system is viewed on receivers having specified band-pass characteristics, a monitor should be provided which not only conforms to the standard receiver characteristic but also yields a signal that is a true sample of the radiated energy from the transmitter.

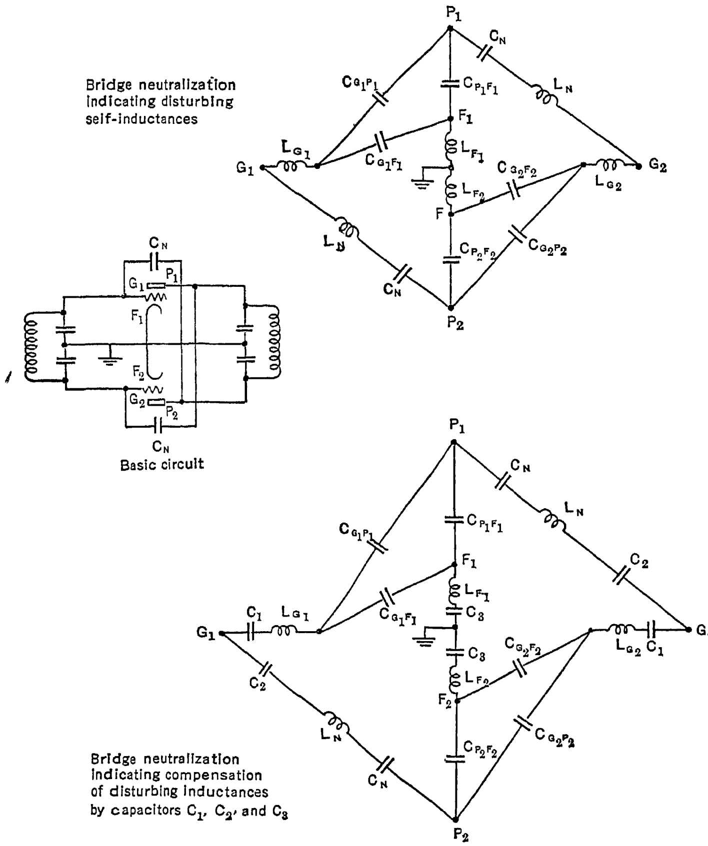

FIG. 22. Neutralization Method to Compensate for Stray Inductance

The aural transmitter may be monitored with equipment similar to that developed for the frequency-modulation broadcast service.

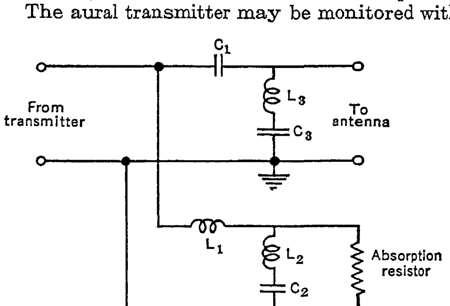

FIG. 23. Single Section Vestigial Sideband Filter

MODULATION MEASUREMENT. The modulation of the television transmitter may be measured in various ways, but the methods that take advantage of the fact that a television transmitter is operated at a constant peak carrier level have been found most satisfactory in practice.

Since the tips of the synchronizing signals represent 100 per cent modulation, one relatively simple method is to observe the carrier envelope pattern at radio frequency on an oscilloscope as shown in Fig. 24. At the high carrier frequencies involved, however, it is sometimes difficult to insure that the cathode-ray pattern is a true representation of the developed carrier envelope amplitude.

A method which avoids dealing with the radio frequency directly utilizes the output of a linear rectifier applied to the vertical plates of the oscilloscope, normal sawtooth sweep of a convenient frequency being used for horizontal deflection. A contactor is provided to short-circuit the output of the diode periodically. This provides a reference level corresponding to complete modulation in the white direction, or zero carrier envelope amplitude. The modulation percentage may be scaled off the cathode-ray screen as indicated in Fig. 24 which shows the appearance of the pattern using high frequency sweep. This simple method is quite accurate and may be utilized periodically as a visual operating check of transmitter modulation during a program (reference 53).

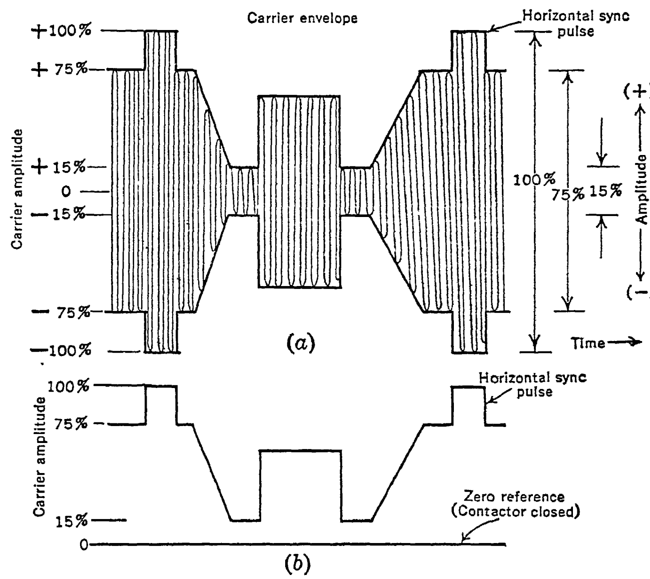

Fig. 24. Video Modulation Measurement. (a) Oscilloscope presentation of video modulated RF envelope (HF sweep). (b) Oscilloscope presentation of output of linear detector with shorting contactor (HF sweep).

MEASUREMENT OF R-F OUTPUT POWER. Television transmitters are rated in peak power output, i.e., the power output level attained during the synchronizing pulse portion of the transmitted signals.

The following methods of measuring power output assume that the transmitter power output can be held at the operating peak level. For transmitters that cannot be held at peak output for measurement purposes, other methods have to be used or a reliable correction factor must be applied.

The transmitter output power may be determined by measuring the power delivered to a water-cooled resistance load with circuit adjustments capable of transmitting a good picture. The rate of water flow and the temperature rise of the water stream on passing over the resistor must be accurately measured. Then the power delivered is given by

$$P = 263TF \tag{7}$$

where P = power delivered to load in watts.
T = temperature change of water in degrees centigrade.
F = water flow in gallons per minute.

It is often desirable to know the power delivered to the actual operating load. Since most practical transmission line installations are not perfectly matched to the radiator, a finite reflection occurs on the line. It is, therefore, necessary to determine the average value of transmission line voltage. One satisfactory method utilizes a slotted section of transmission line and a calibrated vacuum-tube voltmeter for determining the maximum and minimum values of the transmission line voltage.

The power delivered to the transmission line load, neglecting line attenuation, may be calculated by means of the following formula, which is accurate to better than 1 per cent if the voltage standing wave ratio is between 0.8 and unity.

$$P_0 = \frac{(E_{\text{max}})(E_{\text{min}})}{Z_0} \tag{8}$$

where P_0 = power delivered to load in watts.
E_{max} = rms value of voltage maximum in volts.
E_{min} = rms value of voltage minimum in volts.
Z_0 = characteristic impedance of transmission line in ohms.

Alternatively, the output power may be determined by permanently locating two calibrated vacuum-tube voltmeters precisely one-quarter wavelength (electrical) apart and substituting the voltage indicated by these meters for E_{max} and E_{min} in the above formula.

TRANSMISSION LINE. The transmission line system between the transmitter and the antenna must be well matched over the band of frequencies which includes the carrier and the sideband frequencies of appreciable magnitude. Multiple images may appear in the radiated signal of a poorly matched transmission system. Satisfactory results are usually produced when a standing wave ratio between 0.9 and 1.0 over the required band of frequencies exists.

ANTENNAS. Commercial television broadcasting antennas are required to be horizontally polarized. The directivity and radiating efficiency of the antenna should be substantially independent of frequency over the desired transmission band. The input impedance of the antenna must be substantially independent of frequency and must match the transmission line well enough to avoid the development and transmission of multiple images (references 54 and 55). Appreciable effective power gain may be obtained by compressing the radiated energy in the vertical plane.

PERFORMANCE MEASUREMENTS. The response of the visual transmitter from input to radio monitor may be measured using sinusoidal modulation. The modulating frequency should be varied incrementally over the required band while the relative response as a function of frequency is measured on a cathode-ray oscilloscope or vacuum-tube voltmeter. Alternatively, the sinusoidal modulating signal may be injected in the studio equipment before the blanking signals are added, and the relative response at the transmitter input and at the radio monitor output may be measured on a cathode-ray oscilloscope. This method is applicable to transmitting systems which use d-c restoration circuits, and the results are representative of what may be expected under actual operating conditions.

Means of observing and recording the transient response of a television transmission system are desirable. If a 100-kc square wave, having a rise time which is short compared to the rise time expected from the circuit under test, is applied to the transmitter the transient response may be observed on a cathode-ray oscilloscope connected to a r-f monitor. Some square-wave generators provide not only a 100-kc square-wave output but also a synchronous 100-kc sinusoidal output and a synchronous 10- or 20-Mc output. The 100-kc sinusoidal output may be advantageously used for horizontal deflection of the measuring oscilloscope. The 20-Mc output may be used to modulate the cathode-ray beam in amplitude. When the cathode-ray-tube bias is properly adjusted only the positive peaks of the 20-Mc modulation are visible, thus providing an accurate time base which may be used to measure the change in amplitude of the signal for each accurate time interval. The realized rise time, as well as the magnitude of overshoots or oscillatory transients, may thus be accurately determined. Such performance measurements can generally be correlated directly with the appearance of the reproduced television image.

TELEVISION RECEIVERS

By W. F. Bailey and R. J. Brunn

Receivers for television signals in accordance with the present-day standards of the Federal Communications Commission are of the superheterodyne type and receive both the picture and sound transmissions. A block diagram of a typical television receiver is shown in Fig. 1.

The picture and sound carrier signals are received by a single antenna and are amplified in a single channel. The selectivity of this channel protects against image signal and cross-modulation interference. Frequency conversion and some amplification at the intermediate frequencies are also accomplished in a single channel. Then the picture and sound signals are separated and each is amplified sufficiently for final detection. The selectivity in each channel must be adequate to keep the sound and picture signals from interfering with each other, and also to attenuate adjacent signals to a non-interfering level. An f-m detector and an audio amplifier complete the sound channel.

In the picture channel, following the second detector, amplification occurs at video frequency. Either direct coupling, or d-c restoration, or a combination, is used to maintain the voltage corresponding to black constant at the picture tube. In first-grade receivers, both automatic gain control and noise limiting are provided in the picture channel.

Synchronizing signals are extracted from the complete picture signal and are separated for the respective scanning oscillators.

Scanning generators produce sawtooth waves at line and field frequency of either current or voltage, depending on the type of picture tube. Magnetic deflection is commonly used for best resolution since there is less defocusing than there is with electric deflection.

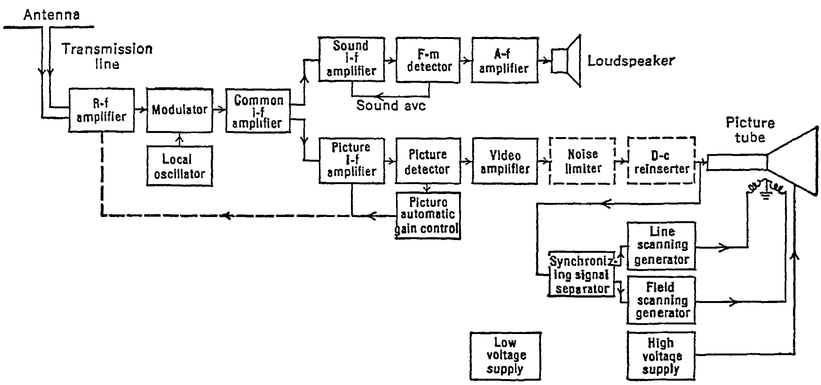

FIG. 1. Block Diagram of a Television Receiver

The d-c accelerating potential for the picture tube is obtained by rectifying the power-frequency wave, an r-f sine wave, or the voltage impulse during the line retrace in a magnetic scanning system.

23. ANTENNAS

The usual antenna for reception is a half-wave dipole in which the radiator diameter is from 0.2 to 2.5 per cent of the antenna length, to improve performance over the frequency range. The folded dipole antenna (reference 55) is also used with a 300-ohm transmission line. Some use has been made of a reflector to improve the directivity, but, with a simple array, not much directive gain can be obtained over the frequency range.

Usually, a balanced line (reference 57) of 75 to 300 ohms impedance is used to transmit the signal from the antenna to the receiver.

24. R-F CIRCUITS

REQUIREMENTS. The r-f circuits of a television receiver couple the signal from the antenna transmission line to the modulator. The following factors must be considered in the r-f circuit design: (1) r-f gain; (2) band width; (3) selectivity; (4) coupling to transmission line; (5) station selection; (6) oscillator radiation; (7) noise factor.

R-F AMPLIFIER. Normally, it is not necessary to provide amplification at radio frequency because it is easier to obtain the necessary amplification at intermediate frequency. However, an r-f stage is helpful in reducing oscillator radiation (reference 58) since there may be an attenuation of 10 to 50 times for signal propagation in the backward direction through the r-f stage.

Most modulators have considerable noise (references 59 and 60). The inherent noise of the receiver may sometimes be reduced by use of an r-f stage (reference 61). A triode r-f amplifier will reduce the noise to the minimum. Generally, a pentode r-f amplifier will provide no improvement. In order to eliminate the need for neutralization, the triode is generally used in a grounded-grid circuit, and a tube having a low plate-to-cathode capacitance is chosen.

ANTENNA COUPLING. With a low-loss transmission line, it is desirable that the receiver input circuit match the line with a low standing wave ratio to eliminate ghosts in the picture caused by multiple traversals of the transmission line (reference 62). The antenna cannot be expected to terminate the line with a standing wave ratio lower than about 10 db in some of the channels. Thus the reflection at the receiver must be kept low. With 2-db attenuation in the line in one traversal, and an antenna termination with a 10-db standing wave ratio, it is necessary that the receiver terminate the transmission line with a standing wave ratio of 0.6 db so that the signal-to-ghost ratio in the receiver be 40 db.

A resistive element must be present in the receiver to achieve termination of the transmission line with a low standing wave ratio. The input conductance of the first tube, the

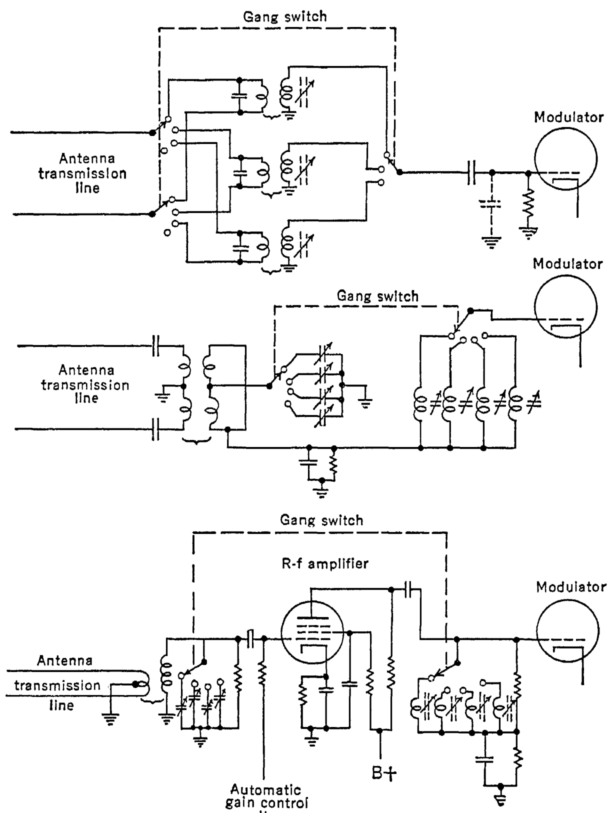

FIG. 2. Typical Antenna to Modulator Coupling Circuits

inherent losses in the reactive circuit elements, and, in some cases, a resistor added for the purpose, constitute the source of loading for the input circuit. The added resistor to produce the required loading increases the noise factor above the minimum (reference 63).

To realize the benefit of the balanced line in minimizing extraneous pick-up, a coupling circuit must be used between the transmission line and the first tube which has good transmission for balanced signals and high attenuation for unbalanced signals. This will reduce interference picked up by the transmission line acting as a single-wire antenna.

Transformers in which the electrostatic coupling is minimized are used to couple to the balanced line. The secondary is usually unbalanced to deliver the signal to a single grid or cathode. The transformer may be coupled directly into a cathode with a good impedance match, but no selectivity.

SELECTIVITY REQUIREMENTS. Because the picture and sound carriers are at opposite ends of a television channel, the r-f circuits should have substantially uniform transmission over a band width of about 5 Mc. This is required because the sound carrier, the main sideband, and the vestigial sideband should be amplified uniformly.

Sufficient selectivity should be provided to give an image ratio of at least 40 db. This provides protection against image signals which are as strong as the desired signal. This order of selectivity requires a minimum of two tuned circuits.

STATION SELECTION. Station selection may be accomplished by switching, with fixed or movable coils, or by continuously adjustable inductors, using tuning cores, or by varying the length of the wire to change the inductance.

The requirements for tuning are: (1) station selection by a single control; (2) reliable long-life, noise-free operation; (3) provision for a number of channels lying between 4 and 12; (4) resettability.

Some typical r-f circuits between the antenna transmission line and the modulator are shown in Fig. 2 (references 64 and 65).

25. MODULATOR AND LOCAL OSCILLATOR

MODULATOR. The tubes commonly used for the modulator are the triode and pentode types. Multigrid converters are rarely used because of their high noise (references 59 and 60).

Because it has the lowest internal noise, the triode modulator is used when the best noise factor is desired. However, the triode presents design problems, since both the input and the output impedances are functions of the oscillator excitation, and the grid-to-plate capacitance makes the input and output circuits interdependent.

The pentode modulator does not produce as low a noise factor because of the partition noise. It is less difficult to use in the receiver, since there is negligible coupling between the input and output circuits. Also, the output impedance of a pentode modulator is normally so high that variations in it, caused by changes of oscillator excitation, have no effect on the performance of the i-f amplifier.

A high transconductance tube is used to maintain high conversion gain and low noise. It is usual to bias the modulator by drawing grid current on the local oscillator signal.

LOCAL OSCILLATOR. The local oscillator is usually a triode used with either capacitive or inductive feedback. Capacitive feedback offers the advantages that the inherent capacitances of the tube may be used directly in the oscillator circuit to produce feedback, and that the tuning coil has no tap.

LOCAL OSCILLATOR DRIFT. Both the picture and sound quality suffer if the oscillator varies from the correct frequency either by oscillator drift or poor resettability of the tuning device. Frequency stability is of prime importance. A frequency shift of ± 150 kc is about the upper limit that can be tolerated by the picture. This drift will produce approximately ± 2-db variation in the amplitude of low-frequency video components relative to high-frequency components. The cost of the sound channel is increased with high shifts. The sound-channel band width and the linear portion of the detector characteristic must be adequate to accommodate the drift. Otherwise the sound i-f may lie on the side of the i-f amplifier transmission characteristic. This produces amplitude modulation of the f-m signal. Further, the performance of the frequency detector may suffer, as the signal may be near one of the peaks and will be on a non-linear part of the detector characteristic.

Receivers have frequently employed an oscillator tuning adjustment so that the resettability errors of the station-selecting device and the oscillator drift can be corrected by the user.

OSCILLATOR INJECTION. The oscillator signal is injected into the modulator grid circuit by either magnetic or capacitive coupling. In many cases, the stray capacitance of the station-selector circuit wiring is sufficient.

26. PICTURE I-F AMPLIFIER

The picture i-f amplifier provides most of the amplification required and also controls the frequency band of the signal in the picture channel. The pass band varies in width from about 2 Mc in a low-definition receiver to about 4 Mc in a high-definition receiver. The i-f amplifier attenuates signals on the adjacent channels so that these signals do not interfere with the picture.

FREQUENCY. The choice of the frequency band for i-f amplification is governed largely by interference from direct i-f pick-up and image signals. The local oscillator is usually located on the high-frequency side of the signal as this simplifies the image interference problem, and thus the picture intermediate frequency is higher than the sound intermediate frequency. A choice of at least 20 Mc for the sound intermediate frequency eliminates other television stations as images, but the f-m broadcast stations are then in the image-signal range. A choice of 29 Mc or higher eliminates both television and f-m broadcast stations as image signals.

The approximate frequencies of the i-f band are chosen with regard to image signals, and the exact frequencies are chosen to eliminate serious interference by direct i-f pick-up. Of the sources of strong signals in the bands cited above, amateur frequencies are worst, since the transmitter may be close to the receiver.

Most current designs utilize a frequency of about 26 Mc for the picture i-f carrier.

VESTIGIAL SIDEBAND REQUIREMENTS. For band-width conservation, picture signals are transmitted by a vestigial sideband system (reference 66. See also article 9). In this transmission system, it is necessary to attenuate the carrier frequency 6 db relative to the transmission of the major sideband, and to adjust the transmission of both sidebands adjacent to the carrier so that a uniform output-frequency spectrum results when a uniform input spectrum is applied to the system. This adjustment is made in the receiver.

In most receivers, the carrier and low video-frequency transmission is equalized prior to detection as shown in terms of the r-f signal by *B* of Fig. 20, Article 9. Over a frequency band of about 1.5 Mc, the transmission drops from full value to 10 per cent or less, with the cutoff characteristic so chosen that the carrier is transmitted at 50 per cent of full transmission.

It is desirable that this cutoff characteristic be as gradual as the standards allow. This reduces the distortion produced by the quadrature component (references 51, 22, and 23) and the non-linear phase characteristic associated with the amplitude cutoff.

ATTENUATION CHARACTERISTIC. A typical picture i-f amplifier transmission characteristic is shown in Fig. 3. The attenuation of the desired sound carrier, which is

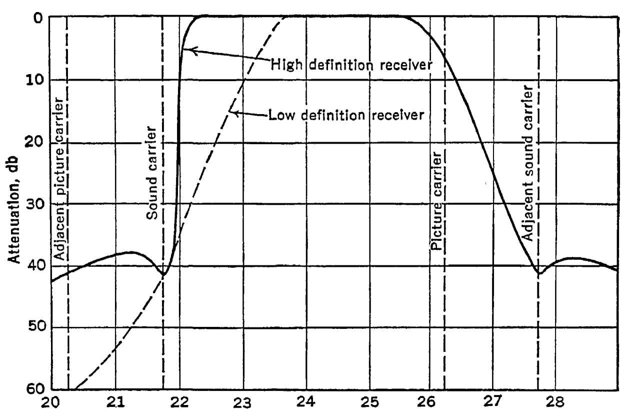

FIG. 3. Typical Receiver Picture I-f Response

normally obtained by the use of traps in the i-f coupling impedances, should not be too steepsided, since a high cutoff slope will convert the sound-frequency modulation to amplitude modulation, which may show in the picture. The sound attenuation should be about 300 kc wide, 3 db above the minimum, so that frequency drift of the local oscillator will not cause sound interference in the picture.

It is desirable that about 40 to 50 db total attenuation be provided for the sound carrier. This may be produced entirely by i-f selectivity, or it may be obtained partly in the i-f amplifier and partly by attenuation at 4.5 Mc in the video amplifier.

Present station-assignment practice is such that adjacent channels will not be allocated in any region. The overlapping service areas of any two regions whose allocations occupy successive channels are small. Therefore, it appears reasonable to provide attenuations of about 35 db minimum relative to the desired picture carrier for the adjacent channel carriers.

It is usually necessary to use traps to secure the attenuation at the sound carrier of the lower-frequency adjacent channel.

COUPLING NETWORKS. Coupling networks used in the i-f amplifier are of several forms: double-tuned transformers (reference 67), filter-type networks, and stagger-tuned resonant circuits are commonly used. See Section 7 for more information.

Various methods are used to incorporate traps in the i-f amplifiers. Traps may be part of the coupling impedance, or they may be used to reduce the effective transconductance of the amplifier tube.

Figure 4 shows several circuits in which traps are employed to reduce the transmission in a desired frequency range. The transmission characteristics are also shown. Figure 4*A* shows a single stage in which a stagger-tuned single resonant circuit is used. The grid leak of the following tube is chosen to provide the required Q. An inductively coupled

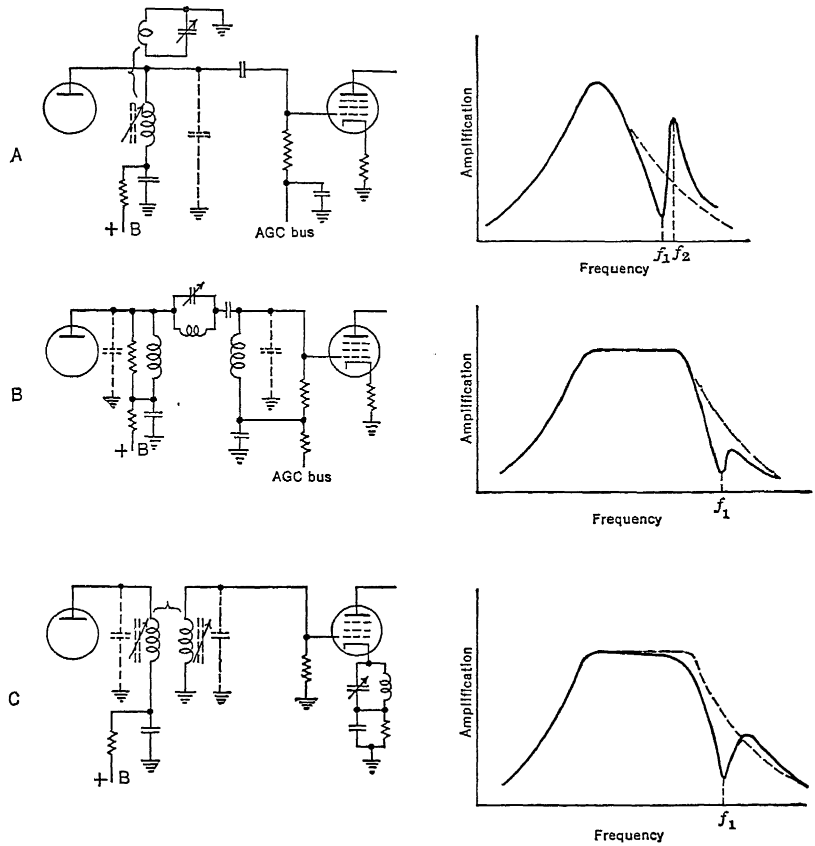

FIG. 4. Typical I-f Coupling Networks

trap is used to secure attenuation at frequency f_1. An undesirable feature of the inductively coupled trap shown is the spurious response at frequency f_2. The magnitude of this spurious response is proportional to the Q and coupling of the trap, and its maximum can be substantially the same as the main response.

Figure 4*B* shows a single stage in which the coupling impedance is a section of an m-derived filter. The response may be made uniform over the desired band with attenuation at a specified frequency f_1.

Figure 4*C* shows a single stage in which the coupling impedance is two coupled circuits. To secure maximum gain, the damping is concentrated on one circuit only. Attenuation at frequency f_1 may be produced by a parallel resonant trap in the second tube cathode circuit. Such a trap usually affects the input impedance of the tube because of feedback to the grid circuit. It is undesirable to use cathode traps with tubes in which the suppressor grid is connected to the cathode. As the cathode has considerable impedance to ground, the suppressor-to-anode capacitance may couple sufficient signal from the output circuit back to the input circuit to cause instability.

As the trap attenuation is a function of both the transconductance of the tube and the impedance of the trap, cathode traps are normally employed in fixed-gain stages.

GAIN CONTROL. Gain control is usually accomplished by varying the bias of one or more i-f amplifier tubes. It is generally necessary, because of the use of high-transconductance tubes, and circuits in which the tube capacitance is a large part of the total capacitance, to stabilize the input capacitance of the gain-controlled stages by an unbypassed cathode resistor (reference 68).

27. PICTURE CHANNEL SECOND DETECTOR

The second detector in the picture channel is usually of the diode type. The video-frequency output-signal load impedance is determined by the shunt capacitance of the diode and the following stage and by the band width to be transmitted. If the impedance band-width product is too low when the total capacitance is lumped as a single capacitor to ground, then video-filter technique may be used. The total capacitance is then broken up into several smaller units, allowing the impedance band-width product to be increased. See Section 7.

DIODE LOAD. If the simple load circuit as shown in Fig. 5*A* is used, the rise time for the video output signal for outward modulation of the carrier will generally be shorter

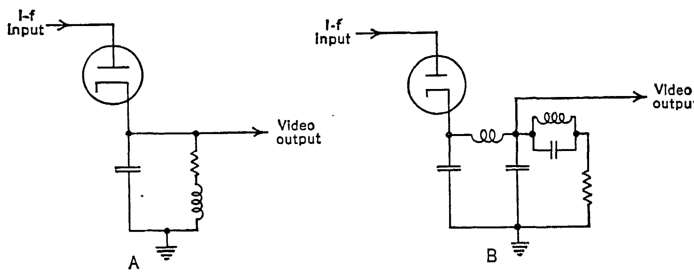

FIG. 5. Picture Detector Circuits

than the fall time for inward modulation of the carrier. The diode and generator resistance shunt the diode load time constant for outward modulation but not for inward modulation.

If the diode load circuit comprises a filter network as shown in Fig. 5*B*, the rise and fall times of the video output signal are more nearly equal because they are determined by the rate at which energy propagates through the filter network. The input should be at the open end of the filter, since, with this connection, there is minimum reflection in the filter which would affect the current supplied by the relatively low effective impedance of the diode and i-f output circuit.

There may be variations in the charging time with the video modulating frequency, since the output impedance of the i-f circuit driving the diode is not, in general, constant. This effect is usually not serious.

TUBE CONSIDERATIONS. The diode load impedance is low, ranging from about 2000 to 8000 ohms. The output voltage generally ranges from about 1 to 5 volts, and this results in high peak currents. To minimize the signal loss in the diode, it is thus desirable to use a high-perveance tube with low interelectrode capacitance.

I-F HARMONIC INTERFERENCE. The use of a four-terminal diode load impedance like that of Fig. 5*B* generally attenuates the ripple frequency component sufficiently so that it, or its harmonics, do not produce spurious patterns in the picture. These i-f harmonics can be troublesome on channels where they fall in the r-f picture frequency band, if they are fed back to the r-f section of the receiver with sufficient level, as a beat-frequency signal lying within the video-frequency passband of the receiver will then be produced. A beat takes the form of alternate dark and light bands in the picture. Since the beat signal is not related harmonically to the scanning rate, the bands continually move about the picture. With full-wave rectification the fundamental ripple frequency superposed on the video signal is twice the intermediate frequency and it is reduced in amplitude, which simplifies the filtering.

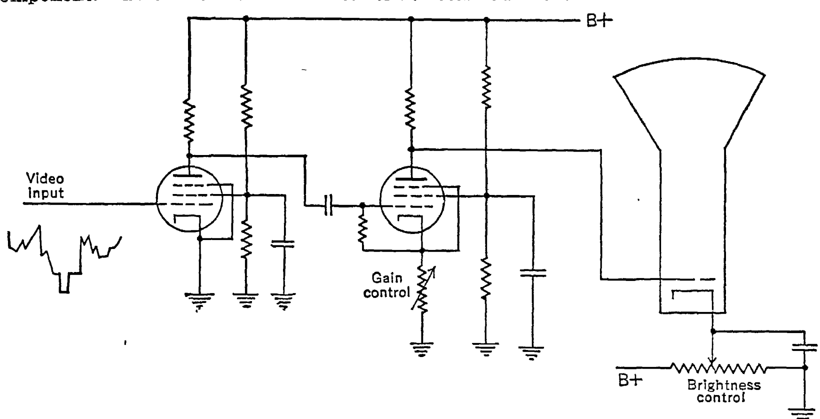
OUTPUT POLARITY. The diode detector may be arranged to produce a video output signal of either polarity. For the negatively modulated signals standardized in the United States, the detector circuits of Fig. 5 will deliver video output signals of negative polarity; that is, the synchronizing signals will be the most positive part of the video-frequency output.

28. VIDEO AMPLIFIERS AND DISPLAY

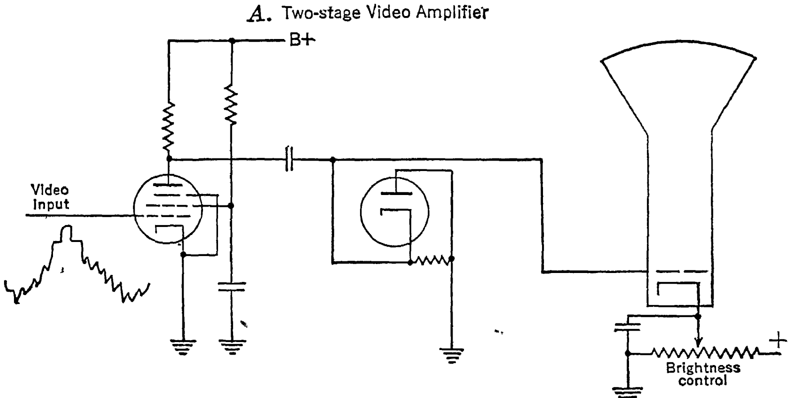
The video amplifier, in a television receiver, raises the level of the picture-detector output signal to a satisfactory value for the picture tube. The input level is commonly about 1 to 5 volts peak-to-peak, and the output level ranges from about 20 to about 100 volts peak-to-peak. It must be remembered that the signal range from black level to the synchronizing-signal peaks does not contain picture information. Thus the video amplifier must handle a complete signal about 40 per cent larger than the black to white signal. One or two stages of video-frequency amplification generally suffice in the usual television receiver.

FREQUENCY REQUIREMENTS. The video amplifier transmits a wide band of frequencies, one cutoff being at some low frequency, which may be direct current. The other cutoff is at some high frequency, usually lying between about 2 and 4.5 Mc, depending on the desired resolution.

Direct coupling is difficult to use in a multistage amplifier because of the problem of obtaining proper electrode potentials. It is simpler to design amplifiers whose lower cutoff lies in the range of about 10 to 10,000 cycles per second. Effective transmission of the d-c component of the signal may be accomplished by means of a locally generated d-c component. This involves a d-c reinserter as described in article 7.



A. Two-stage Video Amplifier



B. Video Amplifier with D-c Reinserter

FIG. 6. Typical Video Amplifiers

In Fig. 6*A* there is shown a two-stage video amplifier. D-c reinsertion is provided by the high grid-cathode conductance for positive grid potentials of the second amplifier tube. The picture tube is direct coupled to the output of the second video amplifier tube.

A gain control which operates by varying the amount of negative regeneration for alternating current is provided in the cathode circuit of the second stage. A change in gain of about 6 to 1 may be obtained with uniform frequency response with a control of this type. The rheostat should be non-inductive, and its range is limited by shunt capacitance which by-passes it for high video frequencies.

A potentiometer is sometimes used as an alternative gain control, in which the signal on the arm of the control is supplied to the amplifier grid. In this case, shunt capacitance to ground from the amplifier grid may vary the frequency response with gain-control setting.

Figure 6*B* shows a circuit in which the signal is a-c coupled from the video amplifier to the picture tube. A d-c reinserter is provided to stabilize the potential of synchronizing signal peaks on the picture tube grid.

For d-c amplifiers or those using d-c reinserters on the input circuits, it is essential that the amplifier stage have the same gain for direct current as for other frequencies within its passband. This requires that the cathode, screen, and anode supply potentials be stabilized against variation with varying direct current flowing in the amplifier tube. Failure to meet this requirement means that the instantaneous brightness of any part of the picture will be dependent upon the average brightness.

If the band width to be transmitted is not extreme, and the shunt capacitance not high, a simple two-terminal constant-*k* type of network is often used for a coupling impedance. This type may be designed for quite uniform amplitude and phase characteristics. When higher impedance is desired, or the circuit is required to work with high total shunt capacitance, it is common to use four-terminal networks. This type allows the shunt capacitance to be broken into smaller lumps, thus giving a higher impedance-band width product. For maximum exploitation of the band width, the circuit is designed as a filter (reference 69). Such a filter, while it provides a maximum of uniform amplitude passband, has a fairly sharp cutoff characteristic and a non-linear phase curve, both of which may produce objectionable distortion in the form of echoes (reference 9) of the original signal. In general, better performance is obtained with a network in which the amplitude characteristic falls gradually with increasing frequency, as this reduces both the phase and amplitude distortion. Section 7 gives more specific information regarding the design of coupling impedances.

The video-frequency coupling network is generally designed to have uniform impedance if it is of the two-terminal type, or uniform transfer impedance if it is of the four-terminal type. Such designs give uniform gain if driven by high-impedance sources but do not produce uniform gain if the driving source impedance approximates that of the network. For the two-terminal type this is true because the network impedance is complex and has a variable phase angle over the transmitted band. For the four-terminal type this is true because, for uniform transfer impedance, the input impedance at the driving point is either uniform in magnitude but complex with a variable phase angle over the transmitted band, or non-uniform in both magnitude of impedance and phase over the transmitted band.

Normally, video amplifiers use the grid-cathode circuit for input, and the plate-cathode circuit for output, and thus the signal polarity is reversed in going through a stage. In the design of a receiver, the picture detector must be so poled that the desired polarity is obtained at the picture tube grid.

PICTURE TUBE. The present-day picture tubes are of the cathode-ray type. The electron beam is focused by an electron gun which may utilize electric fields only or a combination of electric and magnetic fields. Deflection of the cathode-ray beam is produced by either electric or magnetic fields. In the present state of the art, magnetic focus and deflection appear to give the best performance in regard to: (1) spot size; (2) high current in the beam; (3) uniformity of focus over the raster.

For direct-view receivers, the final anode voltages range from about 3 kv to about 15 kv. For projection-type receivers, the final anode voltage in current designs is about 30 kv.

The phosphor produces a white light which may vary in shade from slightly bluish or greenish to yellowish.

It is usual to provide a bias control to adjust the average brightness of the picture. Examples of this are shown in Fig. 6. Sufficient bleeder current flows through the bias control so the picture-tube current does not vary the bias appreciably, and a by-pass is provided for high-frequency currents.

Section 15 contains more detailed information on picture tubes.

PICTURE GAIN CONTROL. Automatic gain control for the picture channel is desirable in television receivers, as it minimizes readjustment of the controls when switching from one channel to another. Radiated signals conforming to the FCC standards include the d-c component. Thus, the average carrier level is dependent upon the picture content as explained in articles 7 and 9. It is necessary that the automatic-gain-control circuit respond to a part of the signal which is independent of the transmitted picture. With a negative polarity signal, as prescribed by the FCC standards, it is most convenient to develop the automatic-gain-control voltage from the synchronizing signal peaks. This requires that the automatic-gain-control rectifier load circuit have a time constant of not less than several lines duration, so that the picture content cannot affect the automatic-gain-control voltage. A separate rectifier operated at the same level as the picture detector may be used as the source of automatic-gain-control voltage. Better performance may be obtained by amplifying the rectifier output voltage with a d-c amplifier. Figure 7 shows

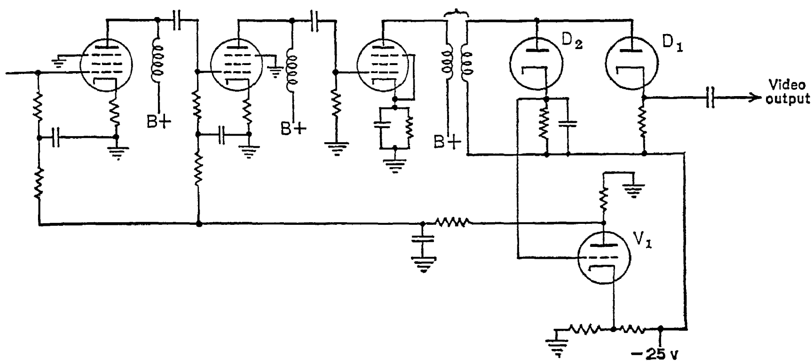


FIG. 7. Picture Automatic Gain Control Circuit

such an arrangement. In this circuit, D_1 is the picture detector; D_2 is a separate diode with a high-impedance load having a time constant of about 200 μsec. The output of D_2 is direct coupled to a triode V_1, the cathode of which returns to a negative potential, in this case, 25 volts. As the signal level increases, the anode of V_1 falls in potential, providing an amplified voltage which is suitable for an automatic-gain-control bias. An alternative of this circuit may be used, in which the additional amplification occurs prior to the automatic-gain-control rectifier. This amplification may take place at intermediate frequency or video frequency.

29. NOISE LIMITERS

Noise limiters are sometimes used to reduce the effects of impulse noise interference upon the picture-tube signal and upon the synchronizing performance. It is desirable to limit the impulse noise to a level no greater than that of the synchronizing signal peaks so that the operating bias of the video amplifier or the synchronizing signal separator is not changed. In circuits where direct coupling is used, impulse noise generally does not greatly affect the operating characteristics. A-c coupled circuits are usually affected considerably by noise.

Diodes connected in shunt or series in the video amplifier have been used as impulse noise limiters An example of a shunt-connected diode limiter is shown in Fig. 8. As the

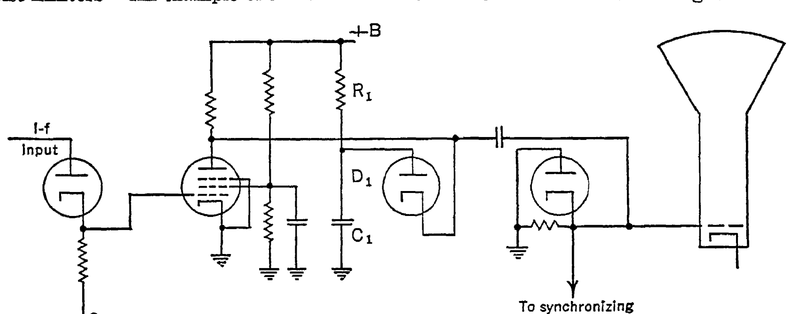

FIG. 8. Impulse Noise Limiter

video amplifier is direct coupled to the picture detector, its operating conditions are not seriously affected by the noise. The limiter diode D_1 is connected in its anode circuit. The d-c reinserter for the picture tube, and the synchronizing signal separator, are actuated by the signal following the limiter and thus operate with increased reliability. The limiter shown adjusts itself to the signal level and normally limits the peak of each synchronizing pulse slightly. If the noise has a high duty cycle, this type of limiter will fail, as the noise will then begin to bias the diode D_1 off, since resistor R_1 will not be able to remove the added charge from C_1 quickly enough. By stabilizing the potential of the anode of D_1 with a bleeder, the limiter will handle noise of high duty cycle but will not adjust itself to the signal level.

30. SOUND AMPLIFIERS

I-F CIRCUITS. The sound i-f amplifier of a television receiver must provide adequate gain with proper selectivity characteristics for the f-m sound signals which accompany the picture. The design features of television receiver sound i-f amplifiers depend largely on the receiver type, whether broadcast a-m or f-m services are to share the channel, and the amount of gain provided by the circuits which precede the point of sound i-f take-off.

Gain Requirements. The sound circuits should be capable of providing a comfortable audio output with 30 per cent modulated sound carriers from 6 to 10 db weaker than the threshold picture level. Where manual or automatic picture-gain-control circuits can reduce the amplification in the overall sound channel by operating on tubes ahead of the sound take-off point, an additional margin of sound gain is required.

With present techniques, the threshold picture level is of the order of 50 μv. An overall sound sensitivity of about 10 μv would therefore seem suitable for television, although an additional 20 db might be desirable for broadcast frequency modulation.

When switched for television, receiver front-end circuits seldom develop more gain than is lost by the modulator in converting to the intermediate frequencies. The sound i-f sensitivity on the modulator grid is therefore about the same as the overall sound sensitivity. The amount of sound-channel gain that may be provided between the modulator grid and the point of sound take-off varies widely with receiver designs. Some picture i-f amplifiers can provide between 40 and 50 db of sound-channel gain in the modulator and first one or two common stages. The most serious objection to this arrangement is the conflict that results from manual or automatic picture gain control of these stages.

The output of the sound i-f usually feeds either a ratio-type f-m detector or a limiter working into a conventional f-m detector. The minimum i-f output required depends on the detector and/or limiter design and is usually in the range of 1 to 3 volts.

Selectance Characteristics. The sound i-f amplifier of a television receiver must be broad enough not only to pass the sidebands of the carrier with full 25-kc deviation but must also pass this signal when the local oscillator is detuned because of drift or inaccurate resettability of the tuning device. Minimum 6-db band widths between 200 and 400 Kc are usual.

For television service, the sound-channel selectors should provide at least 20-db attenuation at the picture carrier and 50 db or more against signals on adjacent channels. This is considerably less severe than the requirements for broadcast frequency modulation as outlined in Section 8. Where dual service is contemplated, the selectivity requirements should be based on the broadcast frequency modulation, and it is then necessary to keep the local oscillator frequency drift within the band width provided.

Sound Take-off Methods. Television receivers which pass 3.5- to 4-Mc video band width usually require traps to provide sufficient attenuation of the sound intermediate frequency in the picture channel. Such traps usually build up a sound i-f voltage or current, and they may be coupled either directly or through additional circuit elements into the grid of the first sound i-f amplifier. This method is applicable to simple coupled traps, to cathode traps, and to coil arrangements in stages coupled by filter circuits.

Receivers passing less video band width may not require sound traps. The sound take-off may then be from the secondary of a transformer whose primary is connected in series with a picture i-f transformer; or the sound and picture i-f amplifier grids may be operated in parallel.

Amplifier Design. There is usually negligible selectivity for the sound intermediate frequency in the common picture and sound circuits. Some selectivity may be designed into the take-off circuits. When its gain and selectivity requirements have been established, the sound i-f amplifier can be designed by the techniques described in Section 7. An adequate number of single- or double-tuned circuits can give acceptable performance provided that 20 to 30 $\mu\mu$f over stray capacitance is added to each circuit. The alignment procedure will be simplified if the circuits are under-optimum coupled.

The mistuning of gain-controlled stages should be minimized either by means of unbypassed cathode resistors or by tapping down the grid.

SOUND DETECTOR AND AUDIO AMPLIFIER. The design of the sound detector and the audio amplifier for a television receiver follows broadcast f-m practice as discussed in Section 8. Since 100 per cent modulation on a television sound carrier corresponds to 25 instead of 75 Kc deviation as in broadcast frequency modulation, only one-third the output voltage is obtained from equivalent f-m detectors. In addition, the output performance of f-m detectors is usually degraded when the carrier frequency is increased, as in television sound i-f amplifiers. The gain deficiency can sometimes be made up by employing high-gain audio amplifier circuits, although this is usually undesirable, as hum-pickup difficulties are inevitable.

An undistorted electrical output of 1 watt is probably adequate for many home television receivers, as the audience is close to the receiver. Television receivers incorporating broadcast f-m or a-m are usually capable of providing greater power output.

Since the current drawn by an output audio amplifier varies with the signal, and since this current may represent a sizable fraction of the total B current drain, special consideration must be given when video circuits obtain power from the same B supply. Either adequate decoupling arrangements must be made or a constant current output amplifier circuit must be used.

31. SYNCHRONIZATION

Adequate synchronizing circuits are among the most important features that a television receiver must possess. The least expensive receiver must be capable of synchronizing on any signal of reasonable strength without readjustment of the speed controls. More expensive receivers may be expected to maintain synchronization on threshold weak signals in the presence of interference.

The procedure for effecting synchronization in the television receiver consists, first, of extracting the synchronizing pulses from the complete video wave. The line and field pulses are then usually separated from each other and the resulting signals are used to synchronize the respective scanning oscillators. See article 10 for a discussion of this.

SEPARATION OF SYNCHRONIZING PULSES. One method for extracting the synchronizing information is to provide a separate diode detector for this purpose. The diode load resistor is by-passed by a capacitor proportioned so that the d-c voltage developed across the load resistor cannot drop more than about 20 per cent during a line interval. The charging current in the capacitor is then a measure of signals in excess of 80 per cent of the peak amplitude of the carrier. A voltage proportional to the charging current may be obtained across a small resistor in series with the capacitor.

This type of separator exaggerates amplitude modulation of the synchronizing signal pulses which may be present in the complete signal. Additional amplification and limiting are usually required.

As full video band width is not required for the synchronizing pulses, the separate detector can be preceded by a high-gain narrow-band-width stage. If sufficient signal is developed, voltage across the entire diode load, which is proportional to peak carrier amplitude, may be used for automatic gain control as described in article 28.

Video Separation. Synchronizing signals can be separated from a composite picture signal by the use of limiter circuits operated in conjunction with suitable d-c stabilization of the wave applied to the limiter. The most frequently used limiter of this type employs a sharp cutoff tube, usually a pentode, with the signal applied to the grid with black positive (reference 70). The tube is usually operated with a grid leak and blocking condenser input circuit, and without bias. Grid current is, therefore, drawn on the tips of the synchronizing pulses. The cutoff characteristic of the tube and the amplitude of the applied video wave are correlated so that the grid swing due to the synchronizing pulses alone exceeds the cutoff.

The self-bias d-c restoring method described above results in poor performance in the presence of impulse-type noise unless preceded by a suitable noise limiter. A strong noise pulse reaching the grid draws current and depresses the grid wave until the blocking capacitor can discharge. Several synchronizing pulses can thus be lost.

The synchronizing information may be extracted from picture signals of either polarity by diode circuits, examples of which are shown in Fig. 9. The time constant of R_1 and C is proportioned so that the voltage across R_1 drops to about 80 per cent during a line interval. The diode then conducts only during the synchronizing pulse. A voltage corresponding to the diode's conduction is obtained across the proportionately smaller resistor R_2 in series with the diode.

The amplitude of the output synchronizing wave from diode separators of this type varies with picture content and usually requires amplifying and limiting for good synchronization. The interelectrode capacitance of the diode may couple high video-frequency component current into resistor R_2.

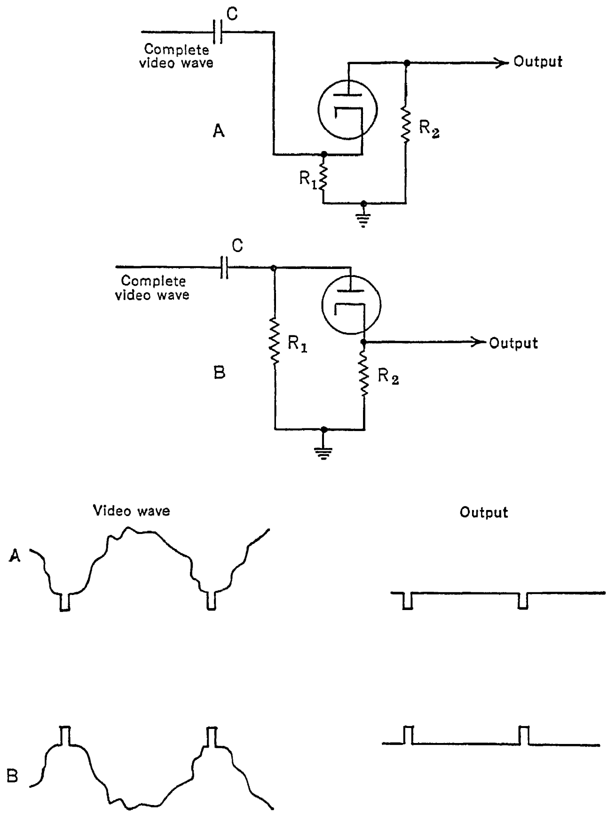

FIG. 9. Diode Synchronizing Separator

SEPARATION OF LINE SYNCHRONIZING PULSES. The line synchronizing pulses are usually separated from the complete synchronizing signal by differentiation. A typical differentiating circuit is shown in Fig. 13, p. 20-13. This operation produces a wave containing a series of narrow pulses coincident with the leading edges of the equalizing pulses, the line synchronizing pulses, and the broad field synchronizing pulses, as shown in Fig. 12, p. 20-12, to assure continuous operation of the line scan oscillator throughout the field retrace interval.

SEPARATION OF FIELD SYNCHRONIZING PULSES. Field synchronizing pulses can be separated from the complete synchronizing signal by integration. To preserve reasonable rise time of the output pulses and still eliminate the line pulses, a multistage integrator is sometimes used. An example is shown in Fig. 13, p. 20-13.

OSCILLATOR SYNCHRONIZATION. Triggering. When the triggering technique is used, the oscillators employed are usually types that free-run at slower than the correct speed and the synchronizing pulses are applied to initiate the retrace. The oscillators should be designed to be insensitive to triggering except towards the end of the trace so that the possible mistiming is limited to the interval between the oscillator's sensitivity to triggering and its self-retrace. Multivibrators, blocking oscillators, and thyratron oscillators are commonly used. Where oscillator voltage appears on the triggering terminal, buffers are usually required.

Good performance is obtained from triggered oscillator circuits only when the synchronizing waves are clean. Video components and other extraneous signals should be small. The effects of random noise can be minimized by restricting the passband into the synchronizing circuits. Impulse noise should neither greatly exceed in amplitude, nor cause a loss of, the synchronizing pulses after the disturbance.

Phase Control. Phase-controlled scanning circuits employ oscillators whose frequency can be controlled by a d-c voltage (reference 17). Scanning oscillators can usually be so controlled through the use of a d-c amplifier or a control tube. The control voltage is obtained by measuring the phase difference between the synchronizing signal and a signal from the scanning oscillator.

The advantage in phase-controlled synchronizing is that an extremely narrow passband can be employed in the coupling between the phase comparison circuit and the oscillator control point to make the oscillator insensitive to instantaneous aberrations of the synchronizing wave. Random noise, impulse noise, and, usually, small amounts of video can be tolerated. The use of a sufficiently narrow passband to achieve the desired degree of stability tends to result in a sluggish pull-in characteristic. Typical performance is to require a second or more to lock.

32. SCANNING

Conventional scanning circuits for television receivers usually employ scanning oscillators and output amplifiers. The oscillator output pulses are shaped as required and applied to the grids of output amplifiers (reference 71) to produce voltage or current waves of proper magnitude and shape.

To achieve economies, the functions of the oscillator, wave shaper, and output amplifier are sometimes integrated, as in the circuits shown in Figs. 9 and 11 of pp. 20-9 and 20-11.

SAWTOOTH WAVE-SHAPING CIRCUITS. The voltage wave required on the grid of scanning output amplifiers departs from being of sawtooth form only by what is required to correct for the deficiencies in the output circuit. The usual method in scanning generators is to integrate current pulses in a capacitor.

A typical sawtooth generator is shown in Fig. 10. The tube is normally cutoff. When a positive pulse is applied to its grid, the capacitor in its plate circuit is discharged. Following the pulse, the capacitor recharges to the supply voltage as shown at *A*. By using a time constant 5 or 10 times as long as the interval between pulses, a reasonably linear sawtooth wave may be obtained.

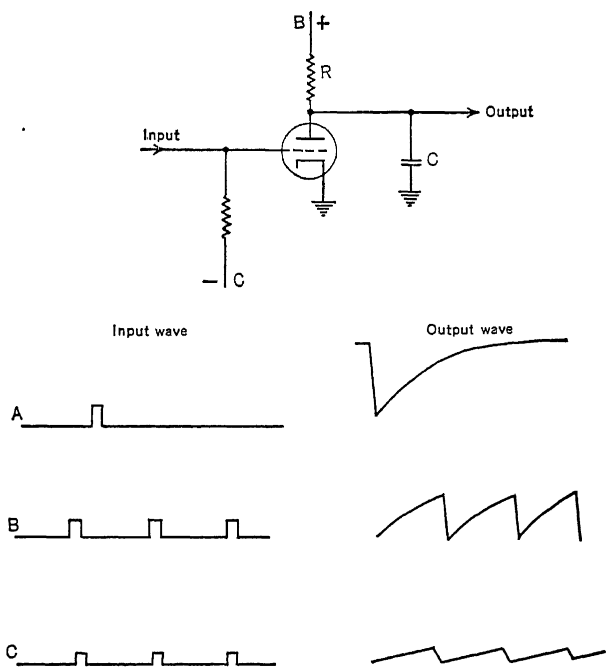

Fig. 10. Sawtooth Wave Generator

SCANNING OSCILLATORS. Blocking Oscillators (reference 72). The blocking oscillator has been the preferred scanning oscillator in television receivers. A blocking oscillator is shown in Fig. 11. When the transformer windings are connected so that the grid goes positive when the plate goes negative, this circuit will start oscillation and will generate a pulse. During the pulse, grid current flows and charges the capacitor C negatively, eventually terminating the pulse. The capacitor then discharges through the resistor R to initiate a new cycle. The free-running speed is controlled by the capacitor, the resistor, and the voltage B_1.

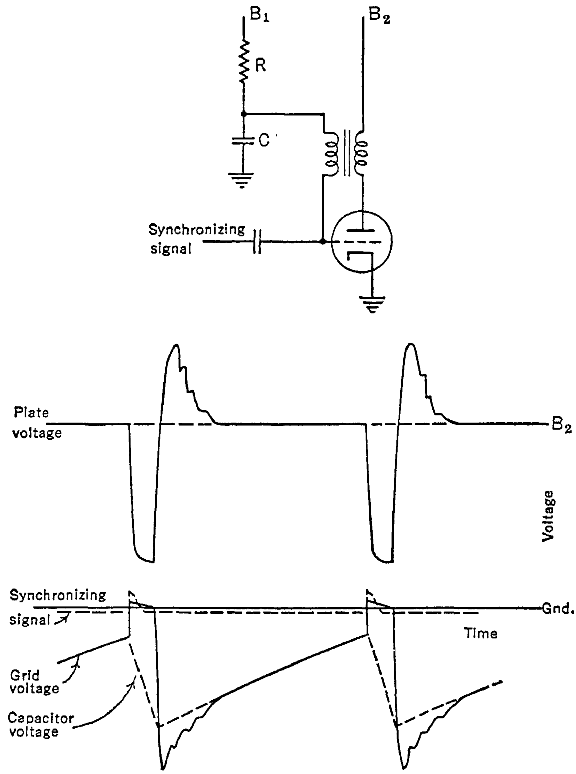

FIG. 11. Blocking Oscillator

The blocking oscillator may be synchronized by applying pulses to initiate conduction in advance of the capacitor discharge. For phase-controlled scanning circuits, the speed of the blocking oscillator can be regulated by controlling the voltage B_1.

Multivibrators. Multivibrators are frequently used in low-priced receivers for economy. These circuits are generally regarded as being less stable, unless considerably more than the minimum number of essential parts are employed.

A multivibrator circuit arrangement useful for television receivers is shown in Fig. 12. The operation of this multivibrator is shown by the wave forms.

Since the current in tube B consists of a recurrent pulse wave, a wave-shaping circuit as described in Fig. 10 may be placed in the plate circuit of this tube for generating a sawtooth voltage wave, as shown in Fig. 12.

Thyratron Oscillators. Thyratron tubes filled with the lighter inert gases can be used as television scanning oscillators. The tubes are connected to discharge a capacitor in the plate circuit. Speed is controlled by varying either the recharge time constant or by the cathode bias. Synchronizing pulses can be applied to the grid.

The advantage of the thyratron tube lies in its ability to pass peak currents of high amplitude, but time delay circuits may be required to prevent application of anode voltage before the cathode has reached proper operating temperature.

OUTPUT AMPLIFIERS FOR ELECTROSTATIC DEFLECTION. The resolving capabilities of most electrostatic receiver tube types can be realized only when the average of the voltages on the deflecting plates of a pair is maintained equal to the second anode voltage. This necessitates balanced deflection as well as balanced centering circuits. The scanning output circuits for electrostatic tubes usually, therefore, produce sawtooth waves of both polarities.

Typical output amplifier circuits employ two voltage-amplifier tubes connected to give opposite polarity outputs. A separate phase inverter is seldom used; the second tube is

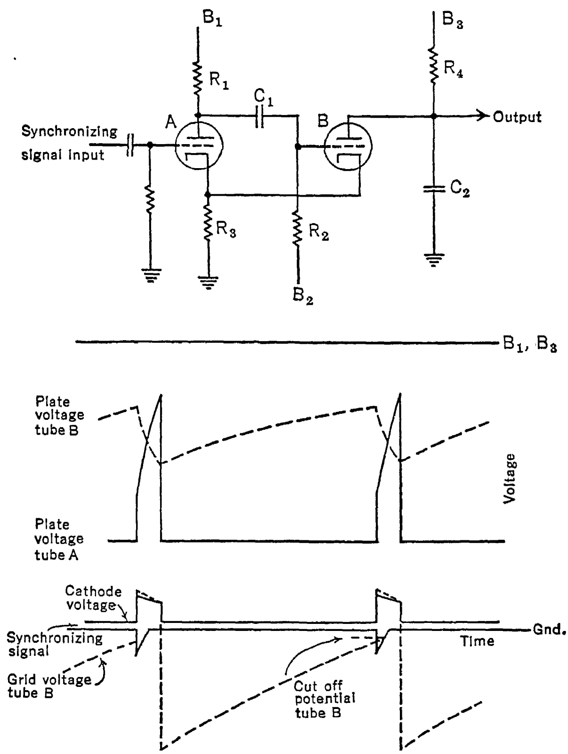

FIG. 12. Multivibrator Scanning Oscillator and Wave Shaper

usually driven by the first, either by the plate connection shown in Fig. 8, p. 20-9, or through the common cathode resistor. Where the total scanning voltage required exceeds the order of 600 volts, the B voltage required for the output amplifier tends to become quite high.

OUTPUT AMPLIFIERS, MAGNETIC. Since most magnetic scanning circuits operate by generating and dissipating energy during each scan, the total power and the circuits for line scanning are considerably different from those of field.

Linear magnetic deflection is accomplished by passing a sawtooth current through the windings of the deflection yoke. The internal resistance of the amplifier, non-linearity of the amplifier, and impedances in shunt or in series with the yoke usually require a wave form other than sawtooth at the amplifier grid. The grid wave is thus sometimes exponential and has a pulse component added by inserting a resistor in series with the capacitor in Fig. 10.

Line (reference 82). The usual receiver line scan circuit employs the idealized scanning cycle shown in Fig. 10, p. 20-10. Where high efficiency is required, the triode dissipating circuit shown in Fig. 11, p. 20-11, is used either with or without the "bootstrap" connection which reclaims some of the scanning energy.

Diode circuits are shown in Fig. 13. A high-perveance diode may be connected across the yoke as shown in *A*. Lower-perveance diodes, having adequate voltage rating, may be connected across the primary as shown in *B*.

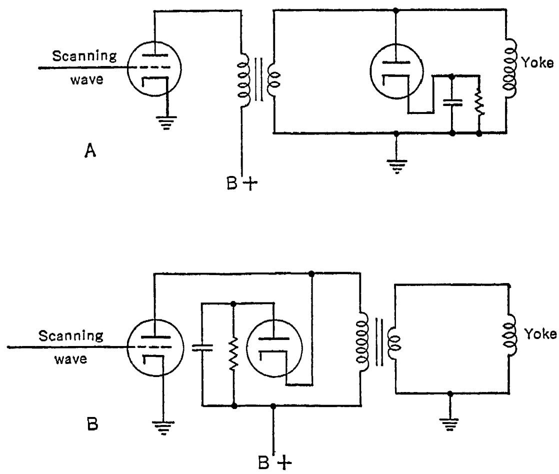

Fig. 13. Diode Damping Circuits

Field. The output load on the field amplifier is essentially resistive so that the controlled dissipation circuits used in line scanning are seldom employed. Occasionally, damping elements are placed across the yoke to remove transients after the retrace. A typical field scanning circuit is shown in Fig. 14.

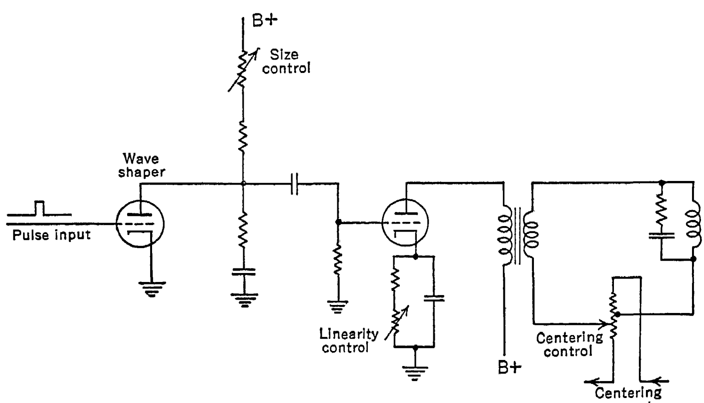

Fig. 14. Field Scanning Circuit

33. POWER SUPPLY

The successful performance of a receiver is largely dependent on its power-supply characteristics. When costs are important, the problems of power supply are among the most difficult which the receiver designer must face.

HEATERS. Coupling. Undesired coupling in the r-f or i-f amplifiers through the heater wiring can be minimized by grounding one side of the heaters. It is usually necessary to provide appropriate by-passing of the heater lead and to interpose occasional r-f chokes.

Heater-cathode Potentials. Except for a few types, most receiving tubes have maximum heater-to-cathode potential ratings in the neighborhood of 100 volts. Since some television circuits employ tubes with cathodes at potentials relative to ground in excess of this rating, it is necessary to provide additional windings on the power transformer when these circuits are used. Where the off-ground cathode is at a-c ground potential, it is customary to connect one side of the heater winding or the center tap to the cathode. If the cathode is not at a-c ground potential, the separate winding may be connected either to the cathode through a high resistor or to a bleeder whose voltage approximates the operating potential of the cathode.

LOW-VOLTAGE B SUPPLY. The two major problems associated with the low-voltage B supply for a television receiver are power-frequency ripple and cross coupling.

Power-frequency Ripple. The entrance of the power-line frequency disturbance in a television picture may cause horizontal bands of light and dark areas, narrowing, widening, and lateral or vertical displacement of parts of the picture, and defocusing. These effects may be caused by the deflection of the cathode-ray-tube beam by the magnetic field of the power transformer, or by insufficient power-frequency filtering in the power supply.

When a receiver is operated from a power line which is non-synchronous with the field scanning, the "hum" pattern drifts upwards or downwards and is very objectionable. It appears essential that commercial receivers be so designed that reception under these conditions remains unimpaired, since programs are even now being relayed over several hundred miles.

As the frequency of the power line at the receiver departs from synchronism with the field scanning, the slowly drifting "hum" pattern jitters and flickers. This is most objectionable in even the slightest amounts. For this reason, "hum" disturbance in receivers intended for operation from power sources whose frequencies are not synchronous with the field scanning must not exceed about 2 per cent.

The technique for securing adequate hum filtering is to provide inductance-capacitance filters in high-current supplies and resistance-capacitance filters in low-current supplies.

Magnetic coupling into the picture tube is most easily cured by placing the power supply at a sufficient distance. When this is impractical, shields of high-permeability material are placed about the tube.

Cross Coupling. Unless precautions are taken, the B supply of a television receiver can be a troublesome source of undesired coupling between the various circuits. Tubes taking high peak currents modulate the B supply, which may disturb circuits that handle low-level signals. To minimize this trouble, multiple power supplies, large filter output capacitors, such as 50 to 100 μf, multisection filters, and separate filters for susceptible circuits are used.

HIGH-VOLTAGE SUPPLIES. The television receiver high-voltage supply provides the power required by the second anode, and, in some cases, the focus electrode, of the cathode-ray tube. The common types rectify power-line frequency voltage, a separately generated sine-wave voltage, or the voltage surge present during the retrace of the line-scanning oscillator. The voltages required range from 2 Kv for small direct-viewed tubes to 30 Kv for projection tubes. The useful current drain from a high-voltage supply may vary between a few microamperes with a dark screen to about 1 ma for a bright picture. Reasonably good voltage regulation is required over the black-to-white current range if noticeable change in picture size and defocusing is to be avoided.

To operate successfully over a number of years, the high-voltage power supply must be designed to withstand the voltage it generates. The spacing around parts at the high potential must be sufficient to prevent sparkover and the formation of corona under unfavorable atmospheric conditions. Insulating materials should be non-carbonizing so that they are not damaged by a single flashover and do not become semi-conducting after periods of service. Insulating paths should be sufficiently long to prevent excessive leakage under conditions of dust and high humidity. Where organic materials must be used, as in a power transformer or paper capacitor, long life can be assured only if these components are impregnated with a good dielectric fluid and are hermetically sealed.

Power-line Frequency Supplies. This type is commonly used where the high voltage required does not exceed 4 or 5 Kv. A single section π filter comprising two capacitors and a resistor is used to remove the power-frequency ripple. The resistor is usually made as large as the voltage regulation requirements will permit and the capacitors as small as will still afford adequate filtering. The capacitors required are usually between about 0.03 and 0.1 μf. Since considerable energy is stored in such capacitors when charged to voltages in excess of a kilovolt, these supplies can be lethal and thus are not suitable for home use unless adequate safety precautions are taken. These include the following:

1. Compartmenting the power supply.
2. Interlocks to prevent access to the power-supply compartment when the power is on.
3. Bleeders capable of discharging the high-voltage capacitors to a safe voltage within a second or less.

4. A substantial connection between the receiver chassis and ground.

Locally Generated Sine-wave Supplies (references 73 and 83). This type is frequently used either where no a-c power line is available or where, for the higher voltages, the cost of the transformer, capacitors, and safety features of a power-line frequency supply are excessive. It comprises a sine-wave oscillator usually operating in the low r-f range, a step-up winding, and one or more vacuum rectifiers in either half-wave or voltage multiplying circuits. The rectifier filaments are customarily powered from the oscillator by windings on the step-up transformer. Adequate filtering is usually obtained with a π filter comprising two capacitors and a resistor, but the capacitors are only a few hundred micromicrofarads. When the energy storage in the capacitors is kept low, this type of supply can be safe even though exposed and usually requires only sufficient shielding to prevent interference by the locally generated wave.

Voltage Surge Supplies (U. S. Patent 2,051,372). This type of power supply rectifies the voltage surge across an inductor when the magnetic field surrounding the inductor is suddenly changed.

The voltage surge type of supply is used in some receivers employing a magnetically deflected picture tube. A high-voltage winding on the line scan output transformer yields the required voltage surge during the scanning retrace. This is rectified and filtered, and the resultant voltage is applied to the second anode of the picture tube. It is necessary to supply added scanning power when the second anode power is thus extracted.

Picture width, when using a high-voltage supply as described above, is adjusted by changing the current through the yoke while not disturbing the currents in the transformer. Otherwise the scanning power and the second anode potential vary together and no significant change in picture width results.

OTHER FORMS OF TELEVISION

By A. V. Loughren

The material of articles 2–33 relates primarily to monochrome, monocular television of sharpness acceptable for home entertainment, for use with power-supply systems of 60-cycle frequency. A change in any of these requirements may affect significantly the design of the entire television system. The more important examples of such changed requirements include: (*a*) television standards of foreign countries; (*b*) theater television; (*c*) color television; (*d*) binocular or stereoscopic television; (*e*) television for special uses (e.g., military, industrial); and (*f*) use of a common transmitter carrier for picture and sound modulations.

34. TELEVISION STANDARDS OF FOREIGN COUNTRIES

With respect to power-supply frequency, the practices of the several countries differ. In addition, since there has been no attempt at international standardization, incidental and unnecessary differences in standards exist. The standards used by the British Broadcasting Corporation (adopted in 1937 and reaffirmed in 1944) illustrate both points. They include:

(*a*) Picture repetition rate: 25 cycles per second (standard power-supply frequency is 50 cycles).
(*b*) Lines per frame: 405.
(*c*) Polarity of picture modulation: positive.
(*d*) Form of picture modulation: amplitude, double side band.
(*e*) Sound modulation: amplitude.
(*f*) Sound carrier location: 3.5 Mc below the picture carrier frequency.

Comparison may be made with the American standards, tabulated in article 10. In most other respects, BBC standards do not differ significantly from those of the United States (references 74 and 75).

35. THEATER TELEVISION

Requirements for theater television differ from those for home television primarily in the following respects:

Highlight Brightness. Motion-picture practice provides highlight brightnesses of 2 to 20 ft-lamberts; the house is dimmed sufficiently to make this acceptable.

Resolution. Pictures projected from 35-mm film have resolution considerably exceeding that of television with a 4-Mc band width. There is some doubt that this factor outweighs the practical advantage of common standards, especially in view of Fig. 1 of article 1.

Operator. Availability of a trained operator.

Picture Size. Motion-picture screens range up to 20 ft in width.

Source of Picture. Provision will probably be required for displaying pictures whether originally picked up for broadcasting or picked up specifically for a chain of theaters. This indicates the desirability of the common standards referred to previously.

36. COLOR TELEVISION

For reasonably faithful reproduction of colored subjects, each geometrical picture element must be represented not by a single intensity, its brightness (as required for monochrome television), but by three separate quantities. These may be the brightnesses of three "primary" colors. Alternatively, one signal may represent the resultant hue, a second the saturation of that hue, and the third, the brightness. Color measurement and specification may be done by either of these alternatives.

Color reproduction systems are divided into additive and subtractive systems. In an additive system, for each picture element an individual stream of light energy in each of the primary colors reaches the eye of the observer. If the light as originally generated is white, a major portion of it is discarded in the filters, which transform it to light of the primary colors. In a subtractive system, the originally produced white light is modified individually for each picture element by subtracting only the unwanted color components. The subtractive system consequently shows an efficiency in the use of a white-light source which is several times that of an additive system. In color photography, subtractive processes such as Technicolor and Kodachrome have found much greater acceptance than the additive processes such as Autochrome and Finlay. In color television, on the other hand, only systems of the additive type have been developed sufficiently to promise practical utility.

For additive systems, desirable reproduction primaries are red, green, and blue, individually chosen as compromises between purity (or saturation to increase the range of producible colors) and transmission loss from white light. Colors equivalent to the transmissions through Wratten filters numbers 47, 58, and 25, when the light source is the International Committee on Illumination's Illuminant "C," have found some acceptance as the red, green, and blue primaries.

METHODS OF TRANSMISSION. Numerous methods of transmission of color television signals have been proposed. Of the several ways of classifying these methods a classification by the time characteristics of the signal seems most important. On this basis, the systems may be classified as:

1. Simultaneous systems, in which the three elements of information required to describe a single picture element are transmitted simultaneously.

2. Sequential systems, in which the three elements of information are transmitted successively. The sequential systems which have been proposed fall into the following subclasses:

(a) *Field Sequential.* A complete picture field is transmitted in one color, followed by successive fields in the remaining colors. In a three-color system with 2 : 1 interlace, six fields must elapse before a picture which is complete both geometrically and in color may be obtained.

(b) *Line Sequential.* A line of one color is transmitted, followed by successive lines in the remaining colors, and the cycle repeats. In this system if the number of colors is an integral submultiple of the number of lines in a complete picture, a given picture line (for example, the eleventh) will always be repeated in the same color unless the color sequence switching is momentarily altered at the end of a frame to produce a new phasing for the next frame. With three colors it is difficult to avoid in a line sequential system a "crawling" tendency in the produced image which has usually been exhibited in systems with orders of interlace greater than 2 : 1.

(c) *Dot Sequential.* The three bits of information describing an individual picture element are transmitted in immediate succession, after which transmission of information for the next picture element takes place. In this system a dot pattern somewhat similar to that of a halftone engraving appears superposed on the colored portions of the picture. It is interesting to note that dot sequential systems are closer in their characteristics to simultaneous systems than to the other sequential systems.

Color television systems may be also classified in accordance with the quantities explicitly represented by the elements of the transmitted signals. Among the many possibilities are the following:

1. Intensities of individual primary colors.
2. Composite intensity (or, alternatively, visual brightness) plus two auxiliary signals representing, for example, the difference between the apparent brightness and the red and blue intensities respectively.
3. Composite intensity, hue, and saturation.

PHYSIOLOGICAL REQUIREMENTS. Resolution. It has been shown that, in a color picture, the apparent resolution is not appreciably impaired when the blue image is severely defocused; it is also known that moderate defocusing of the red image is permissible. Further, the use of a common signal to represent the fine detail for all three colors can be demonstrated as causing negligible impairment of picture quality, when practiced in reasonable amounts.

Since brightness is largely determined by the green content of a color, it appears from the foregoing facts that resolution may be effectively preserved, and yet the frequency band effectively conserved, by a system of transmission in which brightness is transmitted with a band of several megacycles, while hue and saturation are transmitted with relatively narrow bands. If this practice is applied to a system in which separate components of the radiated signal represent the intensities of the primary colors, the low-frequency portion of each color component of the signal will be derived individually (to represent the distribution of light of its corresponding color in the subject) while the high-frequency portion will be identical in all three colors. This common high-frequency signal has been called "mixed highs."

No studies comparable to that of reference 4 have been made for color pictures; in the absence of such information, it seems probable that resolution comparable to that of monochrome television is desirable, *especially for the brightness component.*

Flicker. The apparent brightness of a color image is determined largely by the green component. If the entire image (or an interlaced image field) is produced in each color, the flicker performance is essentially that given by considering the repetition rate of the green component only.

Color Range. The available color reproduction range of a television system using the reproducing primaries suggested above is comparable to the best ranges obtained by commercial color reproduction processes of other sorts such as color film and multicolor printing. Such a range appears adequate.

COMPATIBILITY. When a color television system is put into use in an area already provided with a monochrome television service, the question of compatability arises. A color television system is compatible with a particular monochrome television system when color television signals radiated by the color system may be received as monochrome images of acceptable quality on the receivers of the monochrome system without modification to such receivers. The possession of this characteristic by a color television system contributes importantly to making the commercial introduction of the color system easy since:

1. Color transmissions may be started by individual stations of the monochrome television service as soon as the stations are equipped for color pickup, with no loss of audience or impairment of audience satisfaction.
2. Those viewers who are immediately interested in receiving color may purchase new color receivers with assurance that, since the audience for color broadcasts includes both themselves and the monochrome audience, program service will develop rapidly.

For a color system to be compatible with a monochrome system it must employ essentially the same transmission standards as the monochrome system. Any changes in the standards either must be small enough in amount to be without effect on operation of the monochrome receivers or must be in the nature of additions to the signal of a sort which will go undetected by the monochrome receivers. Dot sequential systems, because of their superior potentialities for band-width economy, seem more likely to be capable of operation compatible with the present FCC monochrome standards with a satisfactory grade of reproduced picture than the systems using slower color sequence rates.

TRANSMITTER. Color television transmitters differ necessarily from monochrome transmitters in requiring the use of a color camera and possibly additional control signals for color synchronizing information, etc. In other respects, however, they may be essentially similar to a monochrome transmitter. The detailed requirements for the camera and the additional control signals are dependent on the particular color television system considered.

RECEIVER. A receiver for color television differs necessarily from a receiver for monochrome television only in the substitution of a display capable of giving color reproduction and the addition of circuits to convert the output of the receiver's detector into signals appropriate to the particular display. The circuits needed are those used to synchronize and phase the effective color of the display to correspond to the color of the bit of picture information being supplied to the display at the corresponding instant. If the system is field sequential so that the color switching rate is once per field, the circuits may control the synchronizing and phasing of a motor driving a color wheel—a disk provided with a series of sectors in the successive colors. In an all-electronic display the color signals must perform a corresponding function; in the electronic arrangements the rate of switching from one color to the next may be arranged to accommodate either dot sequential, line sequential, or field sequential systems.

37. BINOCULAR TELEVISION

In direct viewing of a scene, the images formed in an observer's right and left eyes differ. Depth perception is based, in part, on this difference, as discussed in Section 14. Presentation of suitably different reproduced images to an observer's two eyes will in many cases enhance the illusion of solidity in a reproduced picture.

Binocular or stereoscopic presentation to a viewer must provide that each eye sees only the picture intended for it. Among the means used for this purpose have been (1) barriers and lenses to direct each eye correctly; (2) alternate display of the right and left images with spectacles worn by the viewer containing a synchronized mechanical shutter; (3) alternate display of a red right image and a green left image, with viewer spectacles having no green transmission to the right eye and no red transmission to the left eye; and (4) alternate display of a right image with horizontally polarized light and a left image with vertically polarized light, with complementary viewer spectacles.

For the three-dimensional illusion to be most effective, the spacing between the positions of the camera in taking the images should be equal to the average ocular separation (unless the image is to be magnified in reproduction). The presentation of separate pictures for the two eyes requires transmission of twice the information (and, hence, twice the band width) required for monocular presentation.

The need for special viewing devices has prevented any wide interest in binocular television.

38. TELEVISION FOR SPECIAL SERVICES

Proposals for industrial and for military uses of television have often presented requirements radically different from those of television broadcasting for home entertainment. Examples of these unusual requirements have included: (1) effective protection against jamming; (2) secrecy; (3) severe size and weight limitations; (4) unattended transmitter and camera operation; (5) the high importance accorded to reliability; (6) the usual relatively unfavorable operating conditions (as compared to household use) encountered in many forms of industrial and military apparatus design. Requirements of this sort may affect basically the design of the television system, in addition to their obvious effect on the detailed design of the apparatus. For examples of designs for military purposes, see reference 78.

39. DIPLEXING OF PICTURE AND SOUND

Use of a single carrier for both picture and sound modulations is of interest because of possible simplification of receivers and decrease of radio spectrum space resulting from it. Possible approaches include: (*a*) use of different (and mutually non-interfering) forms of modulation for the two signals—for example, amplitude modulation for the picture, with frequency modulation for the sound; (*b*) sharing of time between picture and sound signals.

Method (*a*) has not been tried widely, probably in view of the general use of vestigial sideband picture transmission, with its inherent introduction of picture frequency modulation sidebands representing all but the lowest frequencies and the consequent likelihood of cross-talk between the two signals in a receiver.

Method (*b*) has been proposed on several occasions and has had some laboratory and field trials. It is found that the frequency of the intervals in which sound signals are transmitted is between two and three times the highest sound modulation frequency which can be successfully transmitted, and that the resulting sound-signal-to-noise ratio is dependent on the fraction of the total time used for sound and on the details of the sound modulation process. The sound intervals must be so located relative to the picture signals, in time, as to produce no visible effect; they may, therefore, be placed between the synchronizing signal and the start of the picture information for each scanning line. See reference 79 for a more complete discussion and bibliography.

ELECTRONIC CONTROL EQUIPMENT

BY

B. J. DALTON

ELECTRONIC CONTROL EQUIPMENT

By B. J. Dalton

FUNDAMENTAL ELECTRONIC POWER CIRCUITS

The fundamental purpose of any electronic rectifier is to convert alternating current into direct current. Therefore, it can be considered as a d-c power supply, the same as a battery or a motor-generator set. There are, however, two important differences between rectifiers and generators or batteries:

1. Batteries supply a smooth d-c voltage output; generators have a number of commutator segments so that the instantaneous voltage at the brushes is nearly constant; rectifiers, on the other hand, generally consist of a relatively small number of phases and rectifying elements and therefore almost all of them have a considerable amount of ripple voltage in the output. The ripple voltage must be considered in many applications, and in particular those involving less than 6-phase rectification, because the ripple voltage may produce a current ripple in some loads which will cause excessive heating not only in the load but also in the rectifier transformer and the rectifying elements. A highly inductive load is a very desirable rectifier load, because the inductance smooths out most of the current ripple. Resistance loads and particularly counter emf or capacitive loads will result in high rms currents which cause additional heating. In some counter-emf type loads it may be desirable to include sufficient reactance in the rectifier output circuit to limit the peak current to a reasonable value. This obviates the necessity for excessive rectifying element and transformer sizes and also minimizes the additional heating which would otherwise be present in the load.

2. Batteries are inherently energy-storage devices and have a constant output voltage; generators not only have a small amount of energy stored mechanically in their rotor but also are usually driven by an a-c motor the speed of which is reasonably independent of a-c line voltage; thus the generator has a constant output voltage. Rectifiers, on the other hand, have no inherent energy storage, and the output voltage at any instant is directly proportional to the a-c input voltage. Therefore, if a constant d-c output voltage is desirable, either the a-c input voltage must be regulated or a regulating means must be provided for the output voltage.

The efficiency of electronic rectifiers is determined by the losses in the rectifying elements themselves together with transformer losses, cathode heating losses, and miscellaneous auxiliary losses. The power factor of a rectifier is determined by the type of load and number of phases and for a controlled rectifier by the amount of phase retard as well. An inductive load will give the highest power factor; a counter-emf load will result in the lowest power factor. For a given type of load, the power factor is inversely proportional to the amount of phase retard, the rectifier being essentially a constant-kva load on the power line.

One or more of the following factors will govern the choice of the type of rectifier for a specific application:

1. The magnitude of the required d-c power.
2. The magnitude of the required d-c voltage.
3. The magnitude of the required d-c current.
4. The required degree of freedom from a-c voltage ripple in the d-c output voltage or current.
5. The effect of the connected load on the rectifying elements.
6. The number of phases and the type of connection available from the a-c power supply.
7. The magnitude of the a-c power supply voltage.
8. The necessity for adjusting the output voltage.
9. The necessity for regulating the output voltage at a specific value.
10. Physical size.
11. Cost.

Electronic rectifiers may be classified in accordance with their controllability as (1) noncontrolled, (2) grid-controlled, and (3) ignitron or pool-type-controlled rectifiers. (These types will be discussed in greater detail later.) Also electronic rectifiers may be classified in accordance with the type of circuit connection used.

The proposed AIEE standards for pool-cathode mercury-arc power converters include a list of 36 standard rectifier circuit connections. Table I, however, illustrates eight circuit connections which are representative of a large number of applications, and in particular those applications in the low- and medium-power field. These circuits and their uses are described below.

1. RECTIFIER CIRCUITS AND APPLICATIONS

Half-wave rectifiers are generally limited in their application to low power circuits. Typical half-wave rectifier applications are: (1) D-c power supplies for small electronic amplifiers. In this application a filter circuit is used to store energy during the half cycle in which the rectifier element is conducting so that a reasonably smooth output voltage can be obtained. (2) D-c power for operating d-c coils of magnetic relays. (3) Charging circuits for capacitors. (4) D-c power supplies for the armature power for small d-c motors. (5) Battery charging equipment. Half-wave rectifiers are generally used because of their simplicity and relatively low cost. Furthermore the half-wave rectifier circuit can be operated directly from a single-phase power supply, without an anode transformer, if the load is designed to match the obtainable output voltage. The half-wave circuit, however, is undesirable in some respects because the energy delivered to the load in an entire cycle must be obtained during one-half cycle. This reduces the transformer utilization (if a transformer is used) and also results in high peak currents in the rectifying element. In addition, this type of rectifier is generally unsuited for application to highly inductive (i.e., iron-core inductance) loads. The time constant of an inductive load is usually sufficiently long so that current will not build up during the half cycle in which the tube can conduct. The small amount of energy that is transferred into the load is inverted during the non-conducting half cycle. Usually the average current is about 10 to 20 per cent of that which would be expected in a pure resistance. A capacitor or a rectifier tube is sometimes connected across an inductive load to prevent the energy stored in the inductance from being transferred to the a-c supply during the normally non-conducting half cycle. Thus the current can build up over a period of time and finally reach a steady-state value.

The diametric (full-wave) rectifier is used in a large number of low-power applications. Typical applications are: (1) d-c power supplies for other electronic equipment; (2) d-c power supplies for magnetic clutches, magnetic chucks, and lifting magnets; (3) battery chargers; (4) d-c power for supplying the fields of d-c motors and generators; (5) d-c power for the armature circuit of d-c motors. This rectifier is a relatively simple and inexpensive unit. In some applications, however, its usefulness is limited by the amount of ripple present in the output voltage. The desirability of obtaining larger amounts of power from polyphase power supplies usually limits its use to applications involving less than 5 kw of d-c power.

The primary advantage of the diametric, double-way (bridge) rectifier is its ability to supply high voltages. The peak inverse voltage across the rectifying element is only half of what it would be in a diametric (full-wave) circuit. Thus a diametric, double-way rectifier can be designed to deliver twice the d-c voltage that a diametric rectifier can deliver, assuming the same rectifying elements in both cases. It also results in high transformer utilization. This rectifier circuit has another advantage in that it can be operated directly from a single-phase power supply without an anode transformer, provided that the output voltage obtained this way is of a suitable value.

Polyphase rectifiers are generally used whenever large amounts of power are required. The selection of a particular polyphase rectifier is largely a matter of obtaining the desired output voltage and current from existing or standard rectifying elements. For example, if rectifying elements of 5-amp capacity each were available and a 15-amp d-c output were required, a delta 3-phase wye rectifier circuit could be chosen. Likewise if 20 amp of direct current were required using the same rectifying elements, a Scott 4-phase cross rectifier circuit could be selected. A delta 6-phase star rectifier circuit could be selected to obtain 30 amp of direct current from the same rectifying elements. However, it might be that the use of such a circuit as the delta 6-phase star would place a severe duty on a particular rectifying element either from the standpoint of the rms current or from the standpoint of the peak current. For example, if an excessive peak or rms rectifier current would exist in a delta 6-phase star circuit, the delta 6-phase double-wye circuit could be chosen. This would reduce the rms and peak currents by a ratio of almost 2 to 1. It is sometimes possible by careful coordination of power supply connections and load voltage ratings to use a delta 6-phase wye double-way rectifier to eliminate the rectifier transformer. Double-way rectifiers, as mentioned before, will deliver higher d-c voltages, for a given peak inverse voltage across the rectifying elements, than single-way rectifiers.

Table 1

Circuit Nomenclature *	Connection Diagram	Output Voltage Wave Form	Secondary Voltage E_S (RMS) †	Output Ripple: Frequency (Principal Component)	Output Ripple: RMS, volts	Peak Inverse Voltage
Half-wave			$2.22 \times E_{d0}$	Line	$1.11E_{d0}$	$3.14E_{d0}$
Diametric (full-wave)			$1.11 \times E_{d0}$	2 × line	$0.471E_{d0}$	$3.14E_{d0}$

* Proposed AIEE standard.

† This is a theoretical value; actual kva will be higher because of transformer exciting current.

Sometimes the requirement of low ripple currents governs the choice of the rectifier circuit, rather than the current capacity. For very large rectifiers above 1000 kw (total installed capacity), 12 or more phase rectifiers may be used to minimize the effect of rectifier harmonics on telephone lines.

EXPLANATION OF TABLE 1. Table 1 consists of four distinct sections appearing from left to right as follows: (1) circuit nomenclature and connection diagrams; (2) output voltage wave shapes, required transformer-secondary voltage ratings, and output-voltage ripple values; (3) rectifying element current wave shapes (for resistance load), rectifying-element current values (for resistance load), and rectifying-element peak inverse voltages; (4) rectifier-transformer kva ratings, for both resistive and inductive loads. All data are tabulated in terms of the theoretical no load d-c output voltage (E_{d0}) and output current (I_d).

The usefulness of this table can best be illustrated by means of an example.

Problem. To specify (*a*) the transformer-secondary voltage rating; (*b*) the transformer-secondary and primary kva ratings; (*c*) the average, rms, and peak current which the rectifying elements will need to carry; and (*d*) the peak inverse voltage which will exist across the rectifying elements, for a diametric (full-wave) rectifier to deliver 10 amp of direct current at 250 volts. Assume that there is no voltage drop in the rectifying elements; also assume a resistance load.

Solution: (*a*) Transformer-secondary voltage each side of center tap $= 1.11 \times 250E_{d0}$
$= 277.5$ volts

Total secondary volts $= 555.0$

(*b*) Transformer secondary kva rating $= 1.75 \times$ d-c, kw

$$= \frac{1.75 \times 10 \text{ amp} \times 250 \text{ volts}}{1000}$$

$= 4.37$ kva

Transformer-primary kva rating $= 1.235 \times$ d-c kw

$$= \frac{1.235 \times 10 \times 250}{1000}$$

$= 3.09$ kva

(*c*) Rectifying-element currents

Average $= 0.5 \times 10I_d = 5$ amp

Rms $= 0.786 \times 10I_d = 7.86$ amp

Peak $= 1.57 \times 10I_d = 15.7$ amp

(*d*) Rectifying-element peak inverse voltage $= 3.14 \times 250E_{d0} = 785$ volts. (The actual ratings will need to be increased to compensate for the voltage drop in the rectifying elements, transformer reactance, and the like.)

2. NON-CONTROLLED RECTIFIERS

The types of non-controlled electronic rectifying devices in common use are: (1) high-vacuum tubes; (2) hot-cathode gaseous rectifier tubes; (3) metallic rectifiers.

Non-controlled rectifiers are used in applications where a fixed amount of d-c voltage is required. Applications for non-controlled rectifiers include battery charging, motor-field excitation, generator-field excitation, magnetic-chuck excitation, lifting-magnet excitation, d-c control power supplies, etc.

The high-vacuum or kenotron rectifier tubes are inherently low-current tubes, because the voltage drop and therefore the power loss in the tube are proportional to the current flowing. High-vacuum rectifier tubes may be classified as low or high voltage. Low-voltage types are used primarily for small amounts of d-c control power for other electronic equipments. Often low-voltage tubes are constructed with two rectifying devices in one tube, thus making a single tube suitable for a diametric (full-wave) rectifier circuit. High-voltage types are used in such applications as dust precipitators and high-voltage power supplies for other electronic equipment.

The outstanding characteristic of hot-cathode gaseous-type rectifier tubes is their inherently low and constant voltage drop which results in high efficiency in high-current applications. These tubes are available in a range of current ratings of 0.1 amp to 20 amp and from about 100 volts to 10,000 volts, peak inverse ratings. Low-voltage types, such as are used in battery chargers, are usually filled with argon. Xenon-filled, argon-and-mercury-vapor-filled, and mercury-vapor-filled tubes are used in applications requiring 750, 2000, and 10,000 volts, peak inverse ratings, respectively. Gaseous-type rectifiers will not operate successfully in parallel without load-balancing devices, because the tube drop of two paralleled tubes may be slightly different and the tube with the lower drop will carry all or most of the load current. A more complete discussion of hot-cathode gaseous-type rectifier tubes of both the non-controlled and the controlled type is presented in Section 4.

Copper oxide and selenium-type metallic rectifiers are used predominantly in the low-voltage high-current field. The general characteristics of these rectifiers are a relatively low peak inverse voltage per rectifying disk and a relatively high current capacity. Stacks consisting of one or more cells can be used in series or in parallel to increase their voltage or current capacity, respectively. The copper oxide rectifier is older, from the standpoint of general usage, than the selenium rectifier. The selenium rectifier can operate at a higher temperature than the copper oxide rectifier, and therefore for a given rating it is a somewhat smaller unit than the copper oxide type. Selenium rectifiers are usually operated nearer their breakdown voltage rating than copper oxide rectifiers; therefore the selenium rectifier is usually more subject to damage on overvoltage. Other materials, such as copper sulfide, exhibit the same rectifying action as the copper oxide and selenium materials but are not as commonly used.

3. CONTROLLED RECTIFIERS AND INVERTERS

Controlled rectifiers generally are used whenever it is desired to adjust the d-c output voltage level over a reasonably wide range, or when it is necessary to regulate the output voltage to compensate for changes in the load current or changes in the input line voltage. Typical applications of controlled rectifiers are: (1) adjustable d-c voltage for motor- and generator-field supplies; (2) adjustable d-c voltage for d-c motor armatures; (3) adjustable d-c voltage for the d-c windings of saturable reactors which, in turn, control motor, lighting, or resistance power circuits; (4) adjustable d-c voltage supply for testing of various d-c devices; (5) d-c power for charging capacitors in energy-storage resistance welders at a given rate and to a given voltage.

In small rectifiers, it may sometimes be more convenient and economical to adjust the rectifier d-c output either by adjusting the a-c voltage input or the d-c voltage output by means of a slide-wire resistor. Also in large rectifiers it may be desirable to adjust the output voltage by means of induction-voltage regulators, adjustable auto transformers, or saturable reactors in the a-c circuit. If these methods are used, the rectifying elements can be of the non-controllable type.

Grid-controlled thyratron rectifiers provide greater flexibility, faster response, and less bulky control equipment than rectifiers controlled in the power circuits. Furthermore, automatic control in larger sizes is generally more economical with thyratron control than with power circuit control.

Thyratron-type rectifiers are always built in a single envelope. Some thyratron tubes are controlled electromagnetically by a plate on the outside of the tube. By far the most common practice, however, is to control the tubes electrostatically with a grid in the electron path. Thyratron tubes can be obtained in ratings as low as approximately 20 ma and have been built in ratings as high as 100 amp. (See Section 4.) The maximum size of standard tubes, however, is about 12.5 amp. (High-vacuum triodes are generally not used in controlled rectifier circuits.)

Controlled rectifier tubes may be connected in any of the circuits shown in Table 1. Tubes and transformers, however, should be carefully selected so that the ratings are not exceeded. As mentioned earlier, the peak and rms currents in a rectifier will be higher on resistance and counter-emf loads than on inductance loads. Not only must this factor be considered, but also consideration must be given to the higher peak and rms currents that will result from the use of grid control on loads such as d-c motor armature circuits. Another factor to be considered is the unbalance in tube currents which may exist in polyphase rectifiers operating with rated current and having a large amount of phase retard. Figure 1 shows the voltage and current wave shapes of a diametric (full-wave) rectifier operating with varying degrees of phase retard on an inductive load, a resistive load, and a fixed counter-emf load all having different electrical characteristics. Although a diametric rectifier is used here for the sake of clarity, the same fundamental information applies to other rectifier circuits. Although three different load classifications are shown, many loads consist of various combinations of resistance, inductance, and counter emf.

The load current on a very highly inductive load is nearly constant even with a diametric rectifier circuit. As the firing angle is retarded, the energy from the inductance is transferred back into the line circuit during a portion of the cycle when the tubes would be normally non-conducting. When the firing angle has been retarded approximately 90°, the inductance current is theoretically zero. Practically, however, the 90° firing point will result in a current of approximately 10 to 20 per cent of the maximum which would be expected as calculated by Ohm's law.

In a sense a purely resistance load is somewhat academic because this type of load seldom occurs in practice. It is, however, a logical stepping stone in estimating what is to be expected from counter-emf loads. It can be observed from Fig. 1 that the load current in a resistance load follows identically the wave shape of the output voltage.

Counter-emf loads fall into two general classifications: fixed and variable. A battery is a typical example of a fixed counter-emf load. The peak value of load current in a fixed counter-emf load is determined by the difference between the peak a-c voltage and the counter-emf potential, and the circuit resistance. Exceedingly high current can be obtained on low-impedance circuits with a very small difference in voltage between the load

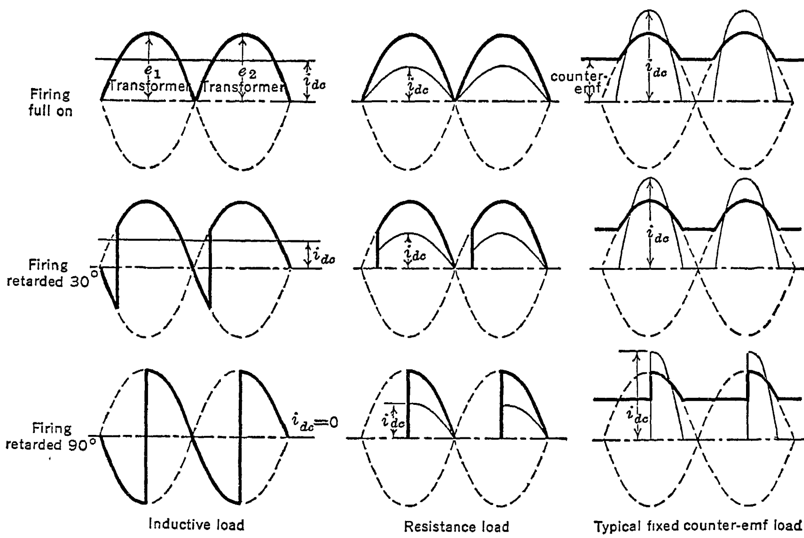

FIG. 1. Rectifier Output Voltage and Load-current Wave Forms for Different Types of Loads and with Several Degrees of Phase Retard with Diametric (Full-wave) Rectifier

and the peak rectifier output. The inherent circuit impedance may reduce the peak current to a reasonable value; if not, external resistance or inductance can be added for that purpose. Figure 1 shows that as the firing angle of a rectifier on a fixed counter-emf load is retarded there is, up to a certain point, no change in the output current, but, beyond the point where the transformer-secondary voltage and the counter-emf voltage intersect, a reduction in current is obtained by a further retard in firing position. A d-c motor armature is a typical variable counter-emf load. This type of load is quite different in its operation from a rectifier or other fixed counter-emf load. A motor armature is a good example of a load which includes resistance, inductance, and variable counter emf.

The thyratron rectifier circuits which have been described can also be used for inverters to convert d-c power into a-c power, provided that both d-c and a-c power supplies are available for the transfer of power and that the grid-control circuits are properly arranged. Many motor-control rectifiers are operated as inverters during reversal of motor armatures and during fast decay of the stored energy in generator fields. In these applications the conventional rectifier circuit is used and the grid firing point is retarded to a point late in the positive half cycle. In the high-power field, highly specialized inverters have been built for several applications.

IGNITRON RECTIFIERS. Ignitron rectifiers are ideally suited to their use in the high-power field, because their cathodes—a mercury pool—can supply electron emission for tremendous overloads. The maximum current is limited by the mechanical forces involved and by the ability of the tube to deionize rapidly enough to prevent arcback. Ignitron rectifying devices are made in capacities from about 12 amp up to 1000 amp d-c continuous rating. (In 1945 approximately 10 per cent of the central-station power generated in the United States passed through ignitron rectifiers.) Continuously evacuated ignitron rectifiers are available in sizes as large as 6000 kw at 600 volts direct.

Figure 2 shows the efficiencies of ignitron rectifiers as compared with synchronous converters and synchronous motor-generator sets. The rectifier efficiency increases with higher voltage because the voltage drop across the arc in the ignitron is nearly the same in all cases, and, therefore, with lower d-c voltage the arc drop has a greater proportional effect than at high voltage.

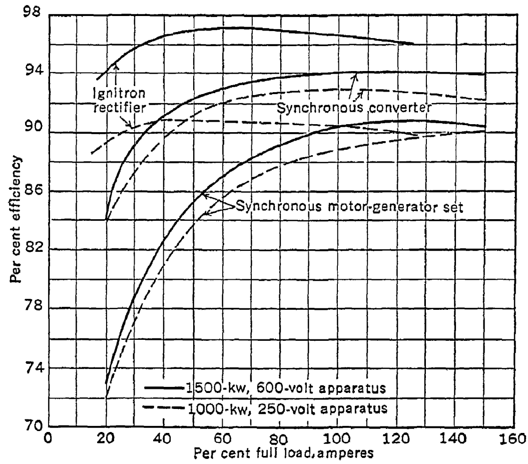

FIG. 2. Comparative Efficiencies of Power-conversion Units

Thyratron rectifiers, like vacuum tubes, may be controlled with very minute power levels on the grid. An ignitron, however, requires a considerable amount of power for a short time for firing. This power may be supplied either by magnetic excitation circuits involving no tubes and purely static control devices, or they may be controlled by electronic firing circuits involving thyratrons in the ignitor circuit. The magnetic firing circuit is used where the maximum of reliability is required. Thyratron-type firing circuits, however, may be less expensive to build, and also their inherently fast operating speed may be more desirable for some applications.

4. THYRATRON AND IGNITRON CONTACTORS

Two controlled rectifier tubes of the thyratron or ignitron type can be connected in inverse parallel and the combination connected in series with a single-phase load to make a single-pole single-throw a-c switch called a thyratron contactor or an ignitron contactor. Likewise, several pairs of tubes may be connected in polyphase circuits to make a polyphase single-throw a-c contactor. This type of contactor has several salient features:

1. In applications involving a very large number of operations, it eliminates the mechanical wear and resultant maintenance of mechanical-type contactors. Furthermore, it is quiet in operation.
2. This type of circuit is inherently fast in response. This means that power circuits may be closed or opened more rapidly than with conventional magnetic contactors.
3. When these contactors are used with the proper phase control systems, they may be fired synchronously at a given phase position in each half cycle to avoid the transient currents that will result in inductive loads if the power circuit is closed at random.
4. These contactors may be used to control the effective a-c load voltage by adjustment of the firing point. Control of load power can be obtained without power loss and without undue voltage regulation due to load changes.

The choice of thyratron or ignitron tubes is dependent on the magnitude of power involved. Typical applications of thyratron-type contactors are: (1) for controlling the speed of some types of a-c motors; (2) for controlling the output voltage of high-voltage transformers; (3) for low-power resistance welders; (4) for high-voltage resistance welders. By far the largest number of applications of electronic contactors, however, has been made in the resistance welding field, in which ignitron tubes are used.

General requirements for resistance welding are: (1) single-phase power; (2) power impulses having a high peak value over a short period of time; (3) a large total number of impulses over a given period of time; (4) control of the effective amount of welding current; (5) controlled firing to eliminate transient currents. These requirements have made the ignitron contactor with its extremely high peak-current capacity and its controllability ideally suited to resistance-welding applications.

Figure 3 illustrates a typical single-phase ignitron contactor for resistance-welding service. This contactor is of the simple on-off type. It is used to give faster operation than magnetic-type contactors as well as to eliminate the maintenance on magnetically operated mechanical contactors. Figure 4 shows an elementary circuit diagram for an on-off type ignitron contactor. This circuit operates as follows: When the initiating switch is open, no current will flow because power is not being supplied to the ignitors for firing the tubes. Assume now that the initiating switch is closed and that anode *a* is positive. Current will not flow through the left-hand tube until the ignitor has been fired. The ignitor firing circuit starts with anode *a*, continues through the lower right-hand metallic rectifier, through the water-flow switch, fuse, and initiating switch, and through the upper left-hand metallic rectifier into the ignitor which is immersed in the mercury pool. Current flows from this pool to the primary of the welding transformer and back to the other side of the a-c line. This means that the entire line voltage and the entire load current are available for firing the ignitor. With this voltage and current available, the ignitor fires the ignitron tube, and then load current flows through the main anode of the left-hand ignitron. When the anode *b* is positive, ignitor firing current flows through the lower left-hand metallic rectifier, through the initiating switch, fuse, and water-flow switch; then through the upper right-hand metallic rectifier into the mercury pool and back to the other side of the a-c supply. The metallic rectifiers provide a path for the ignitor firing current during the half cycle in which a specific ignitor is to be fired. During the other half cycle, the metallic rectifiers prevent the flow of reverse ignitor current which would damage the ignitor.

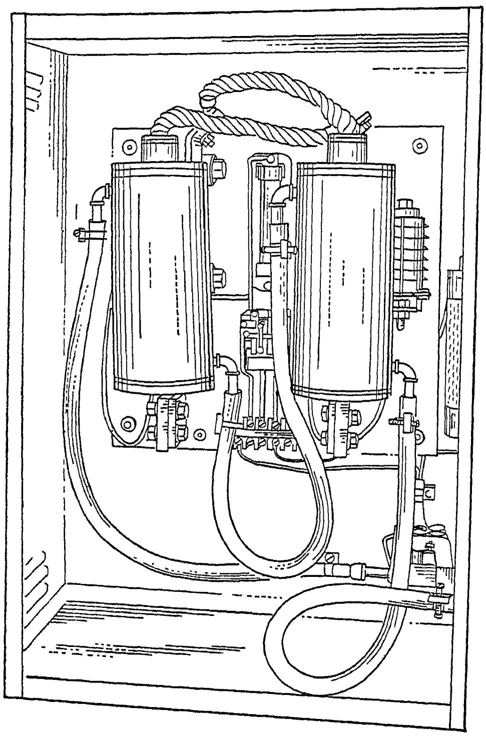

FIG. 3. Single-phase Ignitron Contactor with Size D Tubes (Courtesy General Electric Co.)

Figure 5 shows how thyratron tubes may be used to control the ignitron power tubes in order to obtain phase control or synchronous timing control of the output power. A resistor is used in the anode of the two thyratron tubes to limit the peak current flowing while a fuse is used to protect the tubes against high rms current which would result if the ignitor were continuously fired with no load current flowing.

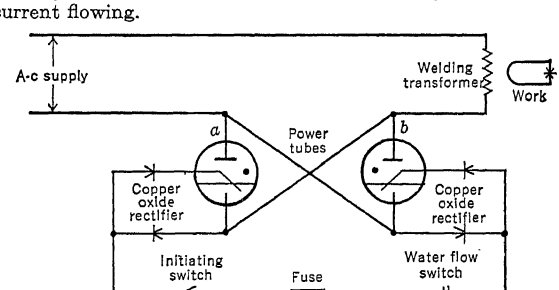

FIG. 4. Circuit Diagram for an Ignitron Contactor with Metallic Rectifier Firing

Figure 6 is a typical duty cycle rating curve for four sizes of contactors (ratings are for two tubes) used on a 460-volt power supply. Three factors affect the amount of current which can be handled by a pair of ignitrons: (1) The maximum current is a function of the line voltage; for low line voltages, the tubes will carry a higher current than for high line voltages. (2) For a given line voltage there is a maximum rms current rating irrespective of the length of time the current flows. (3) If the current flows over an appreciable length of time, even though the duty cycle is low, the averaging time of the tube must be considered to prevent overloading the tube from a thermal standpoint. Per cent duty shown in Fig. 6 indicates the percentage of total time that current is flowing through the tubes.

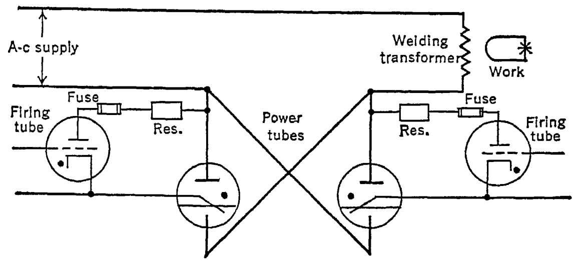

FIG. 5. Ignitron Contactor with Thyratron Firing Circuit

A pair of size D tubes has a continuous rating of 800 amp. As the duty cycle is reduced, however, the maximum current can be increased. If the time involved is short, the rating can reach almost 5000 amp. The size D tubes have an averaging time of 5.6 sec. This means that, for any 5.6-sec period, the average current should not exceed 800 amp rms, even though the actual current during conduction equaled 5000 amp. In other words, the tubes could carry 5000 amp for approximately 0.9 sec (800/5000 × 5.6), provided no

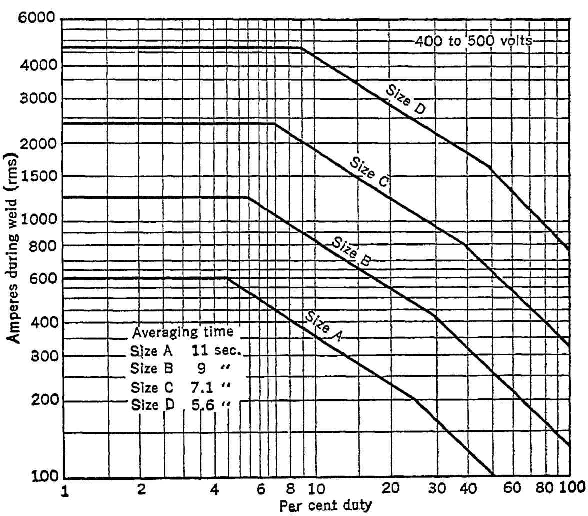

FIG. 6. Ignitron-contactor Duty-cycle Rating Curve

current was carried during the remainder of the 5.6-sec period. If it were necessary to have current flowing over a 5.6-sec period continuously, the tube rating would be the same as for 100 per cent duty, or 800 amp.

FUNDAMENTAL ELECTRONIC CONTROL CIRCUITS

Because the applications of electronic control are so diversified and because most applications are highly specialized it is impractical to describe even a moderately complex circuit with all its ramifications. An attempt will be made in this section to discuss several fundamental control circuits which are commonly used in complete electronic systems, with the hope that these circuits will be recognized when they are a part of complete systems.

5. STABILIZED D-C CONTROL POWER SUPPLIES

Many electronic control equipments include a small d-c power supply usually consisting of a diametric (full-wave) rectifier and a suitable filter. These are similar to the power supplies used in radio receivers which are discussed in Section 7.

In order to provide stability of operation of the associated electronic control equipment, it is often necessary to provide a d-c output voltage which is held constant irrespective of line voltage or changes in load. This may be accomplished in several ways; the most common are:

1. A-c voltage stabilizers. Figure 1 illustrates one typical type of automatic voltage stabilizer circuit. The voltage-regulating action is due primarily to reactor 1 and the parallel capacitor. When the line voltage is high, reactor 1, which operates near the knee of the *B-H* curve, becomes saturated. Under this condition the reactor current and the capacitor current are about equal, the total current being at about unity power factor. As a result there is a voltage drop across reactor 2. When the line voltage drops,

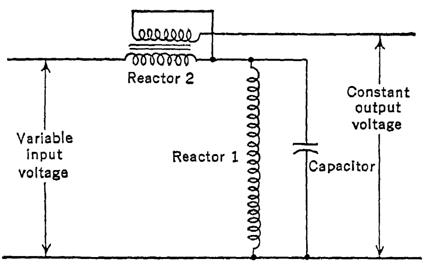

FIG. 1. Circuit Diagram of A-c Voltage Stabilizer

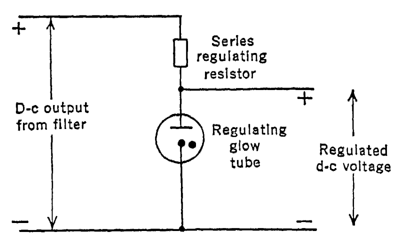

FIG. 2. Glow-tube-type D-c Voltage Regulator

however, the reactor current falls off more rapidly than the capacitor current. As a result the current through reactor 2 is predominantly capacitive and there is a rise in voltage across reactor 2. Units of this type will hold the output voltage to within ± 1 per cent over about a ± 15 per cent change in input voltage.

2. Gaseous-type voltage-regulating glow tubes. These tubes have inherently a constant voltage drop. When the voltage has reached the ionization point a very small increase in applied voltage will result in a comparatively large increase in tube current. These tubes are well suited to control power circuits involving small currents. Three ratings are most commonly used, namely, 75, 105, and 150 volts at 40 ma maximum. Figure 2 shows a regulating circuit, using a glow tube. The constant-voltage characteristic of the glow tube will permit the rectifier output voltage to be increased or decreased, and the voltage difference will be largely absorbed by the series regulating resistor. This results in a nearly constant output voltage across the glow tube.

3. A series-type voltage regulator. This regulator uses a glow tube merely as a reference voltage and involves a regulating principle which will be discussed later. This type of voltage-regulating system will provide larger amounts of voltage and current and at greater accuracy than can generally be obtained with the simple glow-tube arrangement discussed before.

6. TIMING CIRCUITS

Timing circuits are widely used in electronic control systems. In many equipments such as general-purpose timers, resistance-welder sequence timers, timers for cut-off register applications which operate correcting devices for a given length of time, and timing circuits which control the acceleration or deceleration rate of motors, timing is a definite function. Often, however, the use of timing circuits may be incidental to the function to be performed by a given equipment. For example, filter capacitors in d-c control power supplies, capacitors across relay coils which are operated by half-wave rectifiers, resistor-capacitor combinations, and electronic relays involving impulses of very short duration which are used to maintain an operating signal long enough to operate a magnetic relay are all energy-storage-type timing circuits.

A capacitor is used as a basic timing element in most timing circuits. Figure 3*A* shows a simple series resistor-capacitor circuit. When the switch is closed, the capacitor charges through the series resistor. The instantaneous voltage across the capacitor is expressed by the equation $e_{ct} = E(1 - e^{-t/rc})$, where t = time in seconds after the switch is closed. Figure 3*B* shows a similar circuit in which the capacitor is charged almost instantly (assuming that the d-c source has no resistance) and in which the capacitor discharges through the parallel resistor. The instantaneous capacitor voltage after opening the switch is expressed by the equation $e_{ct} = E \times e^{-t/rc}$. The above equations will give the voltage at any time. A more generally used term, however, is the time constant. The time constant is defined as the time at which the capacitor has charged to approximately two-thirds of its final voltage value or the time at which the capacitor has discharged to approximately one-third of its initial voltage value. The time constant is expressed as $T = rC$, where T = time in seconds, r = resistance in ohms, and C = capacitance in farads. Often a basic timing circuit will include a parallel r–C circuit with a resistor in series. This will result in a time lag in the charging circuit and a lag in discharging as well.

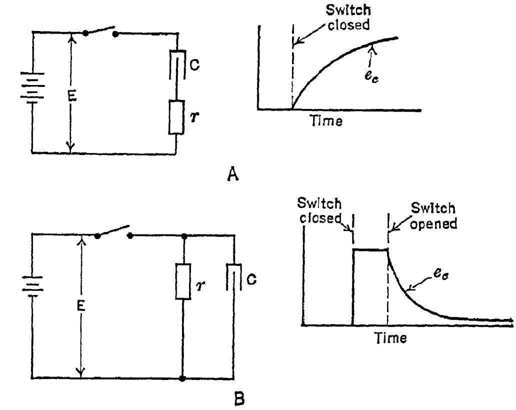

FIG. 3. Basic *R-C* Timing Circuits

r-C circuits are used in complete circuits to obtain a time delay by applying the capacitor voltage to a tube grid to render the tube conducting or non-conducting at a given capacitor voltage. Although different detail circuit arrangements are used in timing, the basic circuits shown are common to most electronic timers.

A general-purpose time-delay-relay circuit which uses a parallel r-C circuit for timing is shown in Fig. 4. This is typical of complete timing circuits. The coil of the relay is energized a definite time after switch S is closed. When switch S is open, the cathode of the vacuum tube is connected through $2R$ (which is a relatively low resistance) to the anode. Resistor $1R$ and the potentiometer P form a voltage divider across the a-c power supply. With the switch open, the cathode is effectively connected to line 1 (through resistor $2R$). Therefore current will flow from line 3 through a section of the potentiometer, through the parallel resistor-capacitor combination into the grid, and back through the cathode. The grid in this instance acts as an anode since it is positive with respect to the cathode during every other half cycle. The voltage drop across the timing resistor R causes capacitor C to become charged. As capacitor C charges, the voltage applied to the grid during alternate half cycles becomes less positive—the grid voltage is the algebraic sum of the a-c voltage and the capacitor voltage. The capacitor will continue to charge until the voltage across the capacitor is equal to the peak of the a-c voltage from line 1 to the slider of the potentiometer. If the potentiometer P is turned to the extreme counterclockwise position, this will be the peak line voltage. As potentiometer P is turned clockwise, the capacitor charges to a lower value. When switch S is closed the cathode is connected to the other side of the line. At this instant the grid of the tube is negative with respect to the cathode by whatever potential the capacitor C is charged. The instantaneous grid voltage, however, is a summation of the d-c capacitor voltage and the a-c voltage from line 3 to the potentiometer slider. Figure 5 shows the action of the capacitor discharge circuit plus the a-c component. It can be seen that, when the switch is first closed, the grid is sufficiently negative at all times so that no plate current flows. As the capacitor discharges, however, the grid potential reaches a point where sufficient plate current flows to energize the relay in the plate circuit. The capacitor C_1 of Fig. 4 across the relay coil is

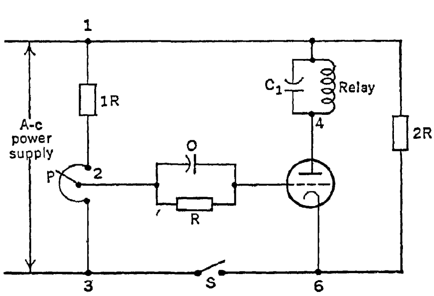

FIG. 4. General-purpose Time-delay-relay Circuit

used as an energy-storage device during the half cycle in which the tube is conducting so that it can supply energy to the coil during the half cycle when the tube is not conducting, thus preventing the relay from chattering.

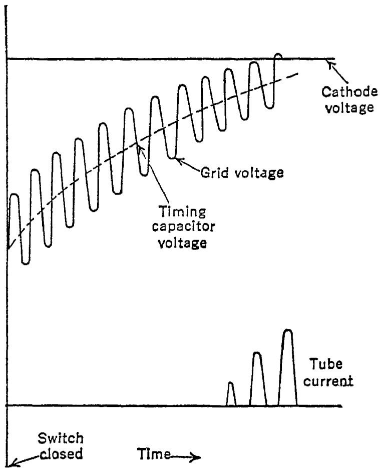

FIG. 5. Grid Voltage and Anode Current after Timing Switch of Timer (Fig. 4) is Closed

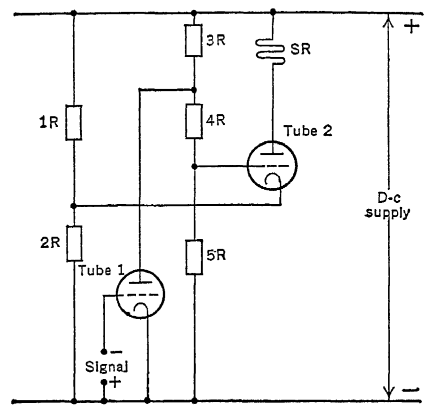

FIG. 6. Typical D-c Voltage Amplifier

7. D-C AMPLIFIERS

D-c amplifiers are commonly used in photoelectric controls, motor and generator controls, electronic voltage regulators, regulated battery chargers, and other equipment where it is desirable to amplify d-c signals. These amplifiers are generally not too well suited for applications where the signal voltage is low and where a high degree of amplification is needed, because the instability of the tube characteristics can result in output variations equal to or greater in magnitude than would be obtained from a complete input-signal range. D-c amplifiers are very well suited, however, to regulating circuits where the difference between two fairly large voltages is applied to the grid circuit. Regulating circuits will be discussed in more detail later.

Figure 6 shows a typical d-c voltage amplifier. Resistors $1R$ and $2R$ form a voltage divider which establishes the cathode potential of tube 2. Resistors $3R$, $4R$, and $5R$ are chosen so that, when plate current is not flowing in tube 1, the grid of tube 2 is positive. When current flows through tube 1, the additional IR drop in resistor $3R$ lowers the grid voltage of tube 2 and reduces its plate current. In the plate circuit of tube 2 is shown a saturable reactor which could be used in a thyratron phase-shifting circuit, although any voltage- or current-responsive device could also be used here. If the signal voltage were zero, the grid of tube 1 would be at cathode potential and tube 1 would be carrying approximately maximum current. As the grid voltage of tube 1 is made negative, the plate current of tube 1 would decrease, thus increasing the plate current in tube 2.

8. A-C AMPLIFIERS

In control circuits a-c amplifiers are usually of the capacitance-coupled type. Though in some circuits they are used in much the same way as in radio circuits they are often employed in circuits in which it is desirable to amplify an impulse signal. For example, in photoelectric cutoff or web-register control systems used in cutting bags or labels at a particular point with respect to the printed material it is desirable for the equipment to respond to small marks on paper which is moving at high speed. The light impulse is obtained by scanning the paper surface with a photo tube. The normal light level may be relatively high, and the mark on the paper may correspond to only a small change in light. Therefore, it is necessary to have a very sensitive amplifier which responds only to rapid light impulses or changes and not to steady-state light or general changes in light level.

A typical impulse amplifier is shown in Fig. 7. Resistor 1*R*, 2*R*, 3*R*, and 4*R* constitute a voltage divider to supply the various voltage levels required in the circuit. The proper grid bias on tubes 1 and 2 is supplied through grid resistors 6*R* and 8*R* respectively. Assume that a steady level of light is applied to the phototube. The circuit constants are arranged so that under this condition current flows in tube 1 but not in tube 2. Now if light suddenly is diminished the phototube current is reduced and capacitor 1*C* momentarily "pulls" the grid of tube 1 to a more negative position. This immediately reduces the plate current in tube 1, which in turn raises momentarily the grid voltage of tube 2 through capacitor 2*C*. Tube 2 is a thyratron type and has a d-c anode supply voltage. Therefore although its grid voltage may go in the positive direction only momentarily this is sufficient to fire the tube and once fired it remains conducting until the reset contact shown is opened.

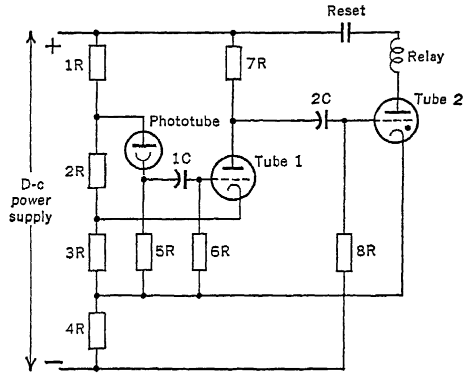

Fig. 7. Typical Impulse-type A-c Amplifier as Used in Photoelectric Cutoff Register Controls

9. REGULATING CIRCUITS

Regulating circuits are used in many applications where it is desirable to hold quantities such as voltage, current, speed, position, pressure, temperature, and the like constant irrespective of conditions, such as load or line-voltage variations, which would normally cause the quantity being held to deviate from the desired value. Any regulating circuit has four fundamental requirements:

1. A standard or a reference voltage, which is held constant at all times and which represents a value against which the quantity to be held constant is compared. The reference voltage is the heart of a regulating circuit because the accuracy of the regulator can never be more accurate than the reference voltage.
2. Means must be provided so that the quantity to be regulated will produce a signal voltage which can be compared with the reference voltage.
3. An amplifier, to amplify any difference that may exist between the regulated quantity and the reference voltage.
4. A controlling means, which will operate from the amplifier to restore the quantity to approximately the value originally held before the deviation occurred.

Figure 8 shows an electronic voltage regulator, the purpose of which is to supply a constant d-c voltage output over a wide range of load current and d-c input line voltage. The total output power from this circuit is limited by the current that can be handled by the 2A3 tube shown. (Parallel tubes or other tube types will deliver more power.) Assume for the moment that switch *S* is open and also that no current is flowing in the plate of the 6J7 tube. Under these conditions, the grid of the 2A3 tube will be at approximately cathode potential. The effective resistance of the 2A3 tube under this condition is very low. Therefore a high voltage will exist across lines 2 and 3. Resistors 1*R* and 2*R*, which are in series with the OA3/VR75 glow tube, are such that with rated regulated d-c output voltage the glow tube will ionize and, once ionized, will conduct a small amount of current. The characteristic of the glow tube is such that, if the voltage between lines 2 and 3 is varied, the voltage across the glow tube will remain reasonably constant. However, the more constant the voltage across lines 2 and 3 can be held, the less variation there will be in the voltage across the glow tube because the voltage across the glow tube changes somewhat with current. Since the objective of this equipment is to hold the voltage output constant, the reference voltage must be held as constant as possible.

The cathode of the 6J7 amplifier tube is connected to the glow-tube anode, point 4. Resistors 3*R* and 4*R* constitute a voltage divider across the output of the regulator and therefore provide a signal to the grid of the 6J7 tube which is proportional to the output voltage. Resistors 3*R* and 4*R* are selected so that with rated regulated d-c output voltage the grid of the 6J7 tube will be at approximately cutoff. The actual grid signal consists of the difference between the voltage across resistor 4*R* and the voltage across the glow tube. If it is assumed that the reference voltage from the glow tube is constant, then any deviation in output voltage will be reflected as a difference in the potential between the grid and the cathode of the 6J7 tube.

As was stated before, if no current is flowing in the 6J7 tube, the effective resistance of the 2A3 tube is very low. The output voltage between lines 2 and 3 therefore will be

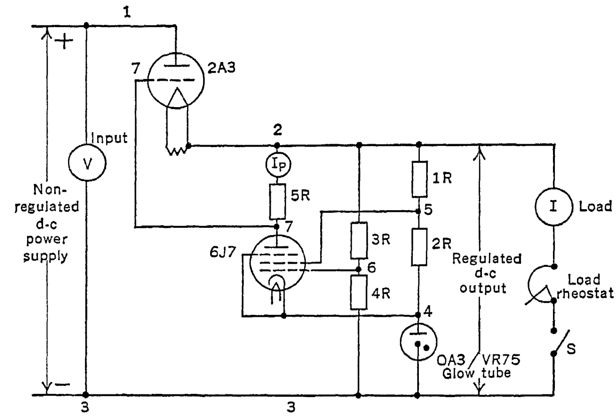

FIG. 8. Electronic D-c Voltage Regulator

high. This, however, results in a grid-to-cathode voltage on the 6J7 tube of a sufficiently high positive value to cause the 6J7 to conduct plate current. This current causes an IR drop between lines 2 and 7 across resistor $5R$, and causes the grid of the 2A3 tube to assume a negative potential. This negative potential increases the effective resistance of the 2A3 tube and thus reduces the output voltage between lines 2 and 3. There is a certain grid-to-cathode voltage on the 2A3 tube which will result in an output voltage across lines 2 and 3 sufficient to adjust the grid potential of the 6J7 tube to give the desired grid-to-cathode voltage on the 2A3 tube.

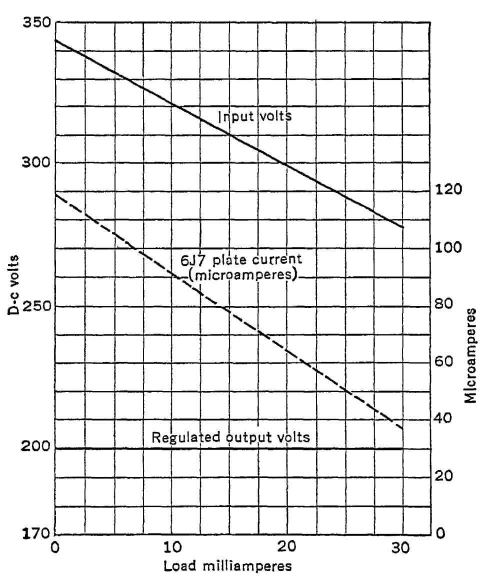

FIG. 9. Performance of Electronic Voltage Regulator Shown in Fig. 8

If now the regulator is holding a given voltage and load is added by closing the switch S, the output voltage between lines 2 and 3 will immediately drop because the effective resistance of the 2A3 tube is in series with the load. In order to correct this low-voltage condition, the regulator must again go into action. When the output voltage is reduced, the grid voltage is made more negative with respect to the cathode voltage on the 6J7 tube. This more negative value of grid voltage reduces the 6J7 plate current and thereby makes the 2A3 grid less negative, which reduces the equivalent resistance of the 2A3 tube, again restoring the correct output voltage. The curves of Fig. 9 show input and output voltage as a function of load current for the regulator. It also shows the plate-current change required of the 6J7 tube to give accurate regulation of the output voltage. It can be seen that, for a wide change in output load current and for a wide change in input line voltage, the regulated output voltage is held nearly constant.

The electronic voltage regulator just discussed is a simple unit when compared with most complex electromechanical regulators; however, it is typical of all regulating circuits in that it includes the fundamental elements of a regulating circuit.

The essential regulating elements can be explained as follows: Referring to Fig. 8, the voltage across the glow tube between lines 3 and 4 is the standard or reference voltage. The voltage across lines 3 and 6 is the signal voltage. Any difference between the voltages 4 to 3 and 6 to 3 is applied to the grid of the 6J7 tube, which amplifies the existing deviation. This in turn controls the grid on the 2A3 tube to correct for the voltage deviation. An important feature of a regulating circuit, as far as obtaining accuracy is concerned, is the use of two relatively large voltages in the comparison circuit. This can be shown best by an example. If the 6J7 tube required 0.1-volt change on the grid to effect a complete swing of the grid of the 2A3 tube, this 0.1-volt change can be accomplished on a 200-volt output circuit with a 75-volt reference voltage by approximately a 0.3-volt total error in the output. In other words, the inherent regulating error of the system does not exceed 0.3 volt out of 200 volts or 0.15 per cent for a wide load and input line-voltage change. Furthermore, if the inherent tube characteristics varied in such a manner that a given 6J7 plate current resulted with a grid voltage 0.3 volt different from the original voltage the output voltage would again be in error by only approximately 0.15 per cent. If lower voltages were used, both errors would increase.

10. THYRATRON GRID-CONTROL CIRCUITS

Thyratron tubes are used in circuits having d-c or a-c anode supplies. When they are used with d-c supplies they are on-off devices and a simple d-c grid-bias control can be used to fire the tubes. In a-c circuits, such as rectifiers or electronic contactors, however, it is usually desirable to control the effective output voltage by controlling the point in each cycle at which a particular tube fires.

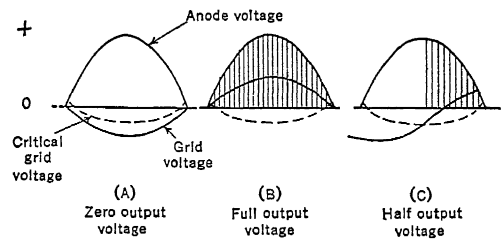

FIG. 10. Method of Grid Control of Thyratron Tubes

When a thyratron is connected to an a-c power supply the anode voltage is different at each point in the cycle. Therefore at the beginning of a positive-voltage half cycle a positive value of grid voltage is required to fire the tube. As the anode voltage increases in the positive direction, the grid voltage required to fire the tube becomes negative. Figure 10 shows a curve of the grid voltage—the critical grid-voltage curve—required to fire a thyratron tube on an a-c power supply. Figure 10*A* shows that with an a-c grid voltage applied 180° out of phase with the anode voltage the tube does not conduct. Figure 10*B* shows that with an a-c grid voltage applied in phase with the anode voltage the tube conducts for the entire half cycle. Figure 10*C* shows that with the a-c grid voltage lagging the applied voltage by 90° the tube conducts for half of the half cycle.

Although a number of different types of grid-controlled circuits can be used for controlling the output voltage of thyratron tubes, the most widely used control circuits are: (1) grid-voltage phase shifting; (2) fixed 90° phase shift with adjustable d-c bias.

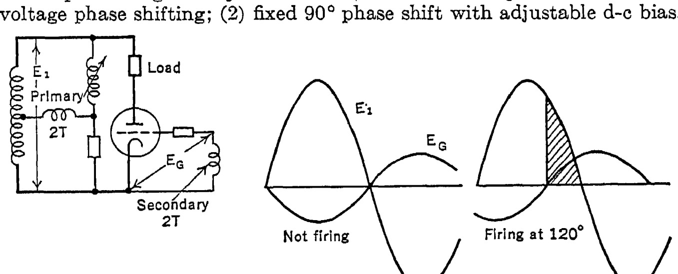

FIG. 11. Basic Circuit for Controlling Thyratron Tubes with Adjustable Grid-voltage Phase Angle

Figure 11 shows the basic circuit for a method of controlling thyratrons by means of an a-c grid potential whose phase angle can be adjusted. The grid-voltage phase position is determined by the ratio between the variable inductance and the fixed resistance shown in the primary of the grid transformer 2*T*. Figure 12 shows the vectors of the voltages involved in the grid circuit. E_1 is the anode-transformer secondary voltage. *Ir* is the voltage across the resistor and is in phase with the resistor-reactor series current. Ix_L is the voltage across the variable reactor. The actual grid voltage E_g can be seen to vary in phase position, but not in magnitude, as Ix_L is changed (change in the reactance). The variable reactor could be an iron-core reactor with a removable plunger, or a small saturable reactor, the d-c winding of which could be energized by a vacuum tube or other means. It is also possible to use a fixed capacitor and a variable resistor to obtain this same type of control. Another method of obtaining this same type of control is by the use of a selsyn (induction phase shifter) which has a three-phase primary stator and a single-phase secondary rotor. As the rotor is turned, the rotor output voltage, which can be applied directly to the grid circuit, changes in phase position.

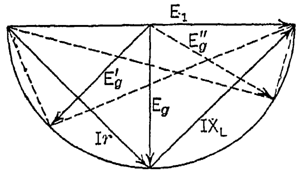

FIG. 12. Vector Voltages of Phase-shift Circuit of Fig. 11

Figure 13 shows the basic circuit for obtaining a fixed a-c voltage phase shift plus an adjustable d-c voltage for controlling the thyratron firing point. The voltage E_g can be seen to be made up of two components: E_2, having a magnitude which is determined by the ratio of transformer 2*T*, and a phase position which is determined by the ratio of resistance and capacitance in the primary of transformer 2*T*; and an adjustable d-c

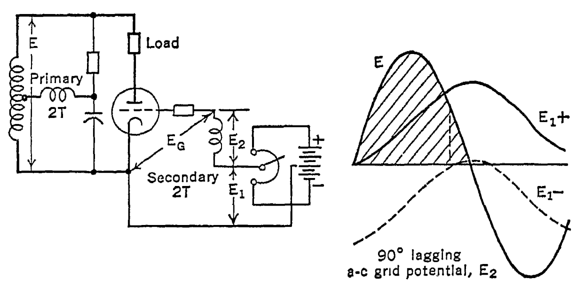

FIG. 13. Basic Circuit for Controlling Thyratron Tubes with Fixed A-c Voltage Phase Shift plus Adjustable D-c Grid Voltage

potential E_1. With this circuit, grid control is obtained by adjusting the d-c grid potential E_1. Figure 13 shows firing full on with positive grid voltage and nearly full off with negative grid voltage. Smooth control can be obtained over the entire range.

COMPLETE ELECTRONIC DEVICES

Many electronic circuits can be built into complete electronic devices, the operation of which is independent of associated equipment. Timing relays, electronically regulated power supplies, rectifiers, and electronic contactors are complete electronic devices which have been discussed previously.

11. ELECTRONIC RELAYS

CONTACT-OPERATED ELECTRONIC RELAYS. Contact-operated electronic relays are used where it is desirable to operate a magnetic contactor or other electrically operated device upon the closure of a circuit which has insufficient current-carrying capacity to operate the final or an intermediate device. For example, it is often desirable to have a power circuit initiated when an instrument pointer reaches a certain mark on the scale. The pointer contacts in most cases are not only inadequate to carry the power in the load circuit but also inadequate to carry the power required to actuate a contactor in the load circuit. The contacts, however, are adequate for insertion in the grid circuit of an electronic relay, which will in turn initiate a magnetic contactor. Other applications of this type of relay are: (1) liquid-level controls where the liquid itself is the conducting medium—in this case a pump or a valve is operated by means of the relay; (2) high-low gaging of small parts where the parts passing between contacts carry the grid signal which in turn operates the relay to actuate reject devices; (3) drop-switch circuits in textile mills to operate signals which indicate broken "ends" of yarn.

Figure 1 shows a typical circuit diagram for a contact-operated electronic relay. When the switch S is open, the transformer secondary supplies power through the half-wave rectifier to charge capacitor $2C$. At the same time the grid of the amplifier tube is at cathode potential. The triode tube conducts full current and relay CR is energized. When the switch S is closed, the grid of the amplifier tube is brought to a negative potential and the relay CR is de-energized. By the proper choice of resistors $1C$, $1R$, and $2R$, this circuit will operate with resistances as high as 10 megohms across the switch terminals. Also, with other resistor and capacitor values it will operate when the switch circuit is closed only long enough to give a very short impulse for charging capacitor $1C$.

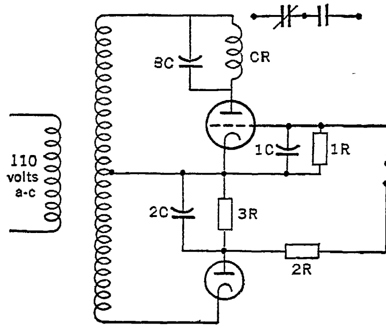

FIG. 1. Typical Circuit Diagram for Contact-operated Electronic Relay

PHOTOELECTRIC RELAYS. Photoelectric relays are often used as limit switches for operating signals, counters, or other devices in applications where mechanical limit switches would be unsuitable because of an excessive number of operations, because of extremely high velocities of moving articles, because of temperature extremes or because the material which is to operate the device has insufficient mechanical strength to operate a mechanical limit switch. There are also many photoelectric-relay applications which are unique to light-responsive devices, as indicated by the following examples: (1) operation by the light reflected by or transmitted through certain colors of material; (2) operation by the amount of light transmitted through holes in cloth, paper, steel, or other material; (3) operation by light reflected from certain types of bottle cracks.

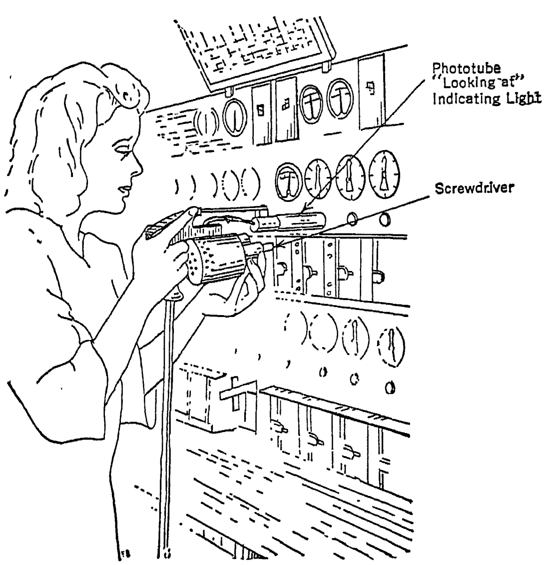

FIG. 2. Application of Photoelectric Relay to Motor-operated Screwdriver (Courtesy General Electric Co.)

Figure 2 illustrates an ingenious application of a simple photoelectric relay. A motor-driven screwdriver is used to make an adjustment on a relay contact. When the contact opens, an indicating light is turned on. A phototube is held over the indicating light to shut off the motor-driven screwdriver automatically when the light comes on, thus assuring proper adjustment of the relay.

A number of special and general-purpose types of photoelectric relays are commercially available. Figure 3 shows several general-purpose photoelectric relays: 1 is an outdoor-type weatherproof relay; 2 is an indoor-type high-sensitivity relay with a large light-collecting lens; 3 is a high-sensitivity relay with a separately mounted phototube; 4 is a simple general-purpose relay; 5 is a general-purpose relay with a separately mounted phototube.

Figure 4 shows the circuit diagram for the general-purpose relay, numbered 4 in Fig. 3. Assume that light is not shining on the phototube and that the slider of potentiometer P

is turned completely counterclockwise. Therefore the full voltage of the lower transformer secondary is connected from the cathode to the grid circuit. During every other half cycle the grid circuit becomes positive. This charges the grid circuit capacitor by grid rectification in the direction indicated. The grid circuit is positive during the half cycle

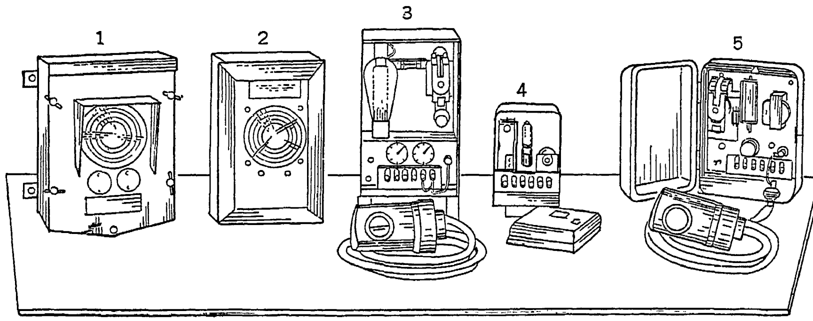

Fig. 3. General-purpose Photoelectric Relays (Courtesy General Electric Co.)

in which the plate is negative. Thus no plate current flows. When the plate circuit is positive, the polarity of point A is negative; also the charge on the capacitor is in a direction to make the grid even more negative, thus preventing the relay from being energized. Now, if light is applied to the phototube, current flows through the phototube and capacitor in the direction of the arrow during the half cycle in which the grid is negative. This effectively discharges the capacitor in proportion to the amount of light on the phototube. If sufficient light is applied to the phototube, the capacitor charge due to the phototube will be greater than the charge due to grid current and the grid will become positive, thus energizing the plate-circuit relay. When the potentiometer slider is in the counterclockwise position, the capacitor charges to a higher value than when it is turned clockwise; therefore more light is required to operate the relay in the counterclockwise position of the slider than in the clockwise position.

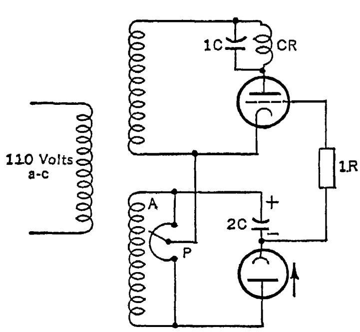

Fig. 4. Circuit Diagram of Relay 4 in Fig. 3

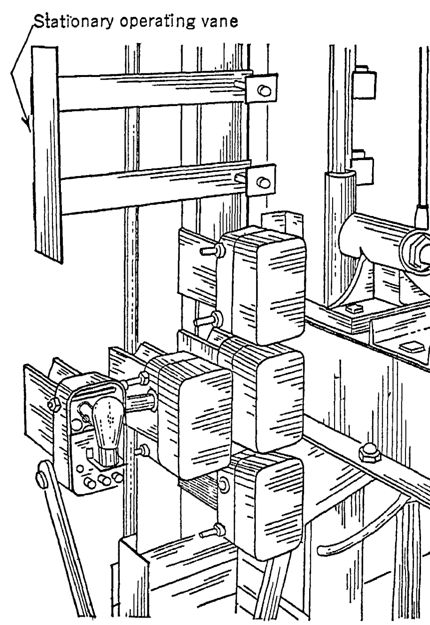

Fig. 5. Oscillator-type Elevator-leveling Relays Mounted on an Elevator Car (Courtesy General Electric Co.)

The a-c operated type of photoelectric relay just described is not suitable for applications where the light impulses are of extremely short duration, because an impulse may occur during the time when the sine wave of anode potential is passing through zero and therefore the relay would not be energized. Impulses of light for a-c operated relays must be at least in excess of 1 cycle. In order to operate relays where the light impulses are of extremely short duration, it is essential to use a d-c power supply for the anode power of the amplifier tube, as well as for the photoelectric tube itself. The circuit diagram of a high-speed photoelectric relay is shown in Fig. 7, p. 21-17.

ELECTROMAGNETICALLY AND ELECTROSTATICALLY OPERATED OSCILLATOR-TYPE RELAYS. The electromagnetically operated oscillator-type relays were probably first used industrially in the leveling of elevators. Figure 5 shows a typical installation of five elevator-leveling relays mounted on an elevator car. Figure 6 shows the connection diagram for this unit. When there is no magnetic material in the oscillator coil circuit, the tube current is low and the relay *CR* is de-energized. As the car approaches a floor, however, an iron channel enters the oscillator-coil magnetic circuit and oscillation stops. This increases the oscillator plate current and energizes the relay *CR* which in turn operates the necessary control equipment to stop the car at the desired level.

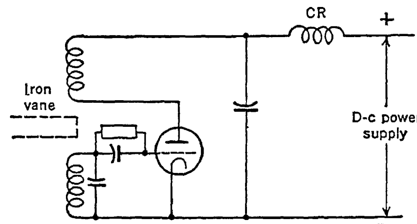

Fig. 6. Circuit of Oscillator-type Elevator-leveling Relay

Figure 7 illustrates the use of an oscillator-type relay which is used in a pyrometer controller. An iron vane on the instrument pointer passes through the oscillator coil and energizes a 15-amp control relay when the pyrometer reaches a predetermined temperature. The point at which the oscillator stops oscillation is very sharp and gives a high degree of control accuracy. Also since no mechanical forces are involved, such as there would be with mechanical contacts, the accuracy of the instrument is not impaired.

Electrostatically operated oscillating-type relays are used as level controllers in grain bins and in tanks which store non-conducting liquids.

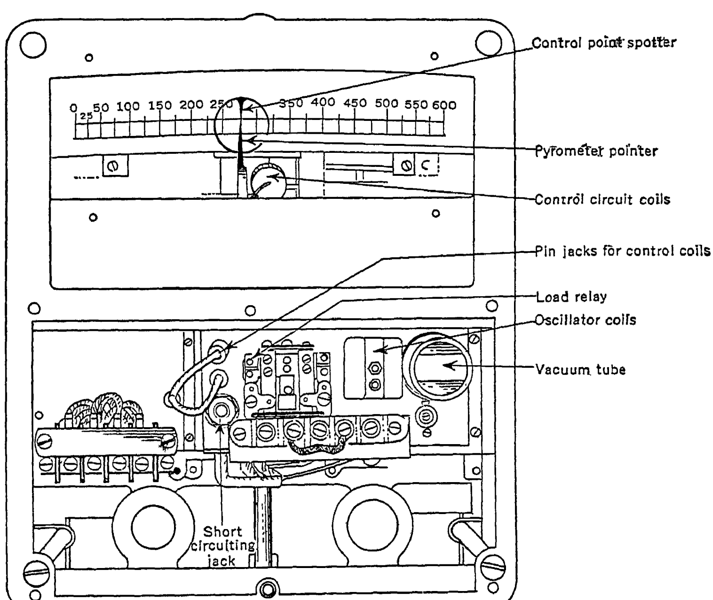

Fig. 7. Free-vane Electronic Pyrometer Controller (Courtesy The Bristol Co.)

12. RESISTANCE-WELDER CONTROLS

The first large-scale applications of electronic control industrially were made in the resistance-welding field. Electronically controlled resistance welders produced results in welding which were previously impossible. Thus a highly specialized branch of control has been developed to meet the many requirements of resistance welders. Resistance welders are divided into three primary types: (1) spot or projection welders; (2) seam or roll-spot welders; (3) upset or flash welders. Most electronic welder-control equipments are used on spot, projection, and seam welders.

The sequence of operation in making a spot weld is as follows: (1) The welder electrodes are applied to the metal during the "squeeze" time. (2) Welding current is passed through the material for a predetermined "weld" time. (3) The electrodes are held closed during a "hold" time, while the material hardens. A pulsation spot weld is made in the same manner as a spot weld except that during the "weld" time the power is intermittently applied with cooling intervals between the power intervals. Seam welds are overlapping or non-overlapping welds made consecutively by intermittent power pulses while the material is passing between two welding wheels.

Most welder controls consist basically of a thyratron or ignitron contactor connected in the primary of a welding transformer. Welding power levels vary from a few hundred volt-amperes for small parts to values in excess of 1000 kva for heavy parts and structures. Because the resistance of the material being welded is very low, a very high secondary current (1000 to 100,000 amp) is required to produce a weld. The relatively long secondary "loop" which is used, in combination with the low resistance of the secondary circuit, results in a low power-factor load.

From a power-system standpoint, a single-phase load with such high peak-power demands of very short duration is sometimes a disadvantage. Energy-storage-type welder controls store energy either in capacitors or in an inductance during the non-welding time and "dump" the stored energy into the material to produce a weld. These controls have three advantages over the conventional single-phase controls, particularly when used in welding aluminum or other high-kva-demand materials: (1) The control operates from a three-phase power supply. (2) The peak-power demand is low. (3) The power factor is higher than for most single-phase controls. Energy-storage type of controls are more expensive and less flexible than single-phase controls, and their general acceptance is thereby limited.

The simplest form of electronic control for resistance welders is the single-phase thyratron or ignitron contactor described previously. This provides high-speed operation and low maintenance, but it is simply an on-off power control. Current starts to flow when the initiating switch is closed, and it stops flowing at the first current zero after the initiating switch is opened. The energy in watt-seconds which is delivered to a weld = I^2RT. The resistance R is dependent on the material being welded. For a given resistance the welding current I is directly proportional to the effective voltage. With an on-off type control the current can be changed only by adjustment of transformer taps. Often manual or mechanical timers are used with ignitron contactors to control the time T.

In some cases the approximate adjustment of current magnitude provided by tap-changing combinations on the welding transformer are sufficient. However, certain metals and alloys which must be welded rapidly (within a narrow temperature range) require more accurate current settings. Phase-shift heat-control equipment can be added to ignitron contactors to provide these accurate settings. Figure 8 shows oscillographs of welding currents under three conditions of heat control.

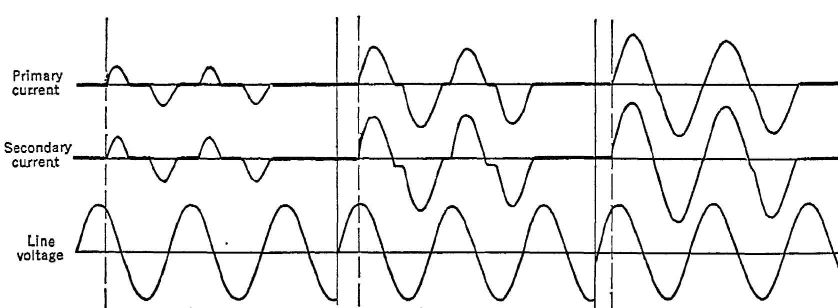

FIG. 8. Oscillograms of Current in Welder when Using Phase-shift Heat Control

Automatic weld timers are often used with electronic contactors to coordinate the various mechanical operations as well as to time the welding power impulse. When welding thin-gage materials, the required time of current flow may be as short as 2 cycles. A variation of 1 cycle would mean a variation in the heat input of 50 per cent and could give a faulty weld. Therefore precision-type timers are required. On the other hand, if the welding time required were 30 cycles a precision timer would not be so important.

If the power tubes are not initiated at a normal current zero a transient current will be present which will result in additional heat in the weld. On short time intervals the transient may add considerably to the total heat. Variations in welds will therefore result from random firing. Synchronous firing is often provided to minimize the transient current by firing the power tubes at a fixed point in the cycle. Figure 9 shows the transient current which will exist when current is started at the zero point on the voltage wave. Figure 10 shows how the transient can be eliminated by starting the current at a normal current zero.

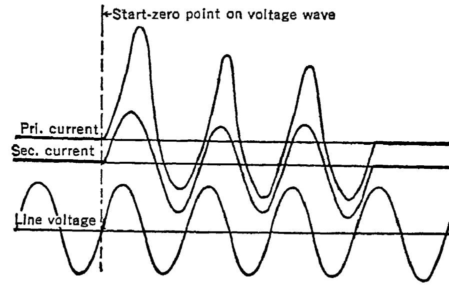

FIG. 9. Oscillogram Made When Current is Started at Zero Point on Voltage Wave

Figure 11*A* illustrates a circuit which will provide phase-shift heat control and synchronous firing. The thyratron firing circuits on both tubes are identical except for the instantaneous polarities of the transformers in the grid circuits. The instantaneous polarities indicated exist when the anode of the left-hand thyratron tube is positive. Figure 11*B* shows the supply voltage E and the grid voltage. The grid voltage consists of two components: (1) E_B, which is the voltage of $3T$ secondary; (2) E_P, which is the voltage of $1T$ secondary. Transformer $1T$ is a "peaking" transformer which has only a small amount of iron in the core. This results in saturation at a particular point in the wave and therefore a peaked output voltage, about 5° or 10° wide. The phase position of the voltage applied to the peaking transformer and therefore the phase position of the voltage peak is adjusted by the phase-shifting rheostat $1R$. The magnitude of E_p when added algebraically to E_b is insufficient to fire the thyratrons. Figure 11*C*, however, shows the grid voltage when switch *SW* is closed. The secondary voltage E_c of $2T$ is of a polarity that subtracts from E_B. Voltage E_p is now of a sufficiently high value to fire the thyratrons. During the half cycles when the grids are positive, the grid capacitors are charged in the direction indicated. This provides a small negative grid bias to prevent misfiring at the beginning of a cycle when the a-c grid voltage is going through zero.

A complete welder control can be made up of a number of individual components, or complete control units can be obtained which include some or all of the above features. Figure 12 is an elementary diagram of a spot-welder control that provides precise timing of the weld impulse, as well as synchronous firing. It does not provide phase-shift heat control. The control essentially is made up of a d-c control rectifier (not shown), a "keying" tube to insure starting the power flow at the desired point in the voltage cycle, a timing circuit which is also a leading firing circuit, a trailing firing-control circuit, and an ignitron power circuit. The keying tube is normally held non-conducting by the negative bias across resistance $2R$. It is fired at a particular point in the wave as determined by the adjustment of resistance $4R$ in series with the primary of the peaking transformer. When the initiating switch $S1$ is in the 1 position, the grid of tube 2 is negative. After the initiating switch is closed in the 2 position, and at the proper time in the next cycle, the grid of tube 2 is made sufficiently positive so that it conducts. This in turn fires the ignitron power tube. As capacitor $2C$ charges (the time being dependent on the setting of resistance $6R$), the grid of tube 2 becomes less positive. At a given time, tube 2 will again have a negative grid voltage and therefore will not fire the ignitron. On an inductive load (a welder load), the current in the left-hand ignitron tube will still be flowing when the voltage applied to the right-hand ignitron tube becomes positive. This means that, as the current in the left-hand ignitron goes to zero, the feedback transformer will put a positive voltage on the grid of tube 3, thus making the right-hand ignitron tube

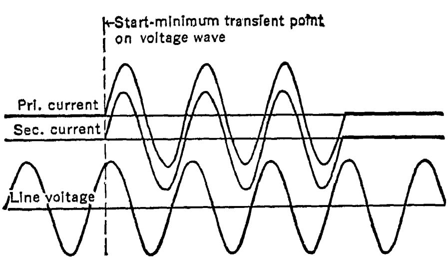

FIG. 10. Oscillogram Made When Current Flow is Started at the Normal Current Zero by Synchronous Firing

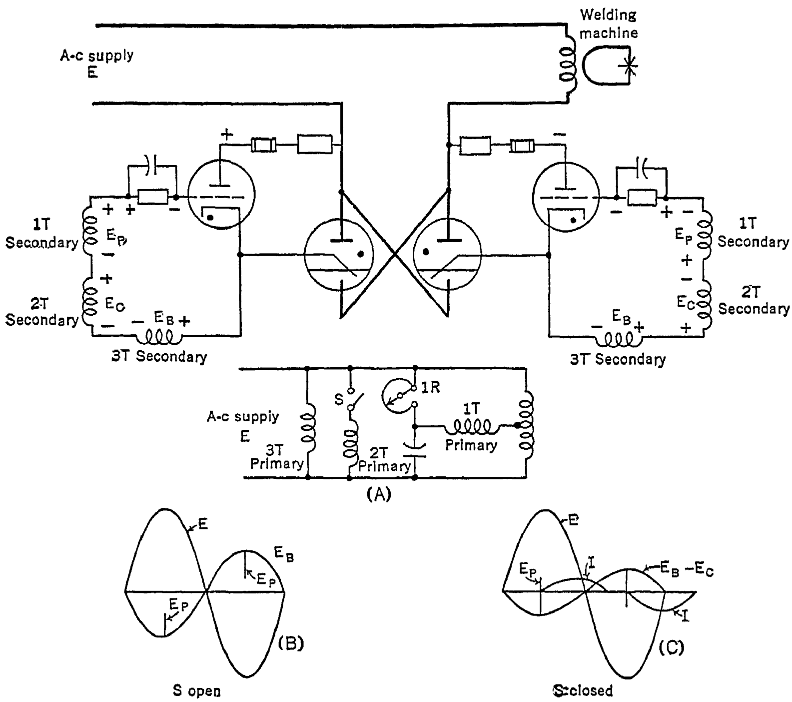

FIG. 11. Phase-shift Heat Control and Synchronous Firing is Provided by the Circuit

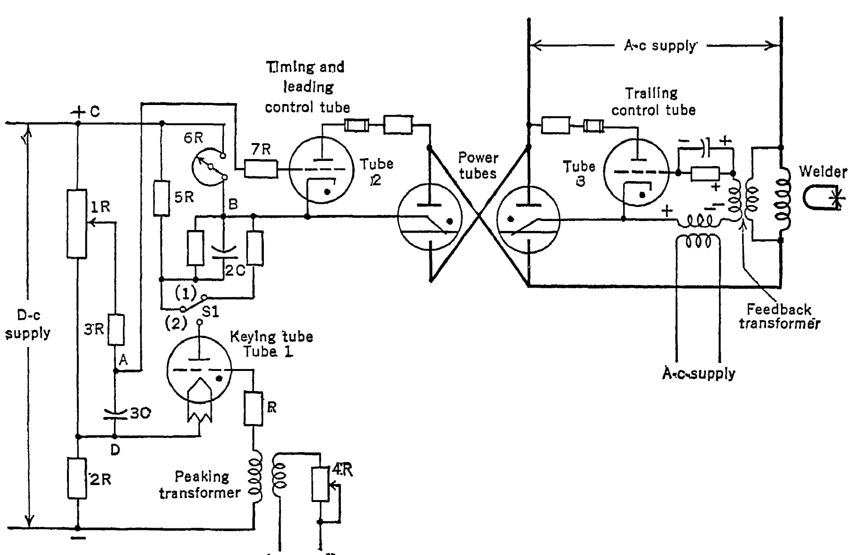

FIG. 12. Circuit of Welder Control Having Precise Timing and Synchronous Firing, but without Heat Control

conduct for a half cycle. For each half cycle which the left-hand ignitron tube fires, there will be duplicate firing on the right-hand ignitron tube. This circuit provides a means of controlling two tubes with different cathode potentials from a single timing source. Furthermore, it eliminates the possibility of obtaining an odd number of half cycles of power, which would cause saturation of the welding transformer. This circuit, however, cannot be used for heat control.

Figure 13 shows a fully electronic welder-control panel. The top section includes an electronic sequence timer for timing the various parts of the machine cycle. The center section includes a synchronous precision weld timer and phase-shift heat control. The bottom section is an ignitron contactor.

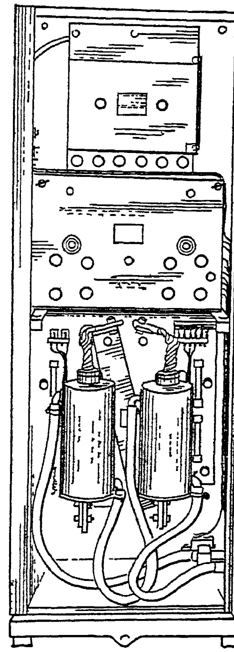

Fig. 13. Fully Electronic Welder Control Having Precise Timing and Synchronous Firing, but without Heat Control (Courtesy General Electric Co.)

13. D-C MOTOR CONTROL

Electronic adjustable-speed drives for d-c motors have been applied in many industries. Typical of these applications are: (1) drives for several types of machine tools, including lathes, grinders, and milling machines; (2) paper-machine drives; (3) rubber-calender drives; (4) conveyor drives; (5) textile-range drives; (6) steel-mill auxiliary drives; (7) testing-equipment drives.

In many applications the entire motor power is supplied through electronic rectifiers of the controlled type. The thyratrons are then usually controlled from vacuum-tube control circuits. Most applications involving electronic power supplies have been made in the low- and medium-horsepower field, between $1/4$ and 30 hp. Although some applications of electronic power supplies have been made as high as 300 hp, the more conventional power converter in the large size is a motor-generator set. In some motor-generator-set applications, thyratron rectifiers are used to control the field of the generator or the motor or both, as necessary. High-vacuum tubes are then generally used to control the thyratrons. In other applications electronic control is limited to the use of vacuum tubes for controlling the low-power fields of pilot exciters, such as the General Electric amplidyne, which in turn control the generator or motor-field power.

Figure 14 is a typical electronic control circuit which provides adjustment of the armature voltage of a d-c motor by thyratron phase-shift control to obtain speed control. Figure 15 shows pictorially the essential components of a complete adjustable-speed drive. This drive provides the following features: (1) adjustable motor speed over a wide range from an a-c power supply; (2) accurate speed regulation; (3) current-limit acceleration to a preset speed; (4) compensation for the internal motor *IR* drop, regardless of motor load; (5) normal motor torque at the instant of closing the motor-armature contactor.

The motor field is supplied by a non-controlled rectifier (not shown). D-c control power is obtained from a small control-power rectifier (not shown). The a-c winding of the saturable reactor *SR*, the d-c winding of which is shown, is connected in the thyratron phase-shifting bridge to adjust the rectifier output voltage in proportion to the amount of current in the d-c winding. Tubes 1 and 2 are voltage-regulating glow tubes. The speed-control potentiometer *1P* which is connected across the lower glow tube (tube 2) provides a reference voltage against which the motor-armature voltage is compared.

Conventional glow-tube voltages are 75, 105, and 150 volts. The d-c motor voltages are commonly 230 volts. Therefore a voltage divider is connected between lines 24 and 26 so that the voltages between lines 22 and 7 will be about equal to the reference voltage when the motor-armature voltage is 230. The voltage from lines 22 to 7 includes an *IR* compensation voltage which will be discussed later. For the moment, however, assume that the *IR* compensation potentiometer, *3P*, is turned counterclockwise so that 26 and 7 are at the same potential. Any difference in voltage which exists between the slider of the speed control and point 22 is applied to the grid of tube 4. A capacitor is connected from grid to cathode of this tube to filter the rectifier output voltage before it is applied to the grid.

If the armature voltage is proportionally lower than the speed-control slider voltage the grid of tube 4 will be negative with respect to the cathode and therefore tube 4 will conduct no plate current. This results in a lower voltage drop through resistor $2R$ and, consequently, a less negative voltage on the grid of tube 3, which increases the plate current of tube 3.

The increased plate current which flows through the d-c winding of *SR* increases the rectifier output voltage until the grid voltage of tube 4 differs from the cathode only by the voltage required to produce the desired rectifier output voltage. A small grid-voltage change will result in a range of output voltage from 0 to maximum. If the speed-control slider is moved, therefore, there exists momentarily a large differential voltage applied to the grid. This will turn the power tubes entirely on or off, as the case may be, until

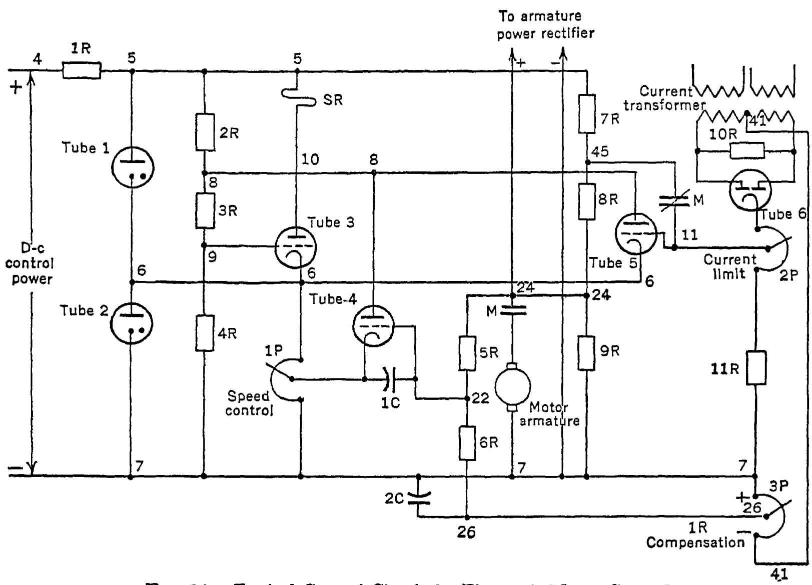

FIG. 14. Typical Control Circuit for Electronic Motor Control

the armature voltage has reached the new level. Once it has reached the new level only a small difference between reference and signal voltage is needed to control the rectifier.

If the field current of a d-c motor is held constant the no-load speed is proportional to the applied voltage. When mechanical load is applied to the motor shaft, however, the armature current is increased. This results in a voltage drop in the internal motor-armature winding which reduces the speed in proportion to the voltage drop. A small motor may have a drop of 23 volts at full load. This is 10 per cent of the rated armature voltage of a 230-volt motor. At rated applied voltage then there will be a speed regulation of 10 per cent between no load and full load. At 10 per cent of speed and no load, however, the applied voltage is only 23 volts. If this voltage is held constant the speed will be reduced to 5 per cent at 50 per cent of load and further reduced to 0 speed at 100 per cent load. This is obviously not a satisfactory method of operating, particularly at low speeds.

Compensation for the *IR* drop is obtained in the circuit Fig. 14 in the following manner.

One primary of a current transformer which has two electrically separate primary windings is connected in each of the two thyratron rectifier-tube anode circuits. The secondary of this current transformer is connected to the rectifier tube 6. A d-c voltage which is proportional to the armature load current therefore appears across potentiometer $2P$, resistance $11R$, and potentiometer $3P$. The polarity of the voltage across potentiometer $3P$ is shown. Assume now that the motor is running at no load at any desired speed and that the *IR*-compensation potentiometer $3P$ is turned clockwise. Since no armature current is flowing there is no voltage across potentiometer $3P$ and therefore the voltage from 22 to 7 is proportional only to the armature voltage. Now, if motor load is applied, line 26 will become more negative than line 7. As a result the grid of tube 4 will also become more negative. This change in grid voltage acts through the amplifier to apply more armature voltage. The armature voltage is thus raised to compensate for the resistance drop in the motor due to load. Potentiometer 3*P* can be adjusted to compensate for the resistance drop in different motors and therefore to hold the speed constant with load changes. Capacitor 2*C* is used to filter the rectifier output voltage.

The current transformer and rectifier circuit also provide a voltage signal to prevent overcurrent which would result in exceeding the rated peak current of the power tubes, the commutating limit of the motor, and perhaps the torque limit of the driven load.

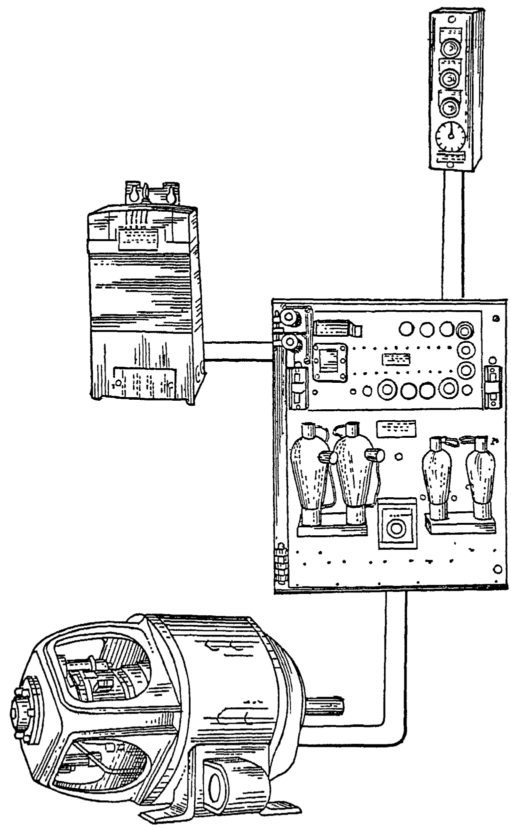

FIG. 15. Pictorial Elements of Electronically Controlled D-c Motor Drive (Courtesy General Electric Co.)

Assume that the speed control is set at a high-speed point and the motor-armature contactor *M* is closed. Tubes 4 and 3 will now control the thyratron rectifiers to give full voltage output. This voltage would result in approximately 10 times normal armature current at the first instant. The voltage between points 7 and 11 is proportional to the armature current. If the armature current is below a normal value (approximately 150 per cent of full-load current), the grid of tube 5 will be negative with respect to the cathode. If, however, it exceeds a normal value, the grid of tube 5 will become less negative and the plate current in tube 5 will control the output voltage of the rectifier (in the same manner as tube 4 does) to hold the accelerating current at a predetermined maximum value.

When the armature contactor *M* is open, the rectifier output voltage is still controlled by the speed-control potentiometer. If the speed-control slider were set for a high-speed position there would still be an initial high current impulse when the armature contactor first closed. To prevent this condition a voltage divider consisting of resistors 7*R*, 8*R*, and 9*R* is connected across the regulated d-c voltage. Also the rectifier output voltage is connected to the divider at point 24. When the armature circuit is open, the normally closed interlock on *M* connects points 45 to 11. Now, as the rectifier voltage is increased, tube 5 draws plate current which holds the rectifier output voltage at a level which will result in approximately normal armature current and therefore normal motor torque at the instant the armature contactor is closed.

Many other features can be obtained by circuit variations. Some common variations are: (1) control of the motor-field voltage by thyratron rectifiers; (2) control of motor- or generator-field current; (3) more accurate speed control by means of a small permanent-

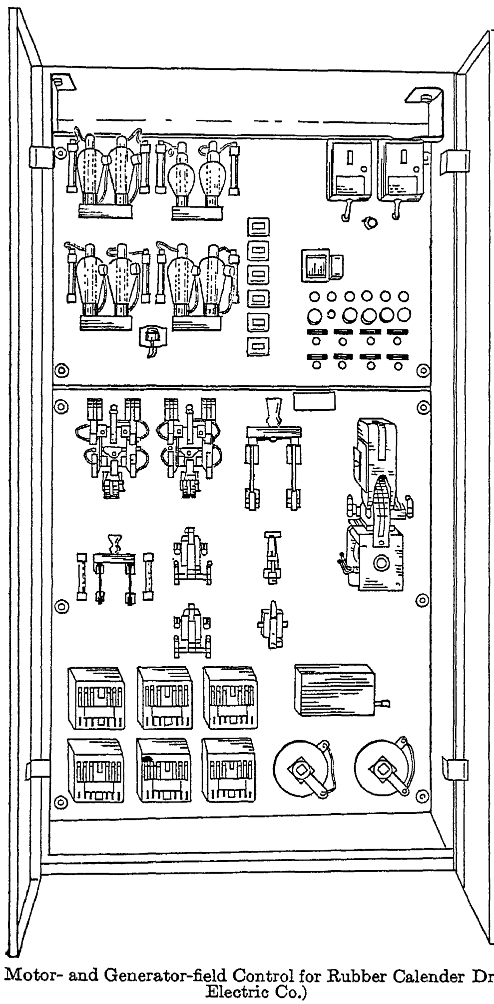

FIG. 16. Electronic Motor- and Generator-field Control for Rubber Calender Drive (Courtesy General Electric Co.)

magnet-type d-c generator mounted on the motor shaft and used as a speed signal; (4) reversing by current-limit regenerative means; (5) speed programming; (6) timed acceleration in lieu of current-limit acceleration; (7) motor-speed control in accordance with external signals.

Figure 16 shows a control panel for a rubber-mill calender drive which includes electronic control of the fields of a generator and a 125-hp motor.

14. SIDE-REGISTER POSITIONING CONTROL

Servomechanism is a term often applied to the general field of follow-up or positioning control. Side-register positioning control is one of the many examples of positioning control which could be selected from this broad, general field. Side-register control is applied to steel-mill "coilers," to papermill "reels," and to textile-mill "beams" to obtain a smooth surface at the edge of the finished-material roll. It is also used on slitters for insulating tape, linoleum, and the like to guide material going from a reel into the slitting knives so that only a certain amount of undesired edge will be trimmed, with a minimum of waste beyond the slitter.

One frequent use is an electronic side-register positioning control applied to a paper slitter. In this application it is desirable to hold the edge of the material at a given point with respect to the slitting knives. A photoelectric scanner, including a light source, a phototube, and a preamplifier, is focused on the edge of the paper. The photoelectric preamplifier supplies a signal to the electronic control panel, which in turn operates an alignment motor to move a large roll of paper, as well as the nip roll, back or forward in order to obtain a fixed position of the edge of the paper. Different types of side-register positioning-control equipment are available to suit varying requirements, such as variation in contrast between the material and its background, range of colors to be used, alignment-motor horsepower, accuracy of positioning, and maximum correction rate required.

The circuit diagram shown in Fig. 17 is that of a simple on-off type control. This control with its associated reversible a-c motor and mechanical brake will meet the requirements of applications where: (1) there is a reasonably large light contrast between the

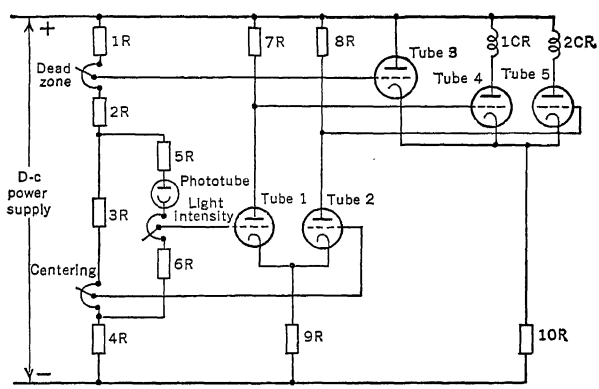

FIG. 17. On-off Type Photoelectric Side-register Positioning-control Circuit

material to be positioned and its background or where direct light transmission can be used; (2) the required accuracy is not greater than plus or minus $^1/_{16}$ in.; (3) the required rate of correction is not greater than 5 in. per min. The correction motor in this case is a reversible a-c motor which is operated in the forward or reverse direction by magnetic contactors, which are in turn operated by relays *1CR* and *2CR*. If there is no light shining on the phototube, the grid of tube 1 will be negative. If tube 1 is not drawing current, the cathode will go slightly negative, but, in doing so, since the cathode of tube 2 is connected to the cathode of tube 1, tube 2 will be turned on. The lack of current in tube 1 will cause tube 4 to conduct and energize relay *1CR*. Since tube 2 is conducting, tube 5 will be non-conducting and relay *2CR* will be de-energized. If a large amount of light is now applied on the phototube, the grid of tube 1 will be positive and tube 2 will consequently be turned off. This will result in the opposite operation of relays *1CR* and *2CR*.

The light-intensity adjustment can be turned clockwise to decrease the intensity that will cause the relays to operate. For a given light intensity, the centering adjustment will make the transition in the relays occur when approximately half of the light beam is intercepted or reflected, depending on the method of light transmission. It is obvious that, if there were no dead zone between the operation of the two control relays, the equipment would be continually hunting from one side to the other. The dead-zone adjustment provides an adjustable amount of distance over which the material can travel without actuating the control relays.

In applications where continuous operation of the correcting motor is desirable, the system just described is not suitable because of the maintenance of the mechanical parts. In these applications the photoelectric amplifier can control two half-wave thyratron rectifiers which are connected in inverse parallel to operate a shunt-wound d-c motor in the forward or reverse direction. For correcting motors of $^3/_4$ hp or larger, vacuum tubes are generally used to operate the field of a pilot generator which will in turn supply power to operate the correcting motor in the forward or reverse direction. Where wide ranges of light intensities and small light differentials are to be encountered, a more elaborate control equipment involving a rotary-lens-type scanning head is often used.

15. PROCESS CONTROLS

Electronic control has recently made its way into the field of process instrumentation and control, where it is now frequently used in measuring, recording, and controlling such process variables as temperature, pressure, flow, pH, moisture, and the like. An electronic control unit included as a part of a complete potentiometer controller is shown semischematically in Fig. 18. The battery supplies a standard reference voltage to the slide

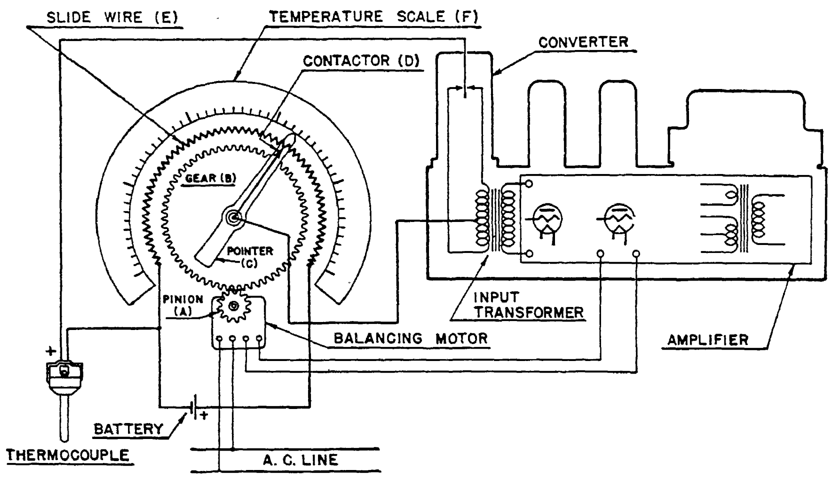

FIG. 18. Semischematic Diagram of Continuous-balance Potentiometer Controller (Courtesy Brown Instrument Co.)

wire. The voltage produced by the thermocouple is compared with the voltage at the slider. Since the voltage magnitudes are so small, however, it is not suitable to apply this voltage difference directly to a d-c amplifier. Instead, it is connected to a vibrating-type inverter which is synchronized with the power-supply frequency to produce a-c voltage impulses of a given phase relation in the amplifier tubes. If a difference exists between the thermocouple voltage and the voltage of the standard, this signal is amplified by an a-c voltage amplifier and further by means of vacuum-type power-amplifier tubes to control the power applied to a small reversible-type a-c balancing motor. The reversible balancing motor repositions the slider until the thermocouple voltage matches that of the battery. Thus, the pointer is positioned to show the temperature which exists at the thermocouple location.

If pressure is to be measured or controlled, the pressure-sensitive element can be a variable reactance. This can be used in an a-c bridge circuit, and the mechanical inverter is not necessary.

16. SYSTEM STABILIZATION

In any electromechanical system there is a time lag between the application of a correction signal and the final corrected value; for example: (1) if a given voltage is applied to the field of a generator, the inductance of the field prevents the field current and therefore the generator output voltage from building up instantaneously; (2) if a given voltage is applied to the armature of a d-c motor the mechanical inertia prevents the motor speed from instantaneously reaching its new value; (3) if a correction voltage is applied to the correcting motor of a servomechanism positioning control not only must the correcting motor accelerate its own inertia plus the inertia of the connected load but it must also run at rated speed until the new position is reached—then it must decelerate.

Assume that a sensitive and instantaneously operating electronic voltage regulator is applied to a d-c generator. If the generator output voltage is lower than that called for by the voltage-adjusting potentiometer, the regulator will immediately apply the maximum field voltage to attempt to correct the output voltage. The output voltage, however, will increase slowly because of the field inductance. However, when the output voltage reaches the desired value the electronic regulator immediately applies the correct field voltage to hold the desired output voltage. Such a system may be slow in response, but it is stable in its operation.

If on the other hand it is assumed that the electronic regulator has internally an inherent time lag, the operation of the entire system will be quite different. If the generator voltage is low, the regulator will again apply maximum field voltage. When the generator voltage reaches the desired point, the regulator will not immediately apply the correct field voltage because of the inherent time lag in the regulator. The correct field voltage will not be established until the output voltage has exceeded the desired value. Now, however, the regulator receives a signal which will result in a weaker field than normal. As a result, the system may be unstable and continue to oscillate above and below the desired voltage level.

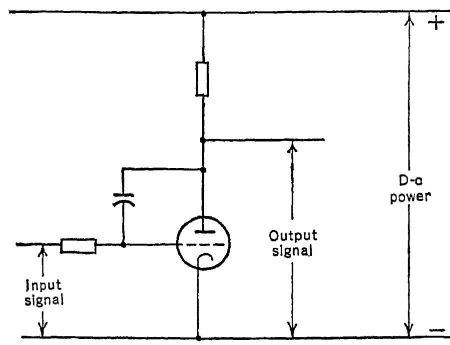

Fig. 19. Method of Adding a Predominant Time Lag to Reduce System Hunting

The frequency of oscillation or hunting is determined by the time constants of a system. If long time constants are involved, the hunting will be at a low frequency; if short time constants are involved, the hunting will be at a high frequency. In order for hunting to exist in any system, two conditions must exist: (1) the total time lags of the entire regulating system must result in the regulating-voltage signal being fed back to the regulator input 180° out of phase with the normal sense of the correction voltage; (2) at the frequency at which the total time lags add up to 180°, the overall system amplification must be equal to or greater than 1.

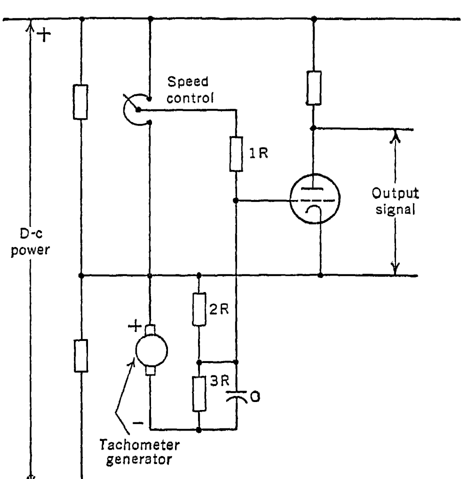

Fig. 20. Method of Adding a Derivative or Rate-of-change Signal to Reduce System Hunting

Obviously hunting is undesirable in most systems. Therefore means must be established to eliminate it. Several methods are in common use.

As was pointed out earlier, a system with a single time constant will not hunt. (Although this is true in general there are single-lag systems which will hunt.) Hunting in a system having two or more independent time lags can be reduced by artificially adding a time constant which is sufficiently greater than the others that it predominates. Such a system will approach a single-lag system in performance. Figure 19 shows how a lag can be added to a d-c amplifier circuit. The grid-to-plate capacitor charges or discharges through the series grid resistor at a rate dependent on the circuit constants. The action of the grid therefore lags behind the input signal.

Since the overall amplification of the system must be at least 1 at the hunting frequency, a simple way of reducing hunting is to reduce the system amplification. Conversely, the higher the system amplification is, the more likely the system is to hunt.

Often rate of change or derivative signals may be added to the input signal to reduce hunting. Figure 20 shows a typical circuit used in a speed regulator. The steady-state grid-voltage signal from the tachometer-generator which is connected to the motor shaft is determined by resistors $2R$ and $3R$. During a change in speed, however, the capacitor C supplies a grid voltage which is proportional to the rate of change of speed and thus provides a grid signal which is ahead in time relation to the speed signal.

Rigorous solutions to stability problems are often complex. Furthermore, assumptions of system constants or simplifying assumptions often are proved to be in error when equipment is installed. As a result most systems are stabilized by empirical methods.

AIDS TO NAVIGATION

RADIO AIDS TO AIR NAVIGATION

By Henry I. Metz

1. INTRODUCTION

Thirty-five thousand miles of federal airways exist today in the airspace over the United States. This mileage, shown in Fig. 1, is constantly and very rapidly increasing. Information about the condition of the airway, weather ahead, and other traffic is available constantly to the pilot by means of automatic radio aids to navigation and two-way radio voice communications.

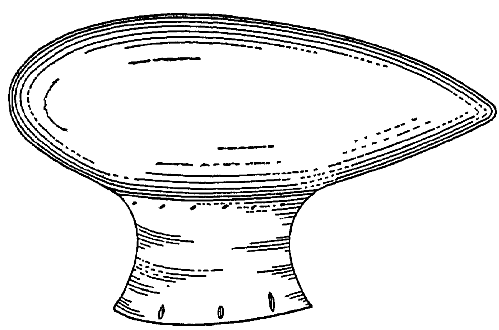

Fig. 2(*a*). View of Aircraft Automatic Direction Finder Equipment Showing the Loop Antenna (Courtesy Bendix Aviation Corporation)

The establishment, operation, and maintenance of the airways are among the functions of the Civil Aeronautics Administration (CAA) under the U. S. Department of Commerce.

When the federal airways program was started in 1926, the development of a reliable radio communication and guidance system was undertaken. Basically, tracks were established in the airspace by overlapping keyed radio patterns, the points of overlap being interpreted aurally by the pilot, who wears a pair of headphones. Although originally produced by a pair of crossed loop antennas, the tracks are today made by an Adcock array of vertical radiators which give greater night-time stability. The transmitting station is called a "radio range station." It produces four tracks called "courses," all of which emanate radially in predetermined fixed directions. There are 399 range stations now in operation. The coordinated alignment of a series of range courses constitutes an airway.

A system of markers has been added to the range courses. These are vertically directed signals at 75 Mc, received on a special receiver in the airplane and connected to a signal light on the instrument panel. The light operates only when the airplane is over the marker station.

An automatic direction finder (ADF), as shown in Fig. 2, is carried today by most commercial airplanes and is required (in some form) by CAA on scheduled airliners. Its pointer indicates the direction to the station tuned in. It may be used as an aid in flying the range course or to determine position by taking bearings on two or more stations.

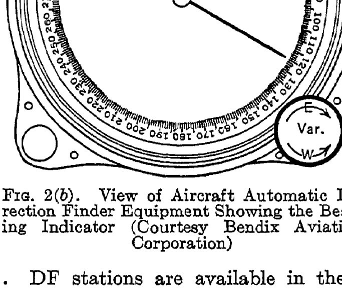

Fig. 2(*b*). View of Aircraft Automatic Direction Finder Equipment Showing the Bearing Indicator (Courtesy Bendix Aviation Corporation)

Countries other than United States, Canada, and Australia have based their traffic operations on ground station direction finding (DF). DF stations are available in these countries to give bearings to the aircraft calling, just as is now done in locating position on ships at sea.

Airborne direction finders have also been used extensively in other countries in cooperation with high-powered, non-directional, transmitting stations on the ground. A system called "radio-phare" has been employed in which three spaced ground stations transmit in time sequence on the same frequency. Without readjustment of the airborne ADF receiver, three bearings can be quickly obtained from the radio-phare. The German 33-Mc "Lorenz" instrument landing system (localizer, glide path, and markers), in particular the localizer, was in quite general use before the war. Its localizer, using interlocked aural dots and dashes (similar to the U. S. Aural AN Radio Range) to differentiate left from right in approaching the runway, was used for distances up to 100 miles in cases where the fixed course alignment agreed with the desired flight direction.

The CAA is engaged in a program of converting all the federal airways aids to static-free VHF, except that a few strategically located low-frequency range stations will be retained (with increased power) to serve for long cross-country flights. In addition to converting to VHF, all future ranges will be of the "visual" type (i.e., using pointer instruments instead of headphones), and will have omnidirectional courses (i.e., instead of only four range courses, the pilot may select any radial track, or course, from the station) to take care of increased numbers of airplanes and airports. Instrument landing systems, developed previously and now installed at 110 airports, will be used at once to relieve airport traffic congestion in bad weather. Radar will be used soon as a traffic surveillance device and, perhaps later, as a direct means of controlling traffic. Pulse techniques will probably be applied immediately in new meter-type distance-measuring equipment (DME) and later in anticollision devices. Long-distance flights across water will be guided by relatively low-frequency aids such as omnidirectional, Loran, Sonne, or other systems.

Automatic flight, controlled by radio signals transmitted from the ground, has already been demonstrated to be more accurate than human-pilot-controlled flight. It will undoubtedly be used by all commercial aircraft in conjunction with automatic computers, to permit controlled, track-type flying *in any direction* regardless of station position.

2. TERMINOLOGY AND DEFINITIONS

Certain terms associated with radio aids to air navigation in engineering discussions are listed below with their definitions:

Radio Range. Any CW radio station whose radiation inherently produces directional courses, or tracks, fixed in their relation to the earth's surface and independent of aircraft heading. A radar range is similar but uses pulse radiation.

Marker. Any station having limited or directed radiation used to give an aircraft its position along a range course.

Heading. Direction (azimuthal and clockwise from north) in which aircraft is pointing. It agrees with direction of flight if there is no crosswind.

Bearing. Azimuthal angle (from north, clockwise) of line between fixed ground station and airplane, or vice versa. It is generally necessary to state where the bearing is from and to, in order to avoid ambiguity.

Track. Actual direction of motion of aircraft with respect to earth's surface, expressed in degrees of azimuth (from north).

Beacon, Non-directional. A radio transmitting station whose radiation is essentially uniform in all directions or which does not use directional radiation characteristics to convey intelligence.

Beacon, Omnidirectional. A beacon whose directional or other radiation characteristics cause it to give information equally in all directions.

Course Sharpness. The relation between angular displacement from course and deflection of the pointer of the indicating instrument, usually expressed in angular degrees of displacement required to give full-scale-left to full-scale-right pointer movement. This sharpness is generally a function of ground-station pattern sharpness and receiver gain setting. Localizers are generally used with 4° to 5° sharpness.

Pattern Sharpness. The difference in pattern amplitudes at a given angular displacement from the equal or on-course line, usually expressed in decibels per 1.5°. Standard figure-of-eight patterns (LF aural ranges) give 0.45 db per 1.5°. The CAA localizer patterns give about 5 db sharpness.

Clearance. The db difference in patterns producing a course, at angles other than those containing the on-course. High clearance is desirable so that the indicator will remain fully deflected everywhere except at the course.

Multiples. Extra or abnormal courses resulting from zero or negative pattern clearance or from severe reflection of signal from buildings, trees, etc.

Bends. Angular deviation or distortion of the on-course signal from a true, straight radial line from the station. Generally, bends are produced by reflection of the signal from buildings or wires near the transmitting station. Bend magnitude is proportional to the ratio of reflected signal to direct signal amplitude and inversely proportional to pattern sharpness. Apparent bends can be caused by poor receiver AVC action, allowing inferior circuit components to unbalance as signal strength changes with distance.

Scalloping. The irregular or wavy shape of an antenna field pattern caused by reflection of the signal from ground objects. Scalloping is evidenced by the periodic hesitation in the course indicator movement as the airplane is flown across the course. Scalloping indicates bends when it occurs near the on-course line. When scalloping is severe, multiple courses are produced.

Wiggles. Rapid, random, and erratic movement of the course-indicating pointer, generally caused by combined signal from several reflecting objects, especially trees. Poor electrical connections and noise also cause wiggles. Wiggles generally do not alter the average course line and can therefore be filtered out of the indicator.

Pushing (or **pulling**). Displacement of indicated course with heading of airplane. Term is derived from observation in cross-course flights that the course was apparently "pushed" ahead of the airplane. Pushing is caused by the radiation of impure polarization (vertical in a horizontally polarized system, and vice versa). *Attitude effect,* in which the indicator shifts with airplane roll, or pitch, is similar in cause to pushing.

Distance Range. Distance in miles from the station at which useful signal is lost, or where course sharpness decreases (loss of AVC). For VHF and above, the line of sight range generally prevails.

3. RADIO AIDS IN THE FEDERAL AIRWAYS SYSTEM TODAY

The present system consists of the following facilities or services:

A. Radio ranges, LF (four-course aural with simultaneous voice).
B. Radio ranges (visual two-course, VHF).
C. Radio markers (75 Mc).
D. Automatic direction finder (ADF) receivers.
E. Communications (HF and VHF).
F. Air traffic control and weather reporting.

Each of these is explained separately below.

RADIO RANGES, LF (four-course aural with simultaneous voice). The radio range of today is a 400-watt, highly developed, four-course facility on which practically all civil air navigation is based. It is not a perfect device but is simple and effective for distance ranges up to several hundred miles. Its irregularities are so well known that many of them appear to the trained pilot as an asset. The change in conductivity of the earth along the course, in some places, usually in mountainous terrain, causes bends and multiple courses to appear. The location of these multiples is known and is plotted on charts. Night effect, which is variable, has been minimized by the replacement of loop-type transmitting stations with Adcock vertical tower systems. Two highly important objections to the range are (1) interference by atmospheric and precipitation static, and (2) interference from other stations in the allotted frequency spectrum.

The present four-course Adcock antenna system consists of five steel towers about 130 ft high. Four towers are placed on the corners of a square; diagonally opposite towers constitute a pair and are about 600 ft apart. The fifth tower is at the center. The pairs are connected, but with reversed phase, so that they, respectively, radiate figure-of-eight horizontal patterns. The two pairs are connected to a crystal-controlled transmitter through the equivalent of a single-pole, double-throw relay called a "link circuit relay." The relay is operated by a motor-driven keyer unit so that one pair of towers gives a series of dot-dash (*A* in code) characters. The back contact of the relay causes the reciprocal character, dash-dot (*N* in code) to be keyed into the other pair of towers. The schematic diagram is shown in Fig. 3.

The two figure-of-eight patterns thus contain reciprocal or interlocking characters. To an observer with a receiver in space the character heard would depend on position around the station. In a position where the patterns overlap, that is, where the *A* and *N* patterns are of equal amplitude, no character would be observable because they are interlocked and the signal is a steady tone. The patterns and courses are shown in Fig. 4.

Actually, the radiation from the two pairs of towers is unmodulated carrier energy and therefore inaudible. The center (fifth) tower is connected to a second crystal-controlled transmitter, but its carrier frequency is 1020 cycles below that used for the diagonal towers. Consequently, in combination, the receiver produces a 1020 cycle-output resulting from

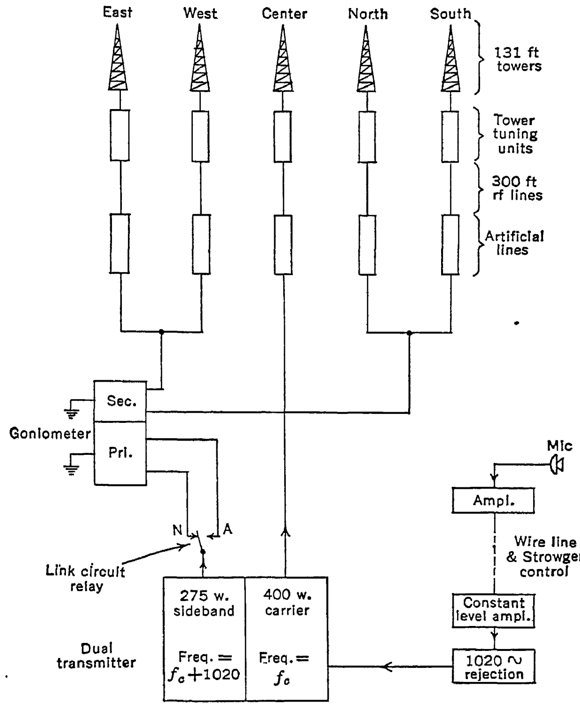

FIG. 3. Schematic Diagram of Four-course Aural LF Radio Range Showing Simultaneous Voice

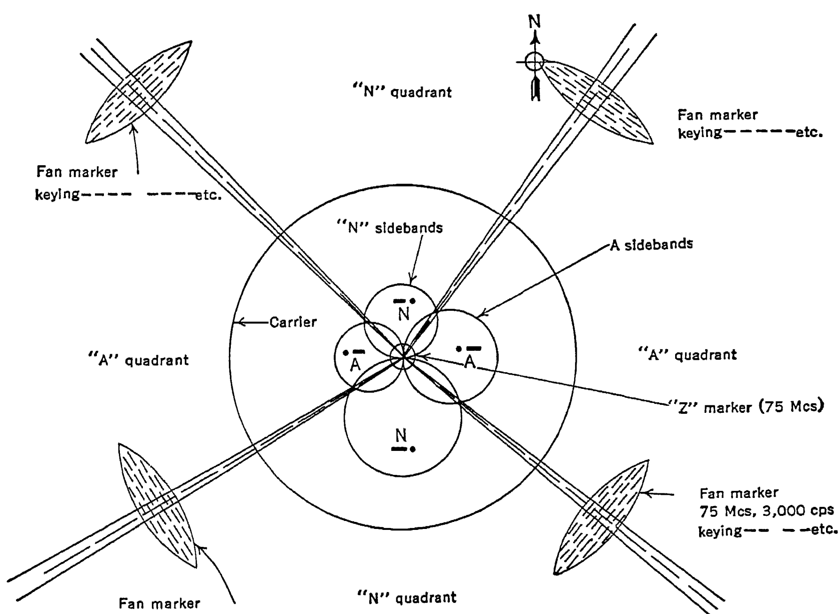

FIG. 4. Patterns and Courses of LF Aural Radio Range Showing Flexibility of Course Displacement and Position of 75-Mc Markers

the beat between the two carriers. In effect, the center tower radiates the carrier and the receiver is tuned to it. The signal from the side towers constitutes sideband energy. The power of the side tower transmitter is adjusted to give 30 per cent of that of the center tower carrier signal along the course. The remaining 70 per cent carrier is used for transmission of voice modulation. The airborne receiver generally contains a combination band-pass, band-rejection filter so that the pilot may select voice or range signals without interaction.

The course of the aural *AN* range is normally about 3° wide. The width depends upon headphone level and the pilot's hearing ability. The change from on-course to full off-course is gradual; that is, a "twilight" zone exists to either side of the course which permits the pilot to estimate (very approximately) his nearness to the course.

Normally, four courses are produced at right angles to each other. All four courses may be rotated equally, clockwise or reverse, by turning a goniometer through which the outside antennas are connected. Or, if other than right-angle courses are required, as shown in Fig. 4, the relative phase of the current in opposite towers is varied by means of artificial lines. The total line length between towers is maintained at an optimum value for maximum phase and current stability. Under optimum line conditions, the detuning of rain, ice, and snow on one antenna reacts to produce an equal effect on the other antenna, giving greatest stability of courses.

RADIO RANGES (visual two-course, VHF). The development of a two-course VHF radio range was started in 1928 to overcome the static, congestion, and dangerous quadrant ambiguity problems existing on the conventional four-course, low-frequency, aural range. Now several airways are operating (temporarily on the 110-Mc frequency band) with this type of facility, pending conversion of the entire federal airways to the VHF omnidirectional system.

The complete designation of the two-course range is: "VHF two-course visual radio range with quadrant identification." This designation signifies particularly that the quadrant ambiguity of the four-course type has been eliminated. Actually, the quadrant identification comes through the superposing of two aural courses on the same visual range, but with these aural courses at right angles to the visual. This facility, therefore, consists of two visual and two aural courses, as shown in Fig. 5. Normally, the visual course is

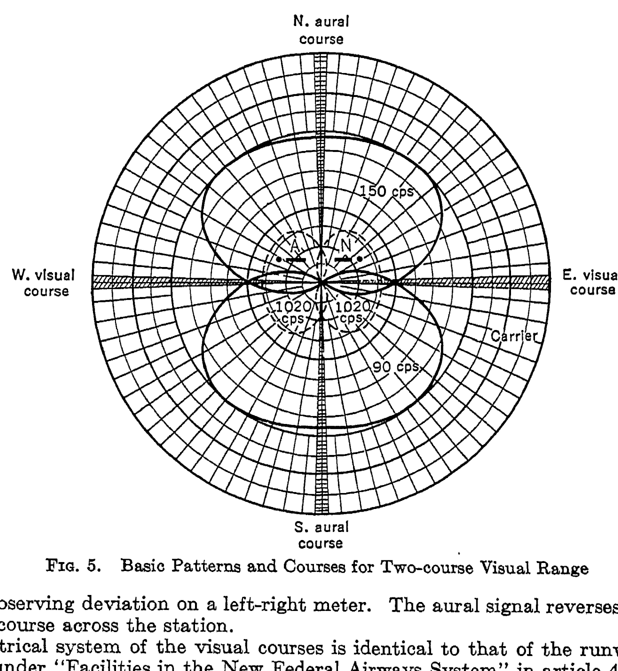

FIG. 5. Basic Patterns and Courses for Two-course Visual Range

flown by observing deviation on a left-right meter. The aural signal reverses when flying the visual course across the station.

The electrical system of the visual courses is identical to that of the runway localizer described under "Facilities in the New Federal Airways System" in article 4. The aural courses are laid down as described above in the discussion of aural radio ranges. Requiring less course sharpness than the localizer, its antenna array consists simply of three horizontal loops for the visual courses and two additional loops for the aural. The central loop serves for both the aural and visual courses (see Fig. 6).

A simultaneous voice feature is incorporated in this range facility by modulating the carrier fed to the center loop with voice. The total modulation capacity of the transmitter is divided approximately as follows: 90 cps 20 per cent, 150 cps 20 per cent, 1020 cps 10 per cent, voice 40 to 50 per cent.

The sharpness of the visual course is dependent upon the transmitted pattern shape and the signal voltages delivered to the receiver indicating circuit. In practice, the

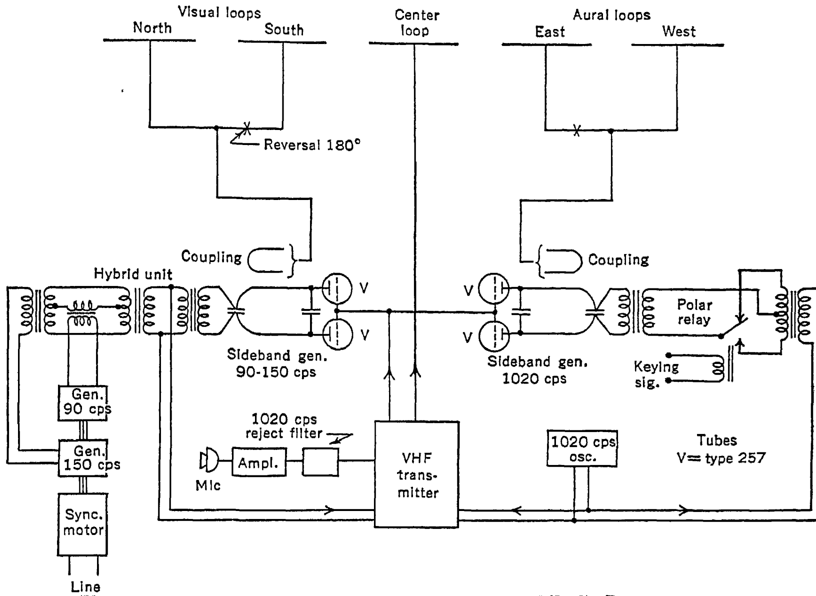

FIG. 6. Diagram of VHF Two-course Visual Radio Range

receiver gain is adjusted to give full scale left to right deflection of the indicator for a 20° azimuthal displacement of airplane (plus or minus 10° from the course). The aural course sharpness depends upon the patterns and also the pilot or observer. On this range it is about 2°.

The pilot selects the voice broadcasts or 1020-cps aural signals of this range through the standard range-voice filter described for the four-course range.

This facility is subject to reflection and propagation phenomena characteristic for 110 Mc VHF. Objects near the station, such as wires, buildings, and trees, reflect the signal and give multiple path transmission to the receiver, causing scalloping of the patterns and sometimes bends or multiple courses. In a moving airplane the random reflections of trees causes wiggles in the course indicator. Elevating the antenna system higher to avoid local reflections destroys the course by introducing low-angle nulls in the vertical pattern of the system. The conventional counterpoise (35-ft diameter) does not eliminate the difficulty. Horizontal polarization, originally adopted for its superior performance in the instrument landing system localizer, aids materially in reducing the reflection amplitude. Probably this is because of its zero radiation at the horizontal angle.

Single reflecting sources at a site generally give smooth (sinusoidal) deviations of the course indicator. From a knowledge of the wavelength of the bends and the position where observed, the direction of the reflection source can be determined approximately by calculation. Distant hills, unless extremely elevated above the station and observed by a low-flying airplane, do not cause course difficulties. Good siting is important. Station sites must be fairly flat and free of the above reflecting sources for a radius of about 500 ft. The site should also be high because propagation at these frequencies is line-of-sight (about 45 miles is realized in an airplane flying 1000 ft above the station elevation).

RADIO MARKERS (75 Mc). An essential part of navigation is position checking along the route. The radio range gives only direction, or lateral, guidance. The null, or "cone" of silence, over each range station (Fig. 7) has been used for years as a means of determining "over the range" position. Intersecting radio range legs exist at some places and are used as "fixes" during flight. Special non-directional, low-power, low-frequency markers have also been used. The difficulties experienced with all of these may be summarized as follows: (1) unexpected fade-out of signal may be falsely interpreted as the zone over the station; (2) intersecting range legs are not always received in bad weather; (3) low-frequency markers have been heard many miles from their desired area at night. The development of the positive cone or *Z* marker overcame these difficulties.

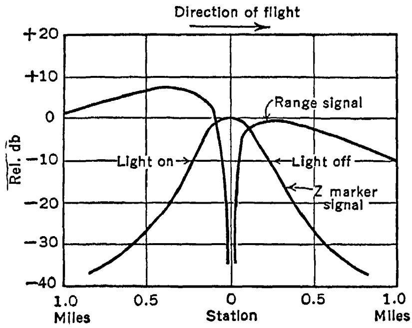

FIG. 7. Range Station Cone of Silence and 75-Mc Marker Signal Levels Experienced in Flight over Range Station at 1000-ft Elevation

The *Z* marker consists of a crystal-controlled, 3000-cps tone-modulated, 75-Mc, 5-watt, dual-transmitter and an antenna array. The transmitter is located within the range station and is a dual unit with automatic transfer in case of any failure. The antenna is located between the radio range towers and fed from the main station building by transmission line. The array may be considered as two pairs of horizontal, collinear, half-wave elements, at 90° to each other, and excited in phase quadrature. The array is one-quarter wavelength above a mesh counterpoise. The resulting service from this marker, when received by a longitudinal doublet under the airplane, is a circular pattern (Fig. 4) several times larger than the cone of silence and extending upward above the station about 10,000 ft.

The receiver generally used with these markers is a crystal-controlled, single-frequency, superheterodyne unit weighing approximately 25 lb and having a maximum available sensitivity of about 150 microvolts. Its audio output is filtered and connected so as to cause lighting of a signal lamp on the airplane instrument panel when marker signal is received. The audio output is connected to the pilot's headphone circuit. Three different kinds of indicator circuits are in use at present as shown in Fig. 8. The simplest is that employing a rectifier and relay, used by the AAF. One white light is connected to the relay contacts. The CAA and airlines use a receiver with no relays but with three output

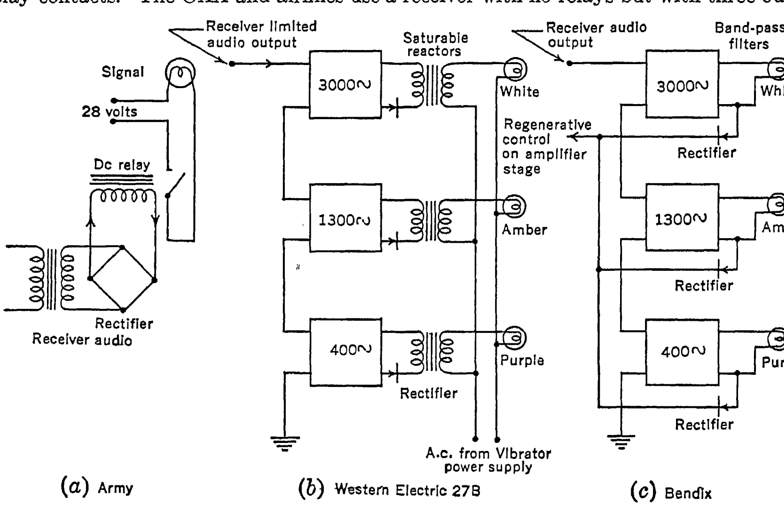

FIG. 8. Marker Receiver Signal Circuits

audio filters and three different-colored signal lamps. The white light, operating from 3000-cycle audio, serves for the airways markers (fan and *Z*). Amber and blue lamps, operating from 1300 and 400 cycles respectively, are used on the instrument landing system markers.

Good audio selectivity is achieved by designing the indicator-reactor circuit to operate at about 0 db and by limiting the receiver audio output electronically to about plus 6 db.

Any undesired signal, being able to produce only this limited output, will be inadequate to operate the lights if attenuated merely 6 db. Only simple filters are required.

The third system uses the audio signal directly to light the signal light. Good filters are employed. When any desired signal appears at the output, some of it is rectified and fed back to increase the gain of a controlled amplifier stage. This action gives regenerative response resembling relay action.

Horizontal half-wave doublet antennas are generally used for receiving marker signals. They are fastened longitudinally about 6 to 10 in. under the belly of the airplane. Sometimes the same antenna is also coupled to the low-frequency range receiver so as to serve a dual purpose. Some success has been achieved using a shortened antenna flush with the airplane skin and having a reflecting sheet inside.

Fan marker transmitting stations are keyed, tone-modulated, 100-watt, 75-Mc, dual transmitters connected by transmission line to a collinear dipole antenna array above a mesh counterpoise. Three thousand cycle tone modulation is used, and it is keyed in groups of dashes to identify the leg of the range on which it is located. The station is located on or near the center of the range course, usually about 20 miles from the range station (Fig. 4). Its antenna is aligned parallel to the range course and is received with greatest efficiency as the airplane passes over or to either side.

The name "fan" is derived from the shape of the marker field pattern. It is fan-shaped, as shown in Fig. 9, extending perpendicularly across the airway so as to be received even

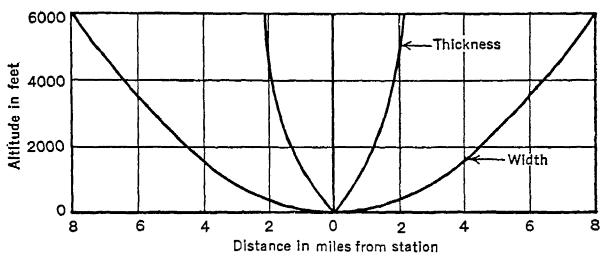

FIG. 9. Typical Dimensions of Airways Fan-type Marker

by aircraft considerably off-course. Its range increases with altitude but is generally receivable 6 miles off course at 1000 ft elevation.

Most of the 257 fan marker stations now operating have an antenna system using four collinear half-wave elements equally spaced 180° and carrying equal currents of the same relative phase. The array is one-quarter wavelength above a mesh counterpoise. Two minor lobes appear in the radiation pattern in the area directly above the station. A new array has been developed and is being installed in which the four elements carry currents in the ratio 1–3–3–1 and are physically spaced 220 electrical degrees. This arrangement eliminates the minor lobes and results in a dumbbell-shaped pattern in horizontal cross-section.

AUTOMATIC DIRECTION FINDER (ADF) RECEIVERS. The most popular and most useful radio receiver today is the ADF receiver (Fig. 2). It is an all-purpose receiver in the present airways system, providing for the reception of signals from radio ranges, CAA radio communication stations, airport control towers, and airline company offices. This receiver operates with a loop and a short-wire or vertical sense antenna. The loop gives accurate directional information as well as being very helpful in reducing the effects of precipitation and thunderstorm static.

The receiver operates as an ADF by virtue of the introduction of an audio modulation into the loop antenna RF circuit as shown in Fig. 10. The audio frequency is non-critical and is usually generated in the receiver at about 48 cps. The loop signal, with its locally superimposed modulation, is coupled through an RF transformer to the non-directional antenna circuit and to the IF amplifier circuit.

When the loop axis coincides with the direction of arrival of the radio waves, the loop contributes no RF signal to the receiver system and consequently none of the 48-cps signal gets through to the receiver IF amplifier or audio output. When the loop is turned so as to admit signal, the polarity (relative phase) of the 48-cps audio output with respect to the original 48-cps oscillator output is dependent upon the direction in which the loop is turned from its original null. A pair of thyratron tubes in a balanced modulator circuit compares these phases and through saturable reactors in the loop motor supply circuit drives the loop back toward the null. The motor and control circuit causes the loop to "seek" and hold the null position of any station tuned in on the receiver. A selsyn follow-up system is used to indicate remotely to the pilot the position of the loop. The loop position indicator is calibrated in degrees (0 to 360) and is called the bearing indicator.

In most installations there is some distortion of the received waves because of the structure of the airplane. This causes an error in indicated bearing called "quadrantal error." The error is of fixed amount in given directions, and the amount can be determined by experiment. Cam systems on the loop shaft are usually employed to compensate for the error automatically.

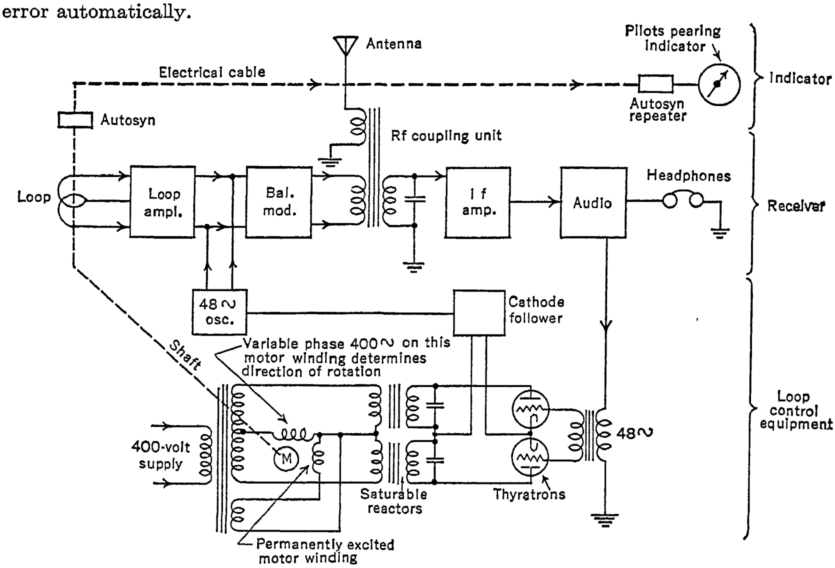

Fig. 10. Diagram of ADF Receiver Operation

COMMUNICATIONS (HF AND VHF). All communications in the United States airways system is by voice. The quality of voice signals received from aircraft, and sometimes that from ground stations, is far below any standard that would be acceptable in other services. As air traffic increases, there will be increasing need for quality, or for a different system, to preclude misidentification or misunderstanding of received calls. This condition is not easily cured. The major cause of poor quality is the enclosing structure needed around the microphone to exclude the 100-db noise in the present-day airplane cockpit. The ordinary microphone is overmodulated by this noise, and voice cannot be superimposed without severe distortion. The aircraft microphone is designed to be relatively insensitive by enclosing it in plastic. High-level voice, obtained by close talking, is admitted through small holes in the plastic.

Two other microphones are used. One, the "throat microphone," is designed to pick up vibrations from the throat by being worn on the neck. The other is the "lip mic" operating on the sound-velocity principle. Most of the noise pressures strike both sides of the armature of this mic and are canceled. By attaching it to the pilot's upper lip, high-level voice is applied to one side of the mic, causing modulation.

Service	Approximate Frequency Band
Long-range navigation	70–200 kc
Distress	500, 3105 kc, 121.5 Mc
Localizers	108–112 Mc
Radio ranges	112–118 Mc
Air traffic control	118–122 Mc
Airline communications	122–127 Mc
Air to ground	127–132 Mc
Glide path	329–335 Mc
Distance measuring	960–1215 Mc
Radar surveillance	3000 Mc band
Precision Radar	9090 Mc

Fig. 11. Chart of Proposed Frequencies for Air Navigation and Communication

Airborne transmitters generally operate in the 3 to 6 Mc band and have an output of 5 to 100 watts. The lower-power units are used by itinerant fliers in contacting traffic control towers. Plans are under way to convert all communications to VHF. Many ground station equipments at airport towers and airway stations are already installed. The VHF bands as outlined in Fig. 11 will permit numerous channels of static-free service. The aircraft antenna at VHF is more efficient than the short wires currently used, and consequently reliable service (not beyond line of sight) can be expected with the same or less transmitter power. All airline and itinerant transmitters are now crystal controlled. This practice will continue on VHF to insure reliable service.

AIR TRAFFIC CONTROL AND WEATHER REPORTING. The air traffic control system operated by CAA on the federal airways depends solely on voice communication between the controller and the pilot, assisted by fan markers and "holding" markers about which planes orbit until cleared for landing.

Advanced weather information is, of course, essential. Numerous weather stations now release radio-equipped balloons (radiosondes) to permit study of the upper air regardless of visibility conditions. These radio balloons emit coded signals revealing altitude, humidity, and temperature up to about 50,000 ft altitude. The radio equipment is expendable but is protected by parachute in its fall to earth; some are picked up and mailed back for reward. Direction finder and radar tracking of radiosondes has permitted determination of upper-air velocity and direction.

Two new electronic devices permit automatic measurement and recording of cloud-ceiling height and horizontal visibility, the "Ceilometer" and "Transmissometer" respectively.

The Ceilometer transmitter uses an extremely sharp vertical beam of high-intensity pulsing light. The source is a 900-watt mercury arc, striking 120 times per second. At a short horizontal distance from the transmitter, a photoelectric cell scans the entire beam from its base to top. If the beam is striking a cloud layer, the reflection will appear in the cell output. The vertical angle of cell at the time the output is observed is indicative of the height of the cloud layer. A recording device makes a record of the ceiling altitudes. A unique feature of Ceilometer is the use of pulsing light to eliminate the otherwise obliterating effect of daylight. Daylight, being steady, is filtered out of the system, permitting equally high ceiling measurement performance in daytime as at night.

The Transmissometer, which measures the light transmissivity of the air, is similar to the Ceilometer in utilizing a concentrated beam of light and a photoelectric cell. In the Transmissometer, however, the light is steady and directed horizontally to the cell through a kilometer of air near the airport approach lane. The effect of daylight is removed by shielding and baffling and by proper choice of beam intensity. The output of the cell is converted into pulses, the lowest pulses corresponding to low transmissivity. In the weather bureau these pulses are converted into relative values of direct current for observation or recording of visibility.

4. FACILITIES IN THE NEW FEDERAL AIRWAYS SYSTEM

The new federal airways system, now being placed in operation, will utilize VHF radio for ranges, instrument landing, and communications. The adoption of VHF relieves the troubles of static, both atmospheric and precipitation types.

The new radio ranges will be omnidirectional to satisfy the need for more airways, better traffic control, and most particularly to give useful navigation information regardless of position from the range station.

Distance-measuring equipment is planned as an ultimate replacement for fan and Z-type radio markers. Operating with the omnirange it will provide the basic requirement for safe air navigation—accurate knowledge of position at all times.

Congestion of traffic at air terminals will be reduced by the VHF instrument landing system now installed and by closer coordination in air traffic control.

In the new system all navigational information will be received visually, that is, by meter-type presentation. Some use of cathode-ray tubes may result from development work now under way, especially for anti-collision and air traffic control. Whether the presentation is by meter or cathode-ray tube, some effects from reflection of signal by buildings, trees, or mountains near the ground station will exist. These may cause bends, multiples, or wiggles in the course as indicated by the meter. In radar systems, wherein all the intelligence is obtained by visual study of the cathode-ray tube, the operator can generally separate the main from the reflected signal visually. Pulse technique does not in itself eliminate the effects of reflections, but when displayed against a time base on a cathode-ray tube it permits a study of all signals received. The reflected signals are visibly displaced and diminished by the extra time required to travel their longer paths.

INSTRUMENT LANDING SYSTEM (CAA). Instrument approach, or landing by instrument guidance, is just now being put into practice in the United States. It comprises a runway localizer, a glide path, and three marker beacons.

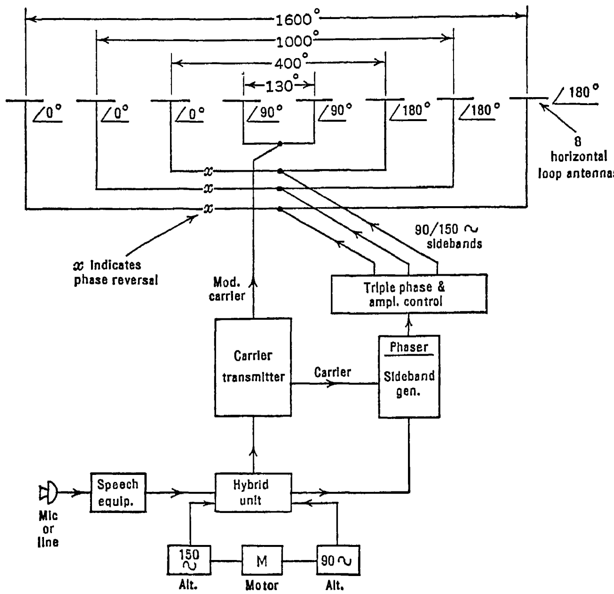

FIG. 12. Diagram of CAA Electronically Modulated Localizer

Localizer. The localizer creates a course, or track, along the center line of the runway, by overlapping two bean-shaped radio patterns having different modulation frequencies (90 and 150 cps). The signal service area extends slightly beyond the line of sight, but is conservatively given as 25 miles at 1000 ft (airplane elevation). The frequency is 110 Mc.

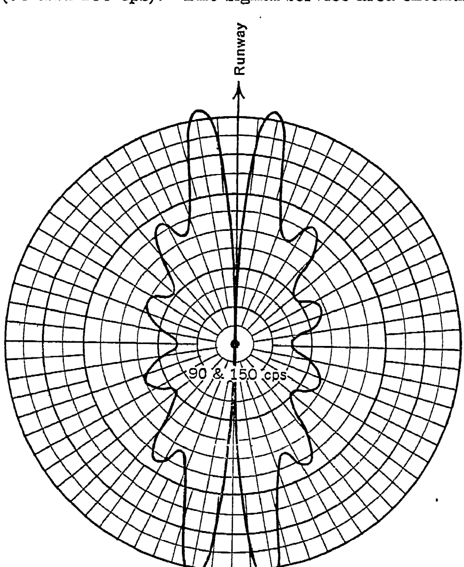

FIG. 13(a). Antenna Pattern of the CAA 8-loop Localizer. Side-band loops.

The localizer transmitting antenna array consists of eight horizontally polarized loops, spaced symmetrically across the center-line extension of the runway. It is generally 1500 ft from the end of the runway and elevated only about 12 ft. Each of the three outside loops on one side is paired electrically with a loop in similar position on the other side. Each pair is connected through a control to a common sideband generator, as shown in Fig. 12. There is a 180° phase reversal in the tie line between the pairs. The sideband energy is radiated with a sharp null down along the runway center line, as in Fig. 13*a*. The center two loops are connected in phase (Fig. 12) to radiate carrier, modulated with equal amounts of 90- and 150-cps voltage. The radiation pattern is shown in Fig. 13*b*. When the sidebands in patterns *a* and *b* of Fig. 13 combine in the receiver and appear at the filtered output, the overlapping patterns of Fig. 13*c* are obtained.

The airplane receiver, Fig. 14, is adjusted initially so that its filtered output of separate 90- and 150-cps voltage is well balanced. The output is connected to a balanced rectifier, and the rectifier is connected to a zero-center microammeter. The meter remains centered as long as equal amounts of 90- and 150-cps modulation are received, as when flying along the runway center line in the sideband antenna null. Deviation of the airplane right or left brings it out of the null. The sideband signal then received adds to that obtained from the carrier. On one side of the null (or course) the 90-cps signal adds to that of the carrier while the 150-cps signal subtracts. This causes deflection of the zero-center meter. The reverse is true on the opposite side of the course. The zero-center meter (Fig. 15) is used by the pilot to determine deviation from and direction to the course. The same instrument usually contains a second pointer, centered horizontally to indicate deviation from the glide path. The "U" receiving antenna is shown in Fig. 21*a*.

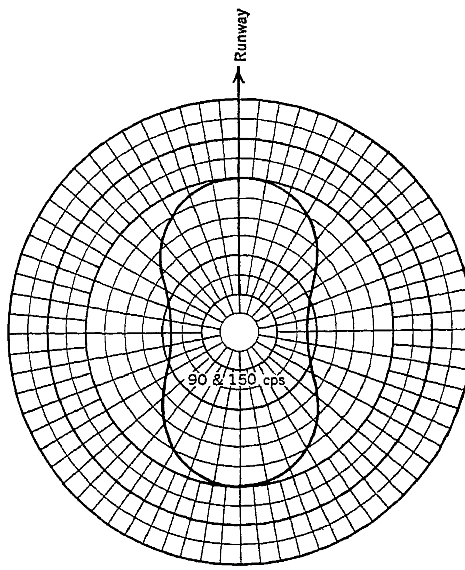

FIG. 13(*b*). Antenna Pattern of the CAA 8-loop Localizer. Carrier loops.

Although it is possible to obtain almost unlimited course sharpness in the localizer course by expanding the transmitting array and increasing the receiver output level, there is a maximum that can be used safely and conveniently by average pilots. The sharpness will probably be standardized at 5° (deflection to last dot left, or right, for 2.5° deviation from course).

Only part of the 200-watt carrier (40 per cent) radiated by the center pair of loops is modulated by the 90/150 cps signals. The balance is used to handle tone identification keying and control tower voice modulation. The latter is expected to be an aid in approach control of airport traffic.

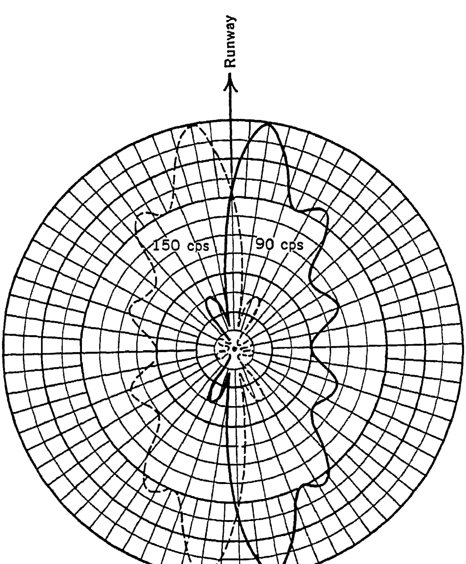

FIG. 13(*c*). Combined Side-band Pattern (*a*) and (*b*)

Glide Path. The glide path is established by a crystal-controlled transmitter capable of delivering about 25 watts at 330 Mc to an antenna system producing two types of lobes. One antenna produces a beam quite broad in the vertical plane (see Fig. 16*a*) which is modulated at 90 cycles. This will be called the upper beam. The other antenna is modulated at 150 cycles and is raised several wavelengths off the ground to produce a multilobed pattern with each lobe quite narrow in the vertical plane. Comparison of the broad upper lobe with the lowest of the narrow lobes establishes the glide path. This equisignal path is generally about 2.5°, although adjustment of the heights of the antennas can bring the crossover at any angle between 2° and 4°. An accurate plot of the lobes involved for the 2.5° path is shown in Fig. 17.

The separate modulation frequencies are generated by a mechanical modulator consisting of a synchronous (1800-rpm) motor and two metal paddle wheels having three and five paddles, respectively. The paddles detune associated resonant sections of transmission line coupled to the respective antennas and create 100 per cent modulation at 90 and 150 cps. The modulator is shown in the diagram, Fig. 16*b*.

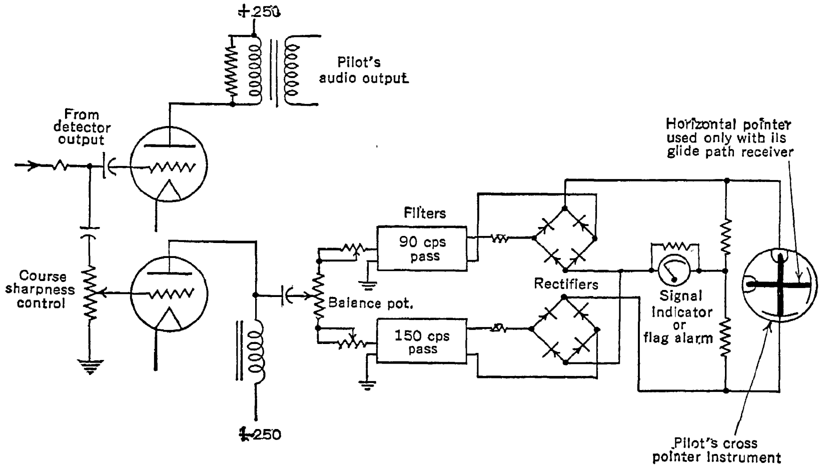

FIG. 14. Localizer Receiver Output Circuit

The equisignal surface represented by the two radiations of the station is obviously conical; paths from all directions terminate at the station. The station had to be placed off the side of the runway for safety reasons. This means that the approaching airplane, if in line with the runway, must follow a hyperbolic path whose minimum altitude exists directly opposite the station. To straighten out the bottom portion a special relation between the horizontal patterns of the upper and lower antennas had to be applied.

The receiver for the glide path uses a crystal-controlled superheterodyne circuit and a 28-volt d-c supply. It requires no high-voltage dynamotor or vibrator power supply.

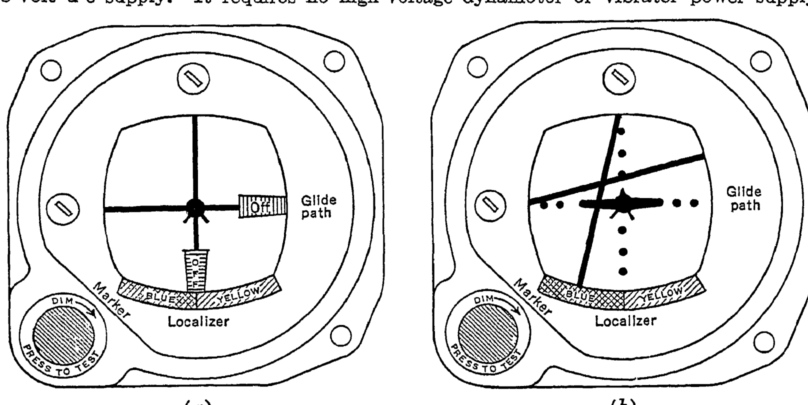

FIG. 15. Cross-pointer Instrument with Flag-alarms to Indicate Signal Failure. (*a*) Dead needle position showing alarm flags in position. (*b*) Operative position with alarm flags behind mask. (Courtesy AAF.)

The output audio (90 and 150 cps) is filtered and separately rectified as in the localizer receiver, Fig. 14. The resultant direct current is connected to a zero-center instrument (horizontal pointer of cross pointer instrument, Fig. 15). The pilot flies on the path, keeping the pointer centered, or horizontal. The dipole antenna, shown in Fig. 21*a*, is used in receiving the glide-path signals.

It is evident in that the glide-path equisignal lines converge and become very sensitive to vertical displacement of the airplane near the station and runway. This is offset by designing into the receiver about 9 db of negative AVC. This has the effect of reducing the receiver audio output voltage as the airplane approaches the station. An additional

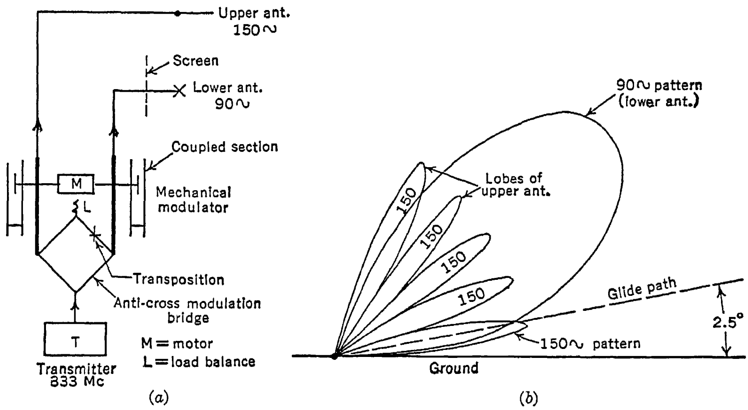

FIG. 16. 333-Mc Straight-line Equisignal Glide Path. (a) The lobes of elevated antennas produce an equisignal glide path. (b) Modulation is accomplished mechanically with coupled sections.

4-db reduction or "softening" of sharpness is derived by beaming unmodulated carrier across the path near its bottom end.

Markers. The markers used in instrument landing are, fundamentally, position-indicating devices similar to the Z markers discussed on p. 22-10. They will be replaced eventually with accurate distance-measuring devices which continuously indicate mileage to the runway. The present two markers are identified both aurally and visually by tone and keying. The outer marker (distance 4.5 miles) is modulated at 400 cps and keyed in long (2 per second) dashes. The middle marker (distance 3500 ft) is modulated

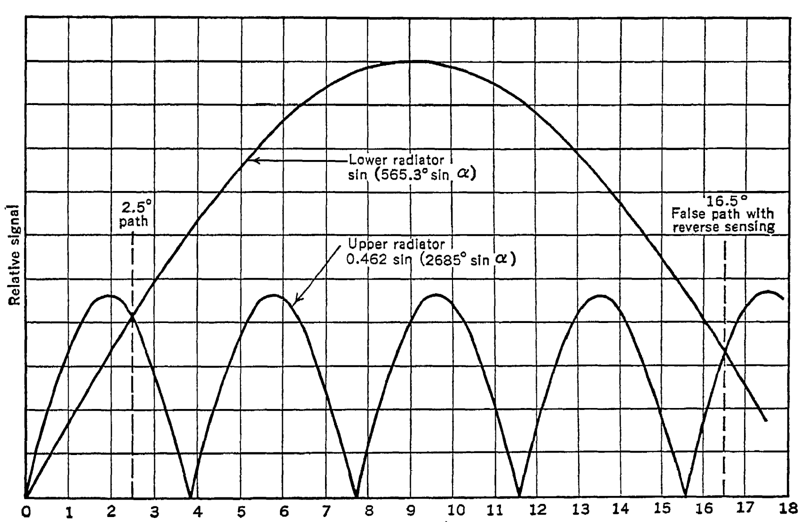

FIG. 17. Accurate Plot of Radiations Showing Formation of Glide Path

at 1300 cps and is keyed in a series of dot-dash characters. The boundary marker, recently discontinued, was modulated at 3000 cps and was keyed in fast dots (6 per second). The outer and middle markers are further identified by signal lamp color, purple and amber respectively.

THE OMNIDIRECTIONAL RANGE (VHF). This facility is produced by radiating simultaneously, from the same antenna array, two signals having the same audio-frequency modulation but having different relative phase for different azimuthal positions around the array. One signal is non-directional, and since its phase is everywhere (in azimuth) the same it is called the "reference phase" or voltage. The second is produced by rotating a "figure-of-eight" pattern. This pattern produces a modulation in the radio receiver, the frequency being dependent on the speed of rotation. Since its relative phase varies with azimuth it is called the "variable phase" or voltage. Since the two frequencies generated are equal, and a standard relation is set for north, comparison of the relative phase anywhere will permit determination of azimuth bearing from the station.

A five-loop transmitting array is used, and it is mounted on a tower 15 ft high with a circular counterpoise. Four loops are installed as diagonally opposite pairs. These are connected (Fig. 18) to the transmitter through a capacitance goniometer whose rotation

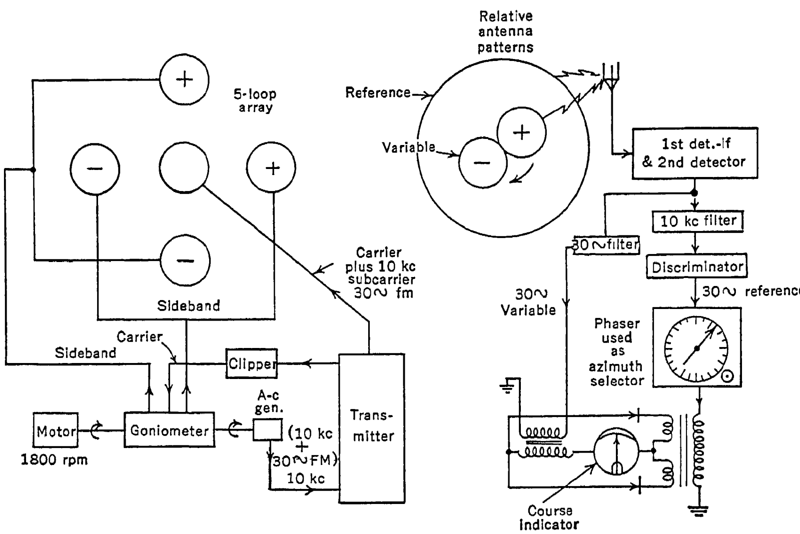

FIG. 18. The CAA VHF Omnidirectional Range System Diagram

at 1800 rpm causes the figure-of-eight space pattern of the loops to rotate in synchronism. It produces a 30-cps modulation of the carrier in the receiver.

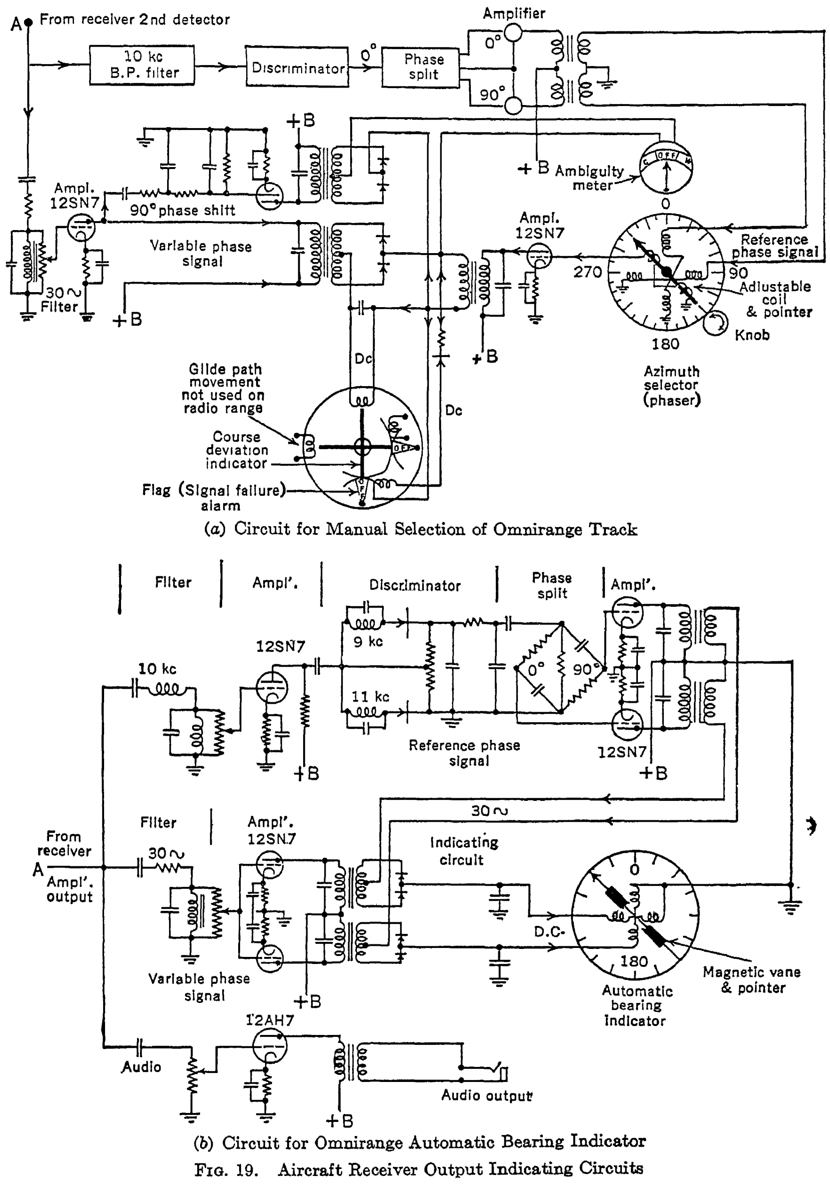
The center antenna is connected directly to the transmitter. The transmitter is modulated by a 30-cps voltage derived from a tone-wheel generator locked on the goniometer shaft. If the two 30-cps signals in the receiver output are in phase when the plane is north of the station, the phase difference in degrees elsewhere agrees directly with the degrees in azimuth of the receiver.

Two 30-cps signals cannot be directly isolated in the transmitter or receiver, so a subcarrier of 10 kc must be used for the reference signal. Further isolation is provided by frequency-modulating the subcarrier with the 30-cps voltage. Both the subcarrier and its required FM are derived from the tone-wheel pickup by using non-uniform spacing of teeth on the wheel. A "clipper" (see Fig. 18) is used to remove modulation on the RF to the goniometer.

The rotating pattern, which is sideband energy, effectively modulates the carrier about 30 per cent. The subcarrier modulation is equivalent to 10 per cent. The remainder of carrier is utilized for tone-keyed identification and voice communications.

The receiver used is a conventional superheterodyne up to the second detector. Here a filter is imposed to separate the 10-kc subcarrier and the variable 30-cps modulation. The 10-kc subcarrier is fed to a discriminator from which the reference 30-cps signal is obtained as illustrated in Fig. 18.

The two 30-cps receiver output signals are connected to a wattmeter circuit. The indicating element of the wattmeter is a zero-center instrument which is used as a course indicator. When the phase difference between the reference and variable signals delivered to the circuit is 90°, the indicating instrument will be centered. This may be standardized as the north, or east, bearings of the station. Varying of the receiving point from this bearing will cause movement of the zero-center meter. Full-scale reading is obtained in the system when the receiving point is displaced 10° from north. A variable phaser, Fig. 18, is provided to delay, or advance, the one signal before delivery to the wattmeter



(*a*) Circuit for Manual Selection of Omnirange Track

(*b*) Circuit for Omnirange Automatic Bearing Indicator

FIG. 19. Aircraft Receiver Output Indicating Circuits

circuit. If sufficient phase change is inserted to center the pointer of the indicating instrument, the amount of phase change inserted is proportional to the azimuth bearing. The phaser is calibrated 0° to 360°. This phaser setting is taken as the airplane-to-station bearing when the zero-center meter pointer is centered.

Obviously, there are two positions of the 360° phaser where the indicating instrument will be centered. This ambiguity is indicated either by a combination of red and green lights or by a smaller zero-center ambiguity meter. When signal lights are used, they are operated from a relay which is normally closed for correct signal and open for incorrect, or insufficient, signal. The relay closing is achieved by combining the two voltages in phase through an amplifier. Since the voltages are normally equal, reversal of one causes complete cancellation, the relay releases, and the red light comes on.

The alternative method uses a wattmeter circuit similar to that in the original course indication; however, its variable signal is shifted 90°. It, therefore, indicates a course 90° displaced to the true course. The ambiguity meter indicates full scale right until the airplane passes over the station. At this instant it swings to the opposite side, indicating that the station has been passed and that the bearing is reciprocal. When the ambiguity meter centers, it indicates failure of one or both signals or an inoperative receiver. One such meter is diagrammed in Fig. 19*a*.

Figure 19*b* illustrates an automatic "bearing indicator" for the omnirange. Its pointer follows up the bearing changes made by the airplane, always displaying correct bearing. It is a magnetic device with crossed coils connected to the respective rectified variable and reference phases from the receiver. Cathode-ray tube and other types of indicators have been developed. One system combines the omni- and the gyrosyn-magnetic compass to give the equivalent of VHF ADF.

DISTANCE-MEASURING EQUIPMENT. The distance-measuring equipment with meter indication depends for its operation on the challenging of a ground "radar transpondor beacon" by an airborne challenger. The challenger is a radio transmitter-receiver which transmits a pulse-type challenge to and receives a pulse-type reply from an automatic radio receiver-transmitter known as a transpondor beacon. The time elapsed between transmission of the challenge and receipt of the reply is a measure of the distance between the challenger and the beacon. This time difference may be converted to a d-c voltage whose magnitude is proportional to distance and can be read on a meter.

The challenge signal consists of a "pair" of RF pulses in the 960–990 Mc band so that a beacon setting must agree with two pulse characteristics before the beacon replies. These are the challenge frequency and the time separation (called mode) between the two pulses of a pair. This "frequency-mode" combination is called a challenge channel. The reply channel consists of a "pair" of RF pulses in the 1185–1215 Mc band. Challenge and reply channels in combination form an "operating channel." The beacon and the challenger receiver distinguish between pulses intended for them and pulses at the same frequency but different modes by use of a "decoder." One form of decoding is to delay the first pulse by an amount equal to the mode and operate only if the delayed pulse is then coincident with the second pulse.

An individual plane identifies the replies to its own challenges, as distinguished from replies of the same beacon to the challenges of other planes, by the fact that its own replies occur after a fixed (or slowly changing) time (i.e., distance) after its challenge, while the replies to other planes occur at a random time. The airborne receiver is "gated on" for a very short time interval at a fixed time (i.e., distance) after each challenge. It is as if the receiver asked the question, "Is there a reply from a beacon at a distance between 20 and 22 miles?" The gate duration is defined as 22 minus 20 or 2 miles. In one design the gate is divided into two subgates called (1) the "early gate" and (2) the "late gate." If the signal occurs in the early gate, the time delay of the gate is decreased for later challenges (it is gated on at 19 instead of 20 miles). Likewise, if the signal occurs in the late gate, the time delay is increased for later challenges (it is gated on at 21 instead of 20 miles). This system of subgates allows automatic following of the signal. The time between the challenge and the "gate" is translated into volts by a measuring sawtooth voltage which defines the volt-time (i.e., volt-distance) relationship.

While searching for a beacon, the gate is made to travel slowly over the total distance, advancing a fraction of its duration after each challenge. It is as if the gate asked the question, "Is there a reply between 20 and 22 miles?" then after the next challenge it asked, "Is there a reply between 20.5 and 22.5 miles?" etc. If the gate finds a high enough percentage of replies to challenges, the search is terminated and tracking begins; that is, the receiver thereafter holds the signal which has been found.

Each beacon is identified by "gap coding"; i.e., its transmission is interrupted by a keyer in such a manner that the gaps form a Morse character. Failure to receive a reply results in lighting a lamp in the cockpit which therefore flashes the beacon's code.

A beacon is disabled for a short time after replying. This time is called "beacon recovery time" or "beacon dead time." While this "recovery time" may serve many useful purposes such as preventing over-interrogation, it also results in failure to reply to those challenges which occur while the beacon is recovering from a previous interrogation. This failure is called "count-down" and is expressed as the ratio of missed replies to the total number of challenges.

The number of aircraft signals that can be handled simultaneously by a given beacon is very important. The system described above, through choice of pulse dimensions and random rate, can handle approximately fifty airplanes per channel simultaneously (sixty channels are repeated in every 500 mile square). A block diagram of the airborne unit is shown in Fig. 20.

Distance can also be measured by the same principle as that employed in the radio altimeter, but with the aid of ground respondor stations. Continuous-wave frequency-modulated transmission is employed. The modulation is varied over a cycle which is, in duration, equal to at least the time required for travel of the signal to and from the most distant beacon to be measured. The frequency of the received signal at any instant is different from that then being emitted. The difference is a function of the time and therefore the distance. The meter-style indicator can be calibrated in miles. The disadvantage of this CW system is that it can handle only one aircraft at a time.

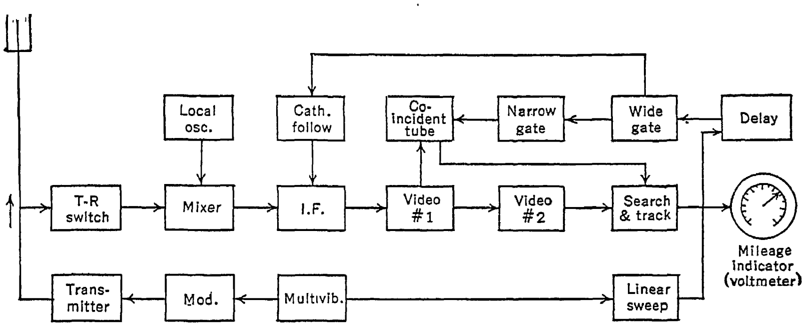


FIG. 20. Functional Diagram of Distance-measuring Equipment (Airborne Unit)

Audio phase comparison methods have been proposed and tried experimentally. In this method an audio modulation frequency is chosen whose wave period (360°) is the same as the time required for transmission to and from the maximum distance to be measured. The radio signal travels 186 miles in 1 ms. Therefore, a 1000-cps frequency will shift 360° in 186 miles. If the airplane and ground station are 93 miles apart, the round trip between them is 186 miles and the 360° shift will prevail as the maximum range for the 1000-cps wave.

By sharing time through random keying of the airborne transmitters, several aircraft may obtain separate distance information simultaneously in the audio phase comparison system from the same ground station.

AIRCRAFT EQUIPMENT (RECEIVING). Almost universally, aircraft receivers have been of the superheterodyne type. Tunable receivers have been used generally, with spot frequency for control towers (278 kc) crystal-controlled or fix-tuned. In the VHF system the superheterodyne principle is again being universally used. Crystal control is being used for most commercial applications and manual tuning for inexpensive units for itinerant fliers. In the crystal-controlled receivers each of the several crystals employed will produce a multiplicity of receiving channels. Over two hundred channels are needed by aircraft on routine instrument flights, in the bands illustrated in the national plan, Fig. 11.

Many companies have, or are installing, dual ADF receiving equipments in each airplane so that automatic indication, or plotting, of aircraft position can be used. Single instruments with dual pointers, one for each ADF receiver, and each receiver tuned to a separate station, are very helpful in navigation.

VHF receivers for navigation are equipped to serve all VHF functions required in flight. Two such receivers in an airplane give adequate stand-by protection. In normal use one is available for communication while the other is being used for navigation or landing.

Two types of output indicating circuits are now used in each of these navigation receivers. The amplitude comparison type (90–150 cps) will be retained only until existing localizers of the instrument landing systems are converted from amplitude to phase comparison principle. Then the phase comparison type indicating circuit will be used for both omni navigation and landing.

An outstanding advancement in receivers was made during the war in the elimination of all receiver high-voltage power supply. Through the development and application of the 28-volt-type tube (28D7) a complete 330-Mc, superheterodyne, glide path receiver, using no vibrator or dynamotor-type supply, was produced in quantity. Twenty-eight volts direct current, available in the airplane, is used as plate supply. An ADF receiver was developed later, also avoiding the HV supply. The reduction in noise and maintenance and the saving in weight by this development are extremely important factors.

Receiving antennas have been an important part of the VHF program. Whip or mast-type vertical antennas are the best for ease of installation. For lateral guidance functions, however, horizontal polarization has been declared superior. Suitable antennas are illustrated in Fig. 21. The patterns of the U and V antennas are essentially circular, as required for their navigational function in range and localizer receptions. The 330-Mc dipole on the U antenna, in Fig. 21, is used for glide path reception. It is required to have only forward glide path reception during the runway approach procedure.

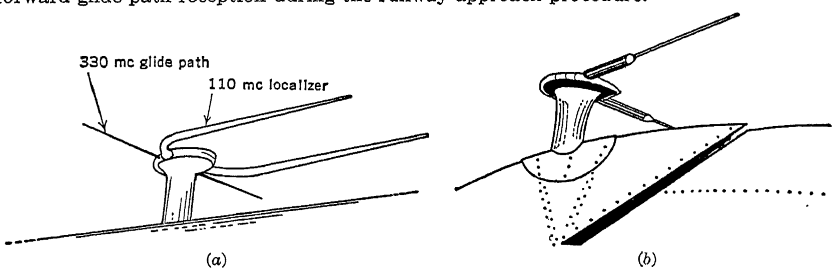

Fig. 21. Receiving Antenna for the Instrument Landing System. (*a*) The U is for 110-Mc band localizers, and the dipole is for the 330-Mc glide path. (*b*) An experimental V antenna for non-directional reception of localizer or range signals.

For navigational service, pure polarization is essential in the radiated wave. If polarization is impure, that is, unintentionally mixed, serious attitude effects are evident in the indicator when the airplane is banked or turned.

Balanced transmitting and receiving antennas are now used.

AUTOMATIC FLIGHT AND LANDING EQUIPMENT. For automatic navigation, the new electric auto-pilot has become the greatest asset. With it, straight and level flight is made by gyroelectric control, or completely coordinated (aerodynamically) turns of the airplane may be made by turning a knob which simply unbalances electrical bridges in the auto-pilot system. If the bridge circuit is electrically connected to the output of the new navigation receiver (localizer or radio range) through an appropriate amplifier or coupling system, the auto-pilot can be made to fly the airplane accurately along the localizer or radio range course. Or the output of the receiver (direct current which is proportional to displacement from the course and whose polarity reverses when crossing the course) may be made to operate a steering motor right or left, to follow the course. The steering motor turns the auto-pilot steering potentiometer.

The operation of one type of electrical auto-pilot, and one way in which the radio signal may be coupled to the auto-pilot, are shown diagrammatically in Fig. 22.

Coupling the radio guiding signal to the auto-pilot and obtaining satisfactory performance involves consideration of the mass and speed of the airplane, sharpness of the radio course, and characteristics of the auto-pilot itself. The desired performance is that giving asymptotic approach to the course. In the off-course position, a "displacement" signal must be applied to turn the airplane right or left as required. The displacement signal is obtained directly from the radio receiver and is proportional to the angular distance from the course. Acting alone, this displacement signal would reduce the turn of the airplane to zero as it crosses the course. But the airplane heading at the time of crossing may be at any angle to the desired course. The airplane travels to the opposite side of the course before a reverse signal is applied. The result of displacement signal alone would be a continuous oscillation of the airplane across the course as it flies toward the guiding radio station.

In the coupling device, a "rate" signal must be applied—a signal whose amplitude is proportional to the rate of change of displacement, and whose control on the airplane through the auto-pilot is reverse from that of the displacement signal. With proper design for any particular airplane, the rate circuit reverses the turn of the airplane as it nears the course and causes it to follow the desired asymptotic curve. Because of the converging sharpness feature of radio courses, a compromise must be made in the coupling system characteristics. In general, however, good performance has been achieved. On the final approach to the airport on the localizer, the vertical pointer of the course indicator seldom deviates from center by more than its own width, regardless of any cross-wind velocity or direction.

Flight toward or away from the station is obtained by reversal of connections (polarity) between the radio receiver and coupling unit. The switch positions are marked "inbound" and "outbound" respectively.

Very flexible radio range navigation is now possible through the use of computers. For the federal airways system these computers would operate in conjunction with the VHF omnidirectional range and distance-measuring equipment. With the computer, it is

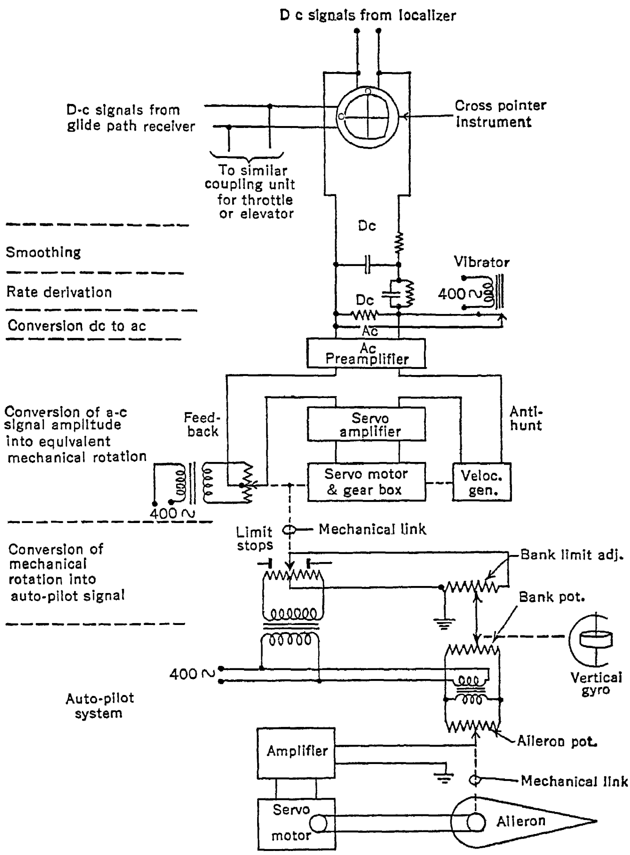

FIG. 22. Auto-pilot and Radio Coupling Systems

possible to fly a synthetic left-right indicated course in any direction, whereas the regular courses are defined only toward or away (radially) from the station.

Referring to Fig. 23, S represents the omnirange station, and the course to be flown lies along the non-radial line AB. The distance-measuring equipment (described above) produces a voltage e_1 which is proportional to r, the distance to the airplane. This is applied to a selsyn primary (rotor) which is connected to the omnirange azimuth indicator. The sinusoidal output of the selsyn secondary winding is

$$e_2 = e_1 \sin \theta$$

because it is designed to vary sinusoidally with rotor angular displacement. Since e_1 is proportional to r, the equation may be written:

$$e_2 = kr \sin \theta = ky$$

The voltage e_2 therefore is proportional to the variation in y, that is to the displacement of the airplane from the line AB. This displacement voltage may be balanced by a fixed voltage and presented on the usual left-right course indicator for manual flight, or it may be coupled to the auto-pilot for automatic flight along the selected line AB.

In setting the computer so that the constant k will be properly handled, the course line to be flown is decided upon and drawn on the range map. The direction and length of the perpendicular from the range station to this line are determined. The direction of the perpendicular is set into a calibrated clutch between the azimuth indicator and the selsyn unit. The length of the perpendicular line is set up on the "lane selector" switch, thereby providing the required fixed balancing voltage. Then the pilot's left-right indicator will be centered only when the airplane is on the desired flight line.

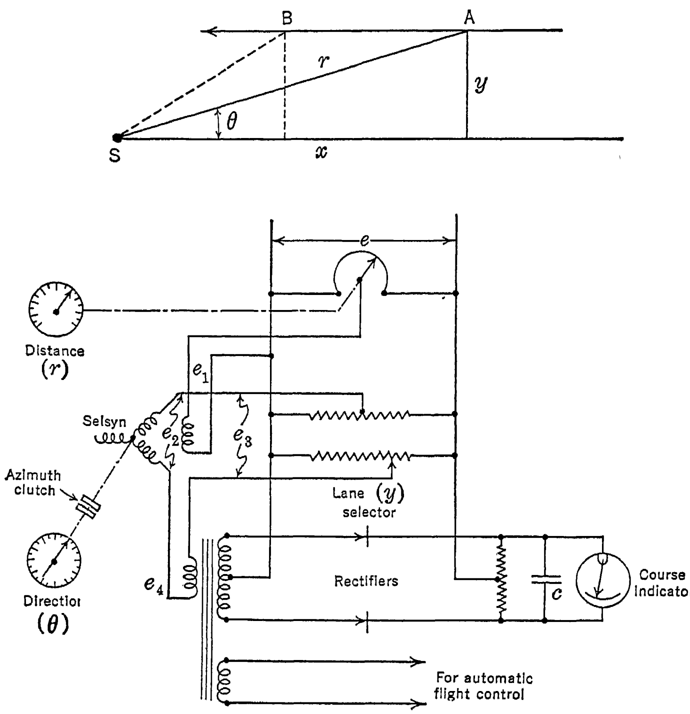

FIG. 23. Computer for Synthetic ($r\theta$) Courses

RADAR MONITOR FOR AIRPORT TRAFFIC CONTROL. Civilian aviation will require the use of radar as a monitor in airport control towers. Development of suitable equipments is under way. Its first use will probably be in expediting the outbound traffic at the congested terminals. The airport tower operator, having accurate knowledge of the displacement of all inbound airplanes, through reference to the radar monitor, may permit the departure of airplanes that otherwise would be required to await position reports from the inbound airplanes.

Three fundamental problems are evident in the application of radar to airport control towers. These problems are typical of all civil radar application. They were overcome in military use by a multiplicity of radar equipments and large operating crews. The problems are: (1) reliable coverage up to about 30 miles, from horizon to zenith; (2) the elimination of undesirable ground clutter; (3) the presentation of resulting radar information in a manner such that the regular tower crew can use it safely, at any instant day or night, without special enclosures.

Relatively high-angle coverage has been obtained by means of antennas giving cosecant-squared patterns, shown in Fig. 24. When the energy is distributed in the required pattern, the maximum distance range is naturally reduced. A peak power output of about 0.5 megawatt is required to give the 30-mile horizontal coverage with a cosecant-squared pattern.

Some work has been done on the elimination of ground clutter as illustrated in Fig. 25. Only moving targets are permitted to appear. Development is being continued to simplify the equipment and reduce the maintenance required to keep it in perfect adjustment.

The presentation feature has not yet been satisfactorily solved. New, high-intensity cathode-ray tubes are being made available as an aid to the daylight presentation problem. Another means of getting the radar scope picture visible in daylight is complementary light filters. For example, if the control tower window glass is colored blue and an amber filter is used over the face of the radar scope, the picture will appear the same as at night. The reflections of the observer's face can be eliminated by installing the amber filter at a 45° angle.

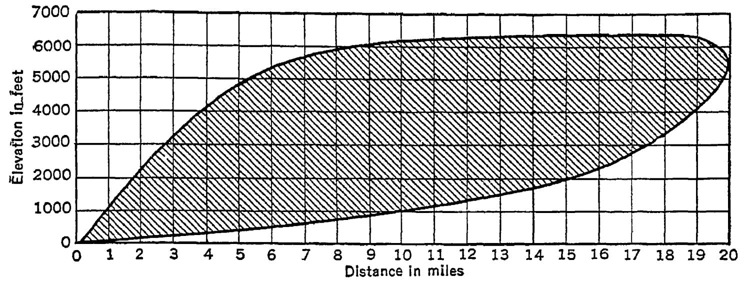

FIG. 24. Cosecant-squared Pattern of GCA Search Antenna

5. PROPOSED NEW LANDING SYSTEMS

GROUND CONTROLLED APPROACH (GCA). At the beginning of the war, a talk-down system was conceived for landing airplanes in bad weather. It became known as GCA because it served in reverse to other systems—it controlled from the ground. Several sets of GCA were put in service before the end of the war. Many sensational landings of military airplanes were made with GCA, saving lives and valuable property. Its use required no new airborne equipment but depended only upon communications and a cooperative pilot.

The GCA equipment is a composite, trailer-type station with three radar systems and complete communications equipment. It is placed about 500 ft to the side of the runway and at the end opposite from that on which the landing is to be made. Air-conditioning and power-generating equipment are carried on the towing truck.

Originally the GCA trailer required a crew of five operators. Four of them constantly watched four radar scopes, and the fifth served as final approach controller to give heading and rate-of-descent instructions to the pilot on the final approach. Now, however, the operation of landing a single airplane may be handled by one operator who shifts his attention from search to precision scopes as the airplane orients and approaches the runway, Fig. 26. If more than one airplane is involved, more operators are required.

The function of GCA, whether operated by one or more men, is as follows: (*a*) *search* for aircraft in all directions, using PPI scope presentation; (*b*) *direct* aircraft into the landing sector about 6 miles from the runway at 1500 ft elevation, on the basis of search radar information; (*c*) *land* the airplane by giving the pilot explicit instructions constantly during the approach as to heading and rate of descent, on the basis of precision azimuth and elevation radar information.

The search function in GCA is obtained at 10 cm by an antenna rotating at 30 rpm. The antenna is a special reflector with two-dipole array fed by rectangular wave guide. Its radiation pattern is illustrated in Fig. 24.

The precision radar system consists of one transmitter (3 cm) sharing time with two special antennas. One antenna is vertical and the other horizontal. Each antenna consists of a multiplicity of collinear dipoles mounted along a wave-guide section and fed from

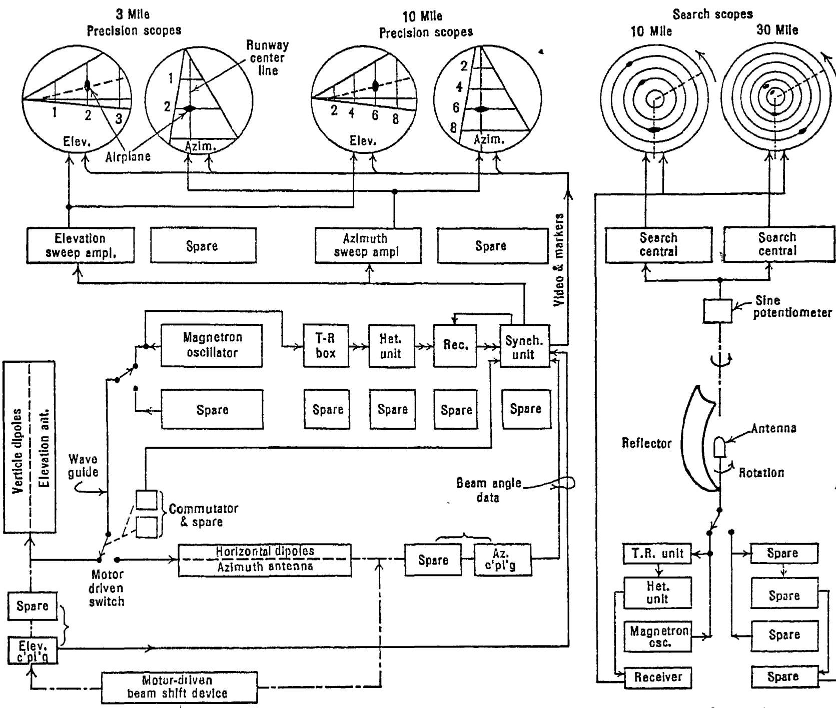

FIG. 26. GCA Search and Precision Radar Equipment Arranged for One-man Operation

small probes projecting into the wave guide. The spacing of the dipoles and phase of their currents create the sharp patterns required for precise direction determination. These patterns are aimed along the approach path and then made to oscillate rhythmically across the path by shifting the dipole current phases (mechanically distorting the rear of the wave guide through a motor-driven mechanism).

The received precision radar echoes are displayed on offset-center PPI scopes as illustrated in Fig. 26. This presentation and the narrow radiated beams permit the operator to obtain great precision in the observation of aircraft displacement. The vertical antenna gives the glide path displacement, and the horizontal antenna gives lateral displacement.

One unique feature in the GCA, which is used in certain other radar equipments, is the optical system of the PPI scopes. The operator views an illuminated map through a 45° glass plate. The scope is directed at the glass from a position complementary to the position of the map below. The scope appears superimposed on the map. It is on the map that the correct approach line is inscribed for use by the controller in detecting deviation of the airplane.

Three important features of GCA are: (1) No equipment is required in airplanes for its use other than already existing communications. All aircraft then may use it. (2) Its precision and straightness of path are unaffected by conditions surrounding the site, such as buildings, hangars, and wires. (3) The precision is not entirely in the system but partly in the ability of the operator to bisect the target image. (4) The identity of aircraft being controlled depends largely upon the skill and attention of the operators. (5) Skill, practice, and experience are required in any blind approach operation. In GCA this skill is on the ground.

NAVAGLIDE (Federal). The navaglide instrument landing system being developed by the Federal Telecommunications Laboratories is a microwave system using only one frequency channel. The four-directional signals of the glide path and localizer indications will operate on this frequency channel simultaneously through the use of a scheme of subcarrier modulation. The receiver of the "Navar" navigation system (described below) may be used, ultimately, also for the landing signals. Accurate distance-measuring equipment will replace the markers of the present instrument landing system, permitting use of automatic landing equipment.

MICROWAVE (Sperry). A complete microwave instrument landing system, operating at approximately 2600 Mc, has been developed and successfully operated experimentally for several years by the Sperry Gyroscope Company. This development, now in production status, overcomes objectionable siting and wave-reflection problems existing on systems using lower frequencies. Reasonably small radiating systems are able to concentrate and confine the radiated energy to the approach sector and avoid nearby buildings, wires, or hangars. Reflections from these objects on other instrument landing systems causes course and path bends.

The present success of the system may be attributed to the development of the klystron tube (2K36/416) for airborne receiver use and to the development of crystal control for both the transmitting and receiving equipment.

The complete system consists of two ground stations (localizer and glide path) and one airborne receiver. The ground stations are identical in electrical circuits and have equivalent outputs of about 70 watts but use different radiating elements. The glide path radiator is a tilted vertical parabola fed by two wave guides through a mechanical modulator. The wave-guide feeds are displaced from the parabola focus in opposite directions and therefore produce two overlapping patterns, the plane of overlap being inclined upward at the desired approach glide angle. The patterns are amplitude modulated 600 and 900 cycles respectively. The parabola is narrow to give wide horizontal coverage. This permits its being placed safely to the side of the runway.

The localizer transmitting antenna is a paraboloid, giving a relatively concentrated pattern in both horizontal and vertical planes. It is equipped with a central vertical dividing shield to separate the two wave-guide feeds. The radiated patterns overlap in a vertical plane thereby forming a course for left-right guidance along the runway center line. The localizer is placed on the runway center line at a safe distance from the end opposite from that on which the airplane lands.

The one receiver used in the airplane has a common crystal-controlled klystron tube oscillator serving two separate IF circuits. The filtered and rectified outputs of the two channels are balanced and connected to the localizer and glide path pointers respectively of the conventional crossed-pointer landing instrument. Two flag alarms on the instrument serve as indicators to warn against failure of the localizer or glide path signals.

An electronic coupling device now in production is used to couple the localizer and glide path signals into the Sperry (A-12) electric auto-pilot for automatic approach flight. It works equally well on the CAA instrument landing system.

6. PROPOSED NEW SHORT-RANGE NAVIGATION SYSTEMS

LANAC (Hazeltine). The word "Lanac" is derived from "*la*minar *n*avigation and *a*nti-*c*ollision."

This system is proposed for the 1000-Mc band and utilizes in each airplane an interrogator and a replier. The replier consists of a pulse receiver and transmitter capable of automatically replying to interrogating pulses of proper frequency and coding. The code key of the replier varies with altitude layers in a prescribed standard manner, through the use of an aneroid cell.

The interrogator includes a pulse transmitter, coded to challenge the repliers of other aircraft, and a receiver to interpret the reply. Normally it interrogates on the code equivalent to its own altitude so as to provide anticollision and traffic control safety. By means of a switch, the interrogation code can be varied to scan the traffic in altitude layers above or below the level being flown. The interrogator antenna is directional and rotatable so that direction as well as distance and altitude of replies can be observed on the L-type (or possibly PPI) scope used in the system.

Ground transpondors and ground interrogator stations are included to permit route navigation by the aircraft and ground surveillance of airways traffic overhead, obtaining position of planes in three dimensions as well as identity of each plane, and affording selective signaling to each plane. The ground transpondors also serve as obstruction warning units. Ground transpondors, properly placed on the approach, aid the airplane on instrument approach to the airport.

The Lanac interrogator may be employed as a radar, in special applications, by tuning the receiver and transmitter of the interrogator to the same frequency so that echoes will be shown on the interrogator's display in the usual radar manner. In this case, of course, no replier is utilized.

This radar mode of operation is used in an aircraft to supply terrain-clearance information when the plane is flying at an altitude of 500 ft or more. It therefore offers an important safety feature for off-airway flying over mountainous country. The radar mode is used in marine anticollision service to warn against unequipped craft. Radar anticollision protection between aircraft is not feasible because of the small size of the targets and their extremely high relative speeds when closing on a head-on-collision course.

The Lanac system is useful in marine navigation, and a description of this application is given under Marine Aids.

TELERAN (RCA) (*tele*vision *r*adar *a*ir *n*avigation). Teleran is a comprehensive system of navigation involving radar as the means of collecting air traffic information and television as a means of displaying the information to the pilot. Radar stations with overlapping 50-mile service areas to form the airway are proposed. Respondors in every airplane are essential, although failures of respondors can be taken care of in the plan by using separate echo-type search radar equipment. The PPI picture obtained in the ground radar is used by air traffic control or tower operators. This same picture, with any desired obstruction, control, or weather instructions superimposed, is televised, transmitted to, and repeated in the airplane by television.

The system permits both pilot and ground operator to see and appreciate the complete air traffic situation. The airborne transpondor units can be coded or varied automatically with altitude to segregate the various flight levels and to permit identification of aircraft. Instructions may be written out on the ground and "handed" to the pilot on the television picture.

For landing at an airport, an airport localizer radar and GCA precision radar units are proposed.

For each altitude level and for the echo-type search radar, separate television transmitting equipment and radio-frequency channels are required. The channels required can be greatly reduced over commercial television because a low scanning rate may be used.

NAVAR (Federal) (*nav*igational and traffic control rad*ar*). A system for traffic control and navigation around airports and along airways. This system provides the following features, which may be applied progressively to an airways system: (*a*) Ground radar surveillance in the form of PPI displays. (*b*) Distance and azimuth information in the airplane. The azimuth information is omnidirectional derived from the ground radar system. (*c*) PPI traffic presentation in the airplane, relayed from the ground station. (*d*) Selective signaling, ground to aircraft; and automatic identity and altitude response, aircraft to ground.

The ground radar equipment and display is conventional except that provision is made to separate known (respondor-equipped) aircraft from others. The distance information in the airplane is obtained by a pulse interrogating system. The azimuth information in the airplane is obtained by measuring the time from the reception of a non-directional pulse radiated from the ground to the reception of the rotating search radar beam. The pulse and beam are synchronized for true north direction. The timing measurement in the airplane is made automatically.

The airborne PPI display, called "Navascope," is obtained by sending synchronized pulses omnidirectionally from the ground radar station. These pulses contain the information of all aircraft in the area as revealed on the ground radar scope and are reproduced in synchronism on the airborne PPI. The airborne PPI display includes positive identification of observer's own airplane and self-centered altitude layer presentation.

Selective signaling of aircraft is obtained by directing a sharp "challenging" beam in the direction of the airplane on which a check-up is desired. The aircraft respondor beacon circuit is to contain a double-pulse gate. The gate is tied in with the aircraft distance indicator, so that it varies with distance. The interrogating pulses, beamed from the ground, are spaced automatically as the operator selects the distance range of the target he wishes to challenge. Thus the challenge is narrowed down to distance and direction.

The complete system proposes one airborne transmitter and two receivers. This does not include communications equipment.

MICROWAVE OMNIDIRECTIONAL RADIO RANGE (Sperry). A radio range operating on the same general principles as described for the CAA VHF omnidirectional range, but in the microwave frequencies (2600 Mc), has been developed by the Sperry Gyroscope Company. Like the CAA system, it utilizes the comparison of phase between two audio waves in the airplane to determine the azimuth bearing to the station. In the microwave system, however, the antenna of the ground station is so small that it can be rotated at 1800 rpm, thereby avoiding the use of a capacity goniometer and avoiding antenna phasing problems.

In this system, as in the Sperry microwave instrument landing system, the cw signal to be radiated is generated by a crystal-controlled klystron tube. A synchronous 1800-rpm motor drives a small alternator, the output of which frequency-modulates a 70-kc subcarrier. The subcarrier, as in the CAA system, amplitude-modulates the microwave carrier. The modulated carrier is conducted to an antenna system consisting of a vertical stack of three small loop antennas. The stack gives vertical directivity for maximum horizontal coverage. The modulated carrier radiation produces the reference audio voltage in the airborne receiver. Its relative phase is the same in all azimuthal directions.

The vertical stack of antennas also has a directive pattern in the horizontal plane. This horizontal pattern is essentially sinusoidal. By rotating the pattern with the same motor as used above, another audio voltage is generated in the receiver. This voltave wave, with respect to the former reference voltage wave, has a phase that varies with position around the station. For the full 360° around the station there is a complete cycle or 360° phase variation in the wave. This is called the variable signal. By comparing the phase between this variable and the former reference signal the bearing from the station can be determined.

The phases may be compared in the same manner as in the case of the CAA range, or the phase detector may be used to control the operation of a motor which turns a map in accordance with movement of the airplane around the station.

The proposal for the complete system includes the addition of distance-measuring signals and communications through the single ground station transmitter and antenna.

The greatest advantage in the use of the proposed system is the elimination of the goniometer through the rotation of the antenna system. Reduction in the amplitude of course bends due to siting (reflections from buildings, trees, etc.) are evident.

AEROTRONICS (Raytheon). The Aerotronics system is a proposal based on radar technique and uses PPI scope presentation in the airplane and on the ground. It includes (1) airborne radar, (2) ground beacons (transponders), (3) ground radar, (4) airborne transponders, and (5) distance-measuring equipment. With this equipment, navigation, collision prevention, airways traffic control, approach, and landing are to be taken care of without other aids.

The airborne equipment includes a rotating antenna for radar search, an omnidirectional antenna for communications, and an antenna for distance measuring. The ground radar includes both azimuth and elevation search. This is for traffic surveillance and control. Ground beacons (transpondors) would be used for route navigation.

The distance-measuring equipment proposed operates on the principle of the optical interferometer. It operates a counter at the ground traffic control station where distance to the airplane may be observed with great accuracy.

MULTIPLE TRACK RADAR RANGE (Australian). A multiple track radar range (MTR) has been developed and successfully demonstrated by the Council for Scientific and Industrial Research of Australia at Sydney. This range produces visually indicated (left-right), positively identified flight tracks, based on the time of arrival of pulses from two spaced ground stations. VHF (212 Mc) is employed, which results in line-of-sight distance coverage. The tracks are hyperbolic in shape, but essentially straight beyond 20 miles. The tracks or courses are flyable to within about $\pm 1°$.

The MTR system is fundamentally the same as GEE, a British development used extensively in the invasion of Europe, except for type of presentation. GEE is a hyperbolic system similar to Loran except for its frequency. Two stations only are used in the MTR system, one a master, sending a series of equally spaced pulses (5000 pps in this case) of peak power about 10 kw. The second, a slave station, is equal to the master, but spaced about 8 miles distant and normally inoperative. The slave station receives the pulses from the master and rebroadcasts them with a suitable fixed time delay. For any position around the pair of stations, the pulses are received in a specific time relationship. The contours of equal time differences are hyperbolas passing between the stations and are used as tracks or courses. Non-directional, vertically polarized antennas are used.

In the airborne equipment, the pulse signals are compared in an automatic circuit similar basically to that in the distance-measuring equipment described before. Standard time differences chosen as the tracks are set up on a calibrated switch dial and numbered (track numbers 1 to 30). When a given track is selected, a left-right indicator signals the pilot any deviation from that track.

The master and slave stations are separated in the receiver by permitting the master (only) to transmit double pulses. MTR equipments at adjacent places are identified by a selected difference in repetition rate.

Distance-measuring equipment, of the interrogator-respondor type, is proposed for use with the MTR system.

7. PROPOSED NEW LONG-RANGE NAVIGATION SYSTEMS

CAA LOW-FREQUENCY OMNIDIRECTIONAL RANGE. The low-frequency omnidirectional range operates like the VHF omnidirectional range, i.e., in the comparison of the phase of two audio signals. In early tests of this range, two individual, basic, carrier frequencies were used—one at 172 and one at 194 kc.

The low-frequency omnirange consists of the conventional five-tower Adcock antenna array, one tower at each corner of a square and the fifth tower in the center. The reference signal, 172-kc carrier, modulated with 30 cps, is fed into the center tower only and is, therefore, radiated non-directionally. The other signal (194 kc) is fed to the corner towers through an inductive goniometer which is mechanically rotated at 1800 rpm. The rotation of the goniometer spins the figure-of-eight pattern of the corner towers, producing the variable phase signal in the aircraft receiver. When compared to the phase of the reference signal in a wattmeter circuit, it can be made to indicate azimuth.

Tests are being conducted using a single low frequency and a subcarrier of 1000 cps. The 30-cps reference is applied to this subcarrier by frequency modulation, as in the case of the VHF.

The wattmeter indicating circuits are the same as those used with the CAA VHF omnireceiver.

Night effect represents a serious problem for radio ranges. The lower the frequency employed, the greater is the ground wave signal strength and the more stable will be the operation of the system. Night effect is minimized by curtailing the amount of unwanted vertical radiation. The fact that the signal arrives via ground or sky does not, in itself, introduce an error in the omni system since the indication does not depend upon the length of the path. The development may result in much more freedom from night-effect errors and swinging than in an automatic direction finding system employing a loop and operating on the same frequency.

SONNE (Consul). This is a German aural CW system used against the Allies during the war and capable of great accuracy over long distances and useful in both air and marine service. For its description, refer to Marine Aids, article 10.

LORAN (*lo*ng-*r*ange *a*ir *n*avigation). Excellent results are being obtained in the extensive use of Loran in transoceanic flights. For a description of this system, refer to Marine Aids, article 10.

NAVAGLOBE (Federal). This is a CW system using very low frequencies for long-range navigation over oceans and continents. The receiver proposed has a narrow-band, noise-rejecting feature and ADF facilities. The ground station consists of three antennas spaced in the corners of an equilateral triangle, and a transmitter which is connected in succession to the three antenna pairs each second. Three dumbbell-shaped patterns, displaced in bearing by 120° from each other, are radiated successively. Relative amplitudes of the three successive signals received during each cycle are measured automatically by a ratiometer, permitting direct visual indication of bearing at all azimuths from the station. For other directions between courses, measurement of ratio in a ratiometer in the receiver permits determination of relative bearing with respect to the antenna array.

8. MISCELLANEOUS RADIO AIDS

VERTICAL SEPARATION INDICATOR. The Stratoscope is an instrument conceived to provide visual indication in an airplane and on a ground monitor of the vertical separation between airplanes (or other obstacles) within a minimum service area of 10 miles distance and 1000 ft elevation.

Basically, the Stratoscope operates by converting aircraft height into frequency and then utilizing panoramic reception to display received signals along a CRT time base calibrated in relative vertical height. The airplane equipment includes a transmitter and a receiver-indicator unit. The ground monitor needs only a receiver-indicator unit.

Conversion of height into frequency is accomplished by means of a precision aneroid cell which operates a variable tuning condenser in a coaxial line oscillator. The oscillator frequency changes 5 Mc in 10,000 ft. This change is accomplished in the frequency band of 148–154 Mc. The height of the transmitter in relative pressure altitude may therefore be determined by measurement of transmitter frequency.

Interference from the plane's own transmitter is avoided by sharing time between the transmitter and receiver at an alternation rate of 30 cps. By coding the transmission, some identity of the airplane can be provided in the receiving indicators.

In tests of this equipment an accuracy of 200 ft was observed. The required 10- or 20-mile distance range can be covered with about 5 watts (transmitter power output).

ABSOLUTE ALTIMETERS. Absolute altimeters have little utility in navigation over land because of the rapid variation in indication in rough territory, but they do have utility in navigation over water, which is flat, as a means of maintaining constant height above the surface. Variations then in the pressure altimeter indicate flight toward or away from atmospheric-pressure areas. Flights directed laterally so as to give constant-pressure altimeter reading (for constant absolute altitude) avoid storm areas over the oceans.

Many absolute altimeters have been invented over a period of twenty years, including sonic, capacity, frequency modulation, and radio-pulse types. A reference is given for detailed information as space permits only summary remarks here.

One absolute altimeter, called a "terrain clearance indicator," was developed for commercial use just before the war. It operates on the FM principle at about 432 Mc. The transmitter continuously radiates its energy downward from a doublet antenna. The frequency is varied from 410 to 445 Mc sixty times per second. The receiver takes in the energy reflected back from the ground and also some of the original transmitted energy. The receiver output, which may be considered a beat between the two signals, has a frequency depending upon and increasing with altitude.

The FM type absolute altimeter is capable of operating down essentially to zero altitude. It has greatest accuracy at lowest altitude but is subject to possible serious errors from adjustment and noise which prevent its immediate use on instrument landing.

The radiopulse altimeter developed during the war for high-altitude bombing uses a cathode-ray tube as a means of displaying time between transmitted pulse and echo. The display is calibrated in feet of altitude and arranged circularly around the tube face. Essentially it is a radar distance indicator with its antenna fixed in a position under the airplane. The pulse type altimeter is extremely accurate at high altitude but, at present, useless at altitudes below several hundred feet. Future development may bring about reduction in this minimum altitude.

RADIO AIDS TO MARINE NAVIGATION

By M. K. Goldstein

Table 1 shows an extensive summary and classification of established, recently introduced, contemplated, and proposed electronic aids to marine navigation. It will be noticed that the systems are classified in groups dealing with radio types, sonic and supersonic types, and red and infrared types. Also the various systems are analyzed for essential characteristics falling into the following grouped categories: Type of system (including basic principle and position information supplied); performance of system (including range, accuracy, ambiguities, operating frequency, and band width; system requirements (including required ship and shore equipments); and the system usability (including engineering status and reliability factors). Details concerning each of the specific systems classified are discussed in the following articles in this section.

Table 1. Summary and Classification of Established, Recently

System	Type: Principle Employed	Type: Basic Information Supplied	Performance: Maximum [1] Range	Performance: Accuracy [2]	Performance: Ambiguities	Performance: Frequency (Mc/s)
RADIO						
1. *Beacon:*						
a. Radiobeacon (shore)	Non-directional transmission and directional reception	Azimuth	Short, med.	<2°	None	0.285–0.315 [3]
b. Radiobeacon (ocean sta.) †	Non-directional transmission and directional reception	Azimuth	Medium	<2°	None	0.30–0.55
c. Radar marker (Ramark)	Non-directional transmission and directional reception	Azimuth	Optical	Devel'pm't'l	None	3, 5, & 10 cm.
d. Respondor (Racon)	Non-directional transmission and directional reception	R & az. fix	Optical	±2%, ±3°	None	3, 5, & 10 cm.
e. Reflector (Racon).	Non-directional transmission and directional reception	R & az. fix	Optical	±2%, ±2°	None	3, 5, & 10 cm.
f. Rotating beacon (Consol.)	Dir. trans. & non-dir. reception	Azimuth	Medium	1.7°–2.3°	Multiple [4]	0.20–0.5
2. *Direction finding—ship* (Loop):						
a. MF—Aural null (Standard) †	Directional reception of any transmission	Azimuth	Normal communication range	<2°	None	0.3–3.0
b. MF—Null seeking (ADF) (SCR-269) †	Directional reception of any transmission	Azimuth	Normal communication range	<2°	None	0.2–1.75
c. MF-Instantaneous (DAK) †	Directional reception of any transmission	Azimuth	Normal communication range	<2°	None	0.25–1.5
d. MF—Position plot (Bendix)	Directional reception of any transmission	Az. fix	Normal communication range	<2°	None	0.1–1.6
e. HF—Instantaneous (DAQ, DAU) †	Directional reception of any transmission	Azimuth	Normal communication range	5°–10°	None	1.5–21
3. *Direction finding—shore:* †						
a. MF—Adcock (DAH)	Directional reception of any transmission	Azimuth	Normal communication range	1°–2°	None	0.25–1.5
b. HF—Adcock (DAJ,SCR-291)	Directional reception of any transmission	Azimuth	Normal communication range	3°–4°	None	1.5–30
c. HF—spaced loop (DAB)	Directional reception of any transmission	Azimuth	Normal communication range	3°–4°	None	2.0–18
d. VHF—Adcock (DBF)	Directional reception of any transmission	Azimuth	Optical	3°–5°	None	100–160
e. UHF—Reflector (DBM)	Directional reception of any transmission	Azimuth	Optical	3°–5°	None	90–5000
4. *Radar:*						
a. Ship......... ..	Echo ranging	R & az. fix	Optical	±2%, ±2°	None	3, 5, & 10 cm.
b. Shore......	Echo ranging	Traffic	Optical	±2%, ±2°	None	3, 5, & 10 cm.
5. *Propagation time difference:*						
a. Loran (standard).	PTD [6]—synch. pulsed transmissions	Hyp L of P [7]	Long	0.5%	None [8]	1.7–2.0
b. Loran (SS) [10].....	PTD [6]—synch. pulsed transmissions	Hyp L of P	Long	0.5%–1.0%	None [8, 18]	1.7–2.0
c. Loran (LF) [11]....	PTD [6]—synch. pulsed transmissions	Hyp L of P	Long	<1.0%	None [8]	0.18
d. Gee.............	PTD [6]—synch. pulsed transmissions	Hyp fix	Optical	<0.8%	None [8]	20–85
e. Decca.....	PPD [13]—Synch. CW transmissions	Hyp fix	Medium	±0.02% [14]	Multiple [15]	0.01–0.2
f. POPI...... . .	PPD [13]—Synch. CW transmissions	Hyp L of P	Long	Devel'pm't'l	None	0.75
6. *Interrogator-respondor:*						
a. Shoran...........	Dual beacon ranging	Range fix	Optical	±50 ft	Few [16]	210–320
b. Lanac—ship......	Single beacon ranging	R & az. fix	Optical	±2%, ±2°	None	1000
c. Lanac—shore	Single beacon ranging	Traffic	Optical	±2%, ±2°	None	1000
7. *Composite data relay:*						
a. Teleran...........	Instant. data relay	Gen. nav.	Optical	....	....	Telv. Ch'n'l
b. Facsimile.	Recording data relay	Gen. nav.	Medium	....	....	Facs'm'le Ch'n'l

Introduced, Contemplated, and Proposed Aids to Marine Navigation

Performance	Requirements		Appraisal Factors *	
Signal Band Width	Minimum Equipment for Basic Information Supplied: Ship	Minimum Equipment for Basic Information Supplied: Shore	Engineering Status	General Remarks
≥CW	DF receiver	Coded beacon	Proven	Inaccurate and unreliable beyond predominant ground wave range.
≥CW	DF receiver	Coded beacon	Proven	Combination radiobeacon, rescue ship, weather station.
3–5 Mc	Special radar	Beacon	Under development	Identified by reference to natural target echoes.
3–5 Mc	Special radar	Respondor beacon	Proven	Identification obtained by coded transmission.
3–5 Mc	Radar system	Reflector	Proven	Special target for increased echo reflection.
≤1 kc	Receiver	1 station	Under trials [5]	Minimum range—25 mi; accuracy deteriorates at night beyond predominant ground wave range.
≥CW	Standard DF	CW or other transmitter	Proven	2a to 2e inclusive—unreliable beyond predominant ground wave range due to susceptibility to polarization error. Note to 2d: Fix obtained by simultaneous cross-bearing plot on map.
≥CW	Special DF		Proven	
≥CW	Special DF		Proven	
≥CW	2 ADF'S & computer		Under development	
≥CW	Special DF		Proven	
≥CW	MF transmitter	Special DF	Proven	3a to 3e inclusive—designated models have low susceptibility to polarization errors beyond ground wave ranges. Indicated accuracies generally realized up to maximum sky wave range.
≥CW	HF transmitter	Special DF	Proven	
≥CW	HF transmitter	Special DF	Proven	
≥CW	VHF transmitter	Special DF	Proven	
≥CW	UHF transmitter	Special DF	Proven	
3–5 Mc	Radar system	None	Proven	Valuable anti-collision and short-range naval device.
3–5 Mc	Comm. receiver	Radar, comm. transmitter	Under trials	Suitable for traffic control in congested areas.
50–70 kc [9]	Special receiver and indicator	2 stations	Proven	Day range, 750 mi; night range, 1400 mi (over sea water).
50–70 kc [9]		2 stations	Under trials	Night use only; utilizes base line of approx. 100 mi.
10 kc		2 stations	Under trials	Greater ground wave range and more stable propagation over 5a.
1 Mc [12]		3 stations	Proven [5]	Simultaneous fix from 2 hyperbolic lines of position.
3 CW freq's.	Special receiver	3 stations	Under trials [20]	Limited as 1(a) above owing to ionospheric phase shifts.
≤1 kc	Rcvr. & Spc'l ind.	1 station	Under development [5]	Same as 5e; awaits satisfactory phase measurement between sequentially received signals.
3-5 Mc	Special trans. & receiver	2 respondor beacons	Proven [17]	Bombing and mapping aid; may have marine use.
3–5 Mc		Respondor beacon	Under trials	Optional operation: radar beacon or radar system.
3–5 Mc	Respondor beacon, comm. receiver	Spc'l. trans. & rcvr., comm. trans.	Under trials	Traffic control utilizing shipboard transponders.
3–5 Mc	Television receiver	Television transmitter	Under development	Air traffic control system; also feasible for marine use.
1–10 kc	Facsimile receiver	Facsimile transmitter	Proven	Permanent recording of any general information, data, etc.

[9] Provisions are made for 16 different channels on the same carrier frequency by utilizing different pulse repetition rates.

9. ESTABLISHED NAVIGATIONAL AIDS

RADIOBEACON SYSTEMS (MF) (See references 2 and 3.) The non-directional medium-frequency (MF) radiobeacon system, maintained by the Coast Guard in the United States and by similar organizations in foreign countries throughout the world, is the most extensively used radio navigational aid today. The system consists of fixed radiobeacon stations located at lighthouses, lightships, and other points, which transmit distinctive identifying coded tone signals, enabling navigators at sea to take bearings on them by means of medium-frequency loop direction finders. Bearings obtained from two or more such beacon stations, in conjunction with charts of the geographical locations of the radiobeacons, uniquely establish the ship's position. A single radio direction-finding (DF) bearing crossed with a line of position of a heavenly body, two bearings on the same station and the distance run between bearings, or a bearing and a synchronized air or submarine fog signal also suffice to determine the position of the vessel. In the last case, blasts from the sound signal are synchronized with the radiobeacon signals and the difference in time of reception of these two signals can be converted into an approximate station distance. Owing to the many factors which enter into the transmission and reception of radio signals, a ship cannot estimate its distance accurately from a radiobeacon either by the strength of the signal received or by the time at which the signals were first heard. However, a line of direction obtained from a single radio bearing enables a ship to proceed toward the radio station by the shortest course. This is especially applicable to a rescue ship, enabling it to head directly toward the ship in distress and thereby arrive in the minimum of time. Such radio bearings are usually accurate to within 2° or less, depending upon the equipment and the operator's skill. DF calibration transmissions are available from radiobeacons upon request, continuous signals being transmitted while the ship's direction finder is being calibrated. The simplicity and reliability of the radiobeacon indicate that such systems will continue to exist as a navigational aid for many years.

The present MF radiobeacon system in the United States (see Fig. 1 for East Coast and Gulf) consists of approximately 200 radiobeacons, each radiobeacon operating on one of the even frequencies in the 285–315 kc/s band. The European system frequency

20 A British Isle Decca facility is in 24-hr operation with performance results indicating a proven system.

band is 290–320 kc/s. Distinctive signals, by which the different stations are positively identified, are obtained by keying a tone-modulated carrier to give simple dot-dash combinations at the rate of thirty characters per minute. Because of the great number of stations and the restricted frequency band, it has been found necessary to share time between stations on the same radio frequency by transmitting signals from any one radiobeacon for 1 minute followed by 2 minutes of silence. This allows two adjacent stations to transmit similar signals on the same frequency without causing interference simply by timing the transmissions to occur during successive minutes. Two-tone modulation is used on some stations in congested traffic areas to add distinctiveness to the identifying signal. During clear weather the radiobeacons follow such cycles of transmission for one or two 10-minute periods of the hour. All six 10-minute periods are utilized during conditions of fog. The beacons are carefully timed and remotely monitored.

Radiobeacons are grouped into four classifications, according to their power output and maximum effective ranges:

Class A	750 watts—200 miles
Class B	150 watts—100 miles
Class C	25 watts— 20 miles
Class D	5 watts— 10 miles

A few special high-power beacons having ranges of 400 miles have also been put into operation. Class A and B stations require identical equipment with the exception of the 750-watt power amplifier used with the A stations. The transmitter, which is coupled directly to the antenna for the B station, is used as an exciter for the power amplifier of the A station. Both types of radiobeacons often use 125-ft insulated self-supporting towers as non-directional antennas, with provision for location up to several hundred feet from the transmitter house when local conditions make such an installation preferable. Sometimes an insulated guyed antenna, approximately 40 ft high, is placed on top of a light tower above the lantern. Lightships use vertical or symmetrical T antennas. Inverted L-type antennas are not used because of the undesired directivity and the horizontally polarized field components. The frequency of the A and B stations can be quickly changed to any one of four pre-set frequencies which are usually crystal-controlled. Class C radiobeacons are used for short-range navigation. The equipment is very similar to that of a class A station except for the much lower power and the reduction in size of equipment. Owing

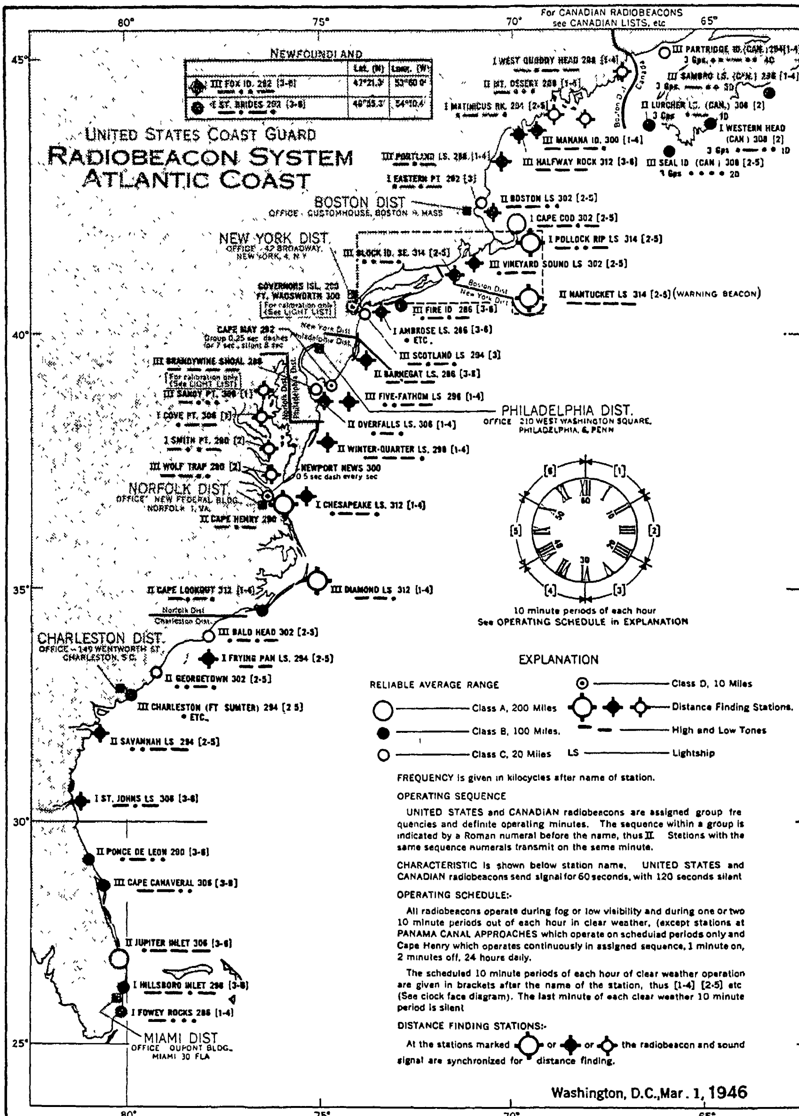

FIG. 1. Typical Radiobeacon Navigational Chart, Published by U. S. Coast Guard

to the necessity of making the signals from these short-range stations especially distinctive in areas of considerable marine traffic, the modulating audio frequency is variable in four steps. The timer cams can be set to give a single tone or any combination of tones. Class D marker radiobeacons are small automatic battery-operated transmitters located on pierheads, buoys, ends of jetties, etc., which serve as local markers to indicate channel entrances, turning points, etc., where careful approach is required. They are not synchronized with other radiobeacons but operate continuously in all types of weather, sending out a characteristic of several dashes during each 30-sec period. The transmitter frequency is crystal-controlled and has a modulation frequency of 1000 cycles per second. A 15-ft welded Monel tripod mast is normally used as the antenna. Special warning transmitters are located at some radiobeacons; each transmitter operates on the same frequency as the beacon and gives a distinctive signal to warn a navigator who is homing into the station that he is approaching dangerously close. The usable range of these warning beacons is, therefore, intentionally reduced to provide warning over only a small but sufficient area surrounding the long-range beacon.

At present the characteristics of some of these stations are being changed to provide satisfactory operation with automatic direction finders. Instead of both the carrier and modulation being interrupted during the keying process, only the modulation will be interrupted. In addition, many of the stations will transmit throughout the hour under all weather conditions rather than just during one or two 10-minute periods.

The well-established aerobeacon system used for air navigation is also used for marine purposes and is discussed in the first part of this section.

DIRECTION-FINDING SYSTEMS. (See references 4, 5, and 6.) The use of shipboard medium-frequency radio direction finding has continued to grow as a navigation aid since the early days of radio broadcasting. By use of the shipboard direction finder, practically every transmitting station within the frequency band and range of the radio direction finder is a potential point for a navigational reference line of position. Shipboard direction finding also plays an important role in directly guiding vessels to other vessels in distress. As an additional aid to navigation in time of distress, medium-frequency direction-finding stations located along the coasts and on the Great Lakes are available to mariners who transmit signals on the international distress frequency of 500 kc/s. Various other frequencies are available for distress and emergency purposes, depending on the range from land or the location of the vessel. For example, 8280 kc/s is used for United States long-range contact and 2182 kc/s is used on the Great Lakes.

While the most widely used shipboard direction finder is of the loop aural-null type, other types are available (see Section 6, article 32).

Environmental Effects. (See reference 5.) The term "environmental effects" is used to describe all local physical conditions which cause DF bearing errors aboard ship and at shore stations. Such conditions normally involve metallic structures near the DF antenna and their radiation fields, induction fields, or shielding effects. For frequencies below 1000 kc/s, shipboard environmental effects can be sufficiently well controlled or compensated (further details are given by C. T. Solt, *Proc. I.R.E.*, Vol. 20, p. 228, February 1932) so that direction finders in this band give highly satisfactory performance on ground-wave transmissions; i.e., the resultant calibration curve is fairly symmetrical and does not exceed a few degrees maximum deviation. Arriving signals of certain frequencies cause partial or complete resonances in, and consequent reradiation and induction fields from, nearby metallic structures. These fields generally impart 90° phase components (called quadrature effects) to the arriving wave fronts, altering their apparent arrival direction by amounts depending on the positions and sizes of the resonating structures. These changes in direction result in deviations of the observed bearing from the true bearing. Deviation, then, is defined as the quantity that "must be added algebraically to the observed bearing in order to make it equal the correct bearing"; the deviation, however, does not affect the resolving power (angular sensitivity) of the DF. The quadrature effect, on the other hand, causes an elliptical polarization condition of the E or H fields, or both, which generally results in failure of the antenna to find a sharp null coupling position to these fields, thus adversely affecting the resolution of the DF. Figure 2(a) shows the maximum deviation that may be expected due to induced currents at frequencies at which the structure may be resonant (worst case). For frequencies off resonance and $f \lessgtr 0.5$ the shapes of the curves of Fig. 2(a) are maintained, but the magnitude of the deviation is reduced approximately as follows:

$$\frac{D_{\text{res.}}}{D} = \frac{e/r}{e/(r + jx)} = 1 + j\left[1 - \left(\frac{f_0}{f}\right)^2\right]Q \tag{1}$$

or

$$D = \frac{D_{\text{res.}}}{1 + jQ[1 - (f_0/f)^2]} \tag{2}$$

where e is the voltage induced in the structure at frequency, f; r, x, L, C, and Q are the electrical constants of the structures; $D_{\text{res.}}$ is the maximum deviation at the resonant frequency f_0; and D is the maximum deviation at any frequency. The resonant frequency, f_0, of structures may be determined from Fig. 2(b), to which some corrections should be

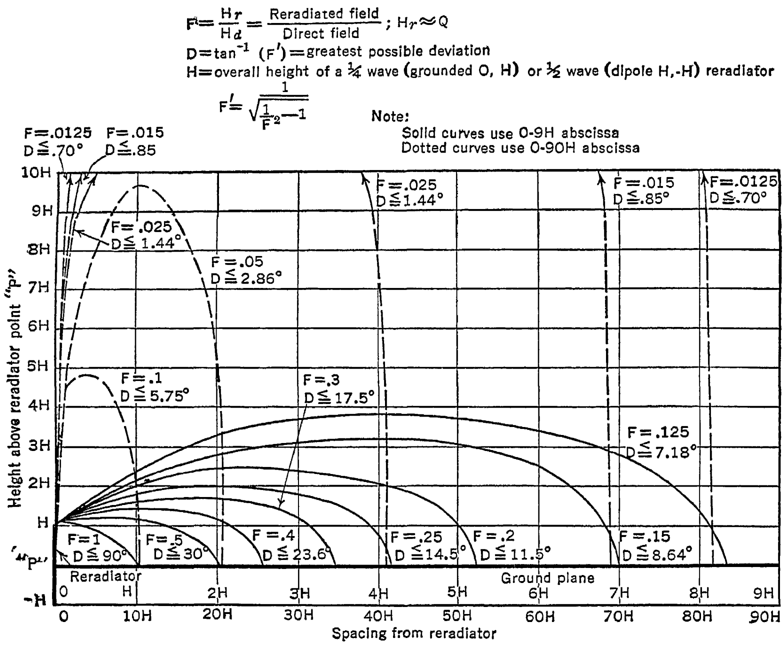

Fig. 2(a). Bearing Deviations Due to Presence of a Reradiator

Notes. 1. D (Worst Possible Deviation) is directly dependent upon the lateral and vertical spacings from the reradiator. 2. A resonant reradiator of $Q = 20$ has been assumed. 3. For other Q's and non-resonant conditions, see text. 4. Curves show reradiator spacings to maintain constant D or F.

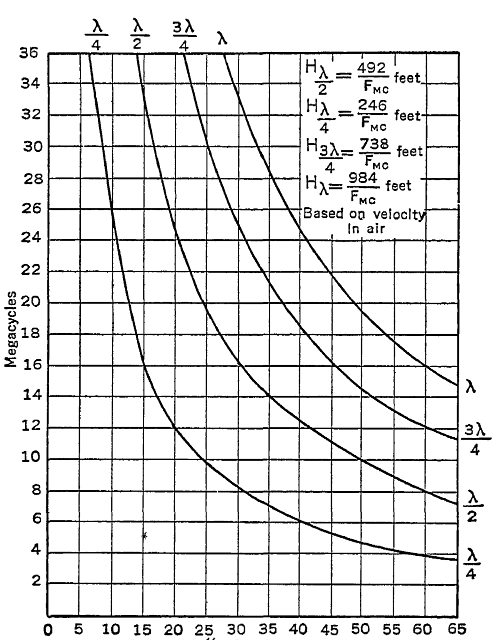

Fig. 2(b). Fundamental and Harmonic Resonant Frequencies of Conductors of Physical Heights H

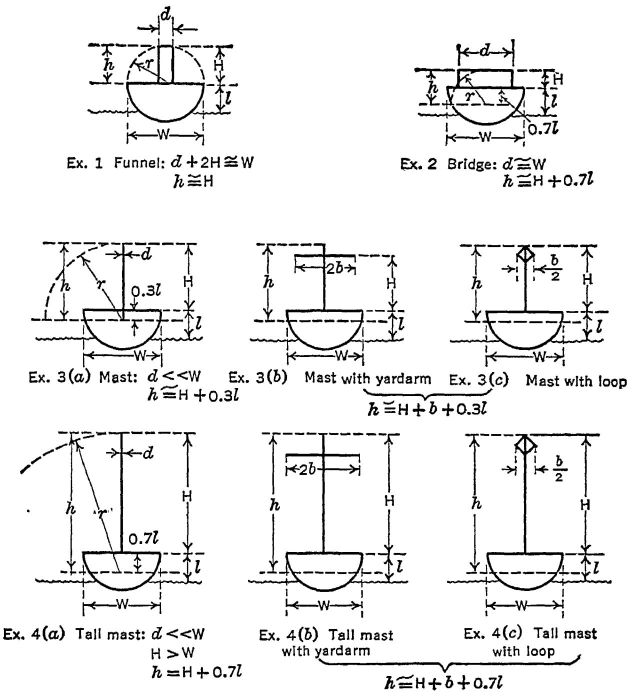
added for end effects and top loading as shown in Fig. 2(*c*). The range of *Q*'s is approximately as follows:

Wide-width reradiators (superstructures)	1.5– 2
Medium-width reradiators (funnels)	2 – 3
Narrow-width reradiators (masts)	5 –10
Very thin reradiators (guy wires, antennas)	10 –20

It can be seen from these results that DF antenna locations on top of the tallest structures give the least reradiation error effect from those structures and, generally, maximum clearance (least error) from the other, surrounding structures. Breaking up structures



Note: *r* shows region of strong reradiated fields

FIG. 2(*c*). Top Loading and End Effect Corrections for Shipboard Reradiator Heights *H*

(e.g., guy wires, rails) with insulators, to reduce the induced currents, further reduces the environmental effects. Partial compensation of environmental effects can often be obtained by judiciously introducing compensator loops or structures, such that an approximately equal and opposite (compensating) environmental effect is obtained. Successful means have been devised for altering the frequency characteristics of structures surrounding a DF antenna in order to reduce and control environmental effects. (See reference 5.)

Quadrature effects are generally reduced by minimizing the environmental effects as stated above. However, in practical direction finders, some polarization effects and residual environmental effects often leave high values of quadrature effect which must be further minimized in order to realize satisfactory DF bearing resolution. Quadrature balance or compensation has long been used for this purpose. It makes use of a non-directional antenna for obtaining a voltage from the arriving wave which, with a properly adjusted phase and amplitude, can be made to cancel out completely the undesired quadrature voltage derived from the directional collector. In practice, the phase shift, if any, required for the above balancing or compensating voltage is a constant value over the frequency band. As a result, most direction finders operating below 2000 kc/s incorporate this balance circuit with only a single associated panel control for positive and negative magnitude of compensation adjustment. The non-directional antenna employed for balancer purposes is actually the same one generally furnished in practically all direction finders for sense determination, i.e., for resolving the 180° ambiguity in the direction of a received signal. When used for that purpose, the phase and magnitude of the sense antenna voltage is adjusted (generally by a fixed circuit) to match (as closely as possible) the phase and magnitude of the directional antenna's maximum coupling output. In this manner the cosine (double null) coupling law is converted to an approximate cardioid (single null) coupling law which possesses the desired single non-ambiguous null. Because the cardioid law yields a poorer bearing resolution, i.e., differential amplitude to angle ratio, in the region of its null as compared to the cosine law null region, the cardioid is rarely used for other than sense determination.

Receiver-introduced modulation for quadrature-effect suppression (see reference 6), which has recently been developed, possesses several advantages over the balancer type. It operates on the principle of phase discrimination for the undesired quadrature component. Phase discrimination is accomplished by introducing the voltage e_1, derived from the non-directional antenna, into the DF as a reference voltage of proper amplitude and phase with respect to the directional voltage, e_2. The directional voltage e_2 is then passed through a mechanical or electronic reversing switch just before it is added to e_1. The resultant e_3 has a maximum $+e_3$ and a minimum $-e_3$ value depending upon the position of the reversing switch as shown in Fig. 3(*a*). It will be noted in Fig. 3(*b*) that the undesired or quadrature directional antenna voltage component e_2', after passing through the common reversing switch, is also vectorially added to e_1. The resultant e_3' thus also has values $+e_3'$ and $-e_3'$ depending upon the position of the reversing switch. However, it will be noted that the desired directional voltage $\pm e_2$ causes a maximum differential effect on e_3, whereas the undesired or quadrature directional voltage $\pm e_2'$ causes a minimum (zero) differential effect on e_3'. Moreover, for small values of quadrature, the magnitude of $+e_3'$ differs negligibly from e_1. Thus, if e_2' is 10 per cent of e_1, $\pm e_3 = \sqrt{(1)^2 + (0.1)^2} = 1.005$, or the presence of 10 per cent e_2' causes only 0.5 per cent increase in e_3 over e_1. By utilizing suitable synchronous commutators, or sweep circuits with a cathode-ray tube, the maximum and minimum resultant voltages $\pm e_3$ can be compared and the desired sharp null position of the collector can be obtained just as readily with considerable quadrature voltage present as when none is present, since the entire quadrature suppression is continuous, automatic, and independent of the operator. It should be noted that positive sense determination is continuously present in this type of system since the non-directional reference voltage, e_1, is automatically a sense voltage, and sense is obtained merely by correlating the instantaneous position of the reversing switch with an increasing (or decreasing) resultant output. It can be shown that the receiver-introduced-modulation principle markedly improves the signal-to-noise ratio (or the bearing sensitivity) by integrating out the random (non-synchronous) noise effects. It can be effectively demonstrated that satisfactory DF bearings can be obtained on broadcast program modulated signals notwithstanding noise levels that obliterate the program intelligence. The cathode-ray tube comparator for "on bearing" indication in some U. S. Navy direction finders is especially desirable for obtaining indication on ICW transmissions. When CW or MCW transmissions are employed the entire DF bearing may be taken automatically by employing a suitable controlled servo system to orient the directional collector for minimum difference in $+e_3$ and $-e_3$. This identical principle is employed in the automatic direction finder (ADF) described in article 3 under Aids to Air Navigation, and as a second mode of operation in the Navy DBD MF/DF system, the latter being especially designed for simplified marine use. Both the balancing and the modulator suppression of quadrature effects may, under certain conditions, introduce a deviation effect. This may occur when a large quadrature (undesirable) voltage, e_1', is induced in the non-directional antenna. This condition, and its amount, can be quickly identified by a shift of the reciprocal bearing (i.e., observed bearing plus 180°) from its normal 180° position. Since this effect is almost identical to, and originates from, the same mechanisms responsible for the normal Deviation, it is as stable as the latter, and can be absorbed by the overall DF calibration when made.

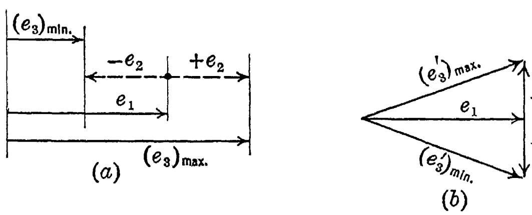


FIG. 3. Vector Relations for Quadrature-effect Suppression by Modulation Method

Calibration Curves. A conventional DF calibration curve is shown in Fig. 4(*a*) which is generally taken for a few of the most received frequencies. The same data can be presented in the automatic interpolation (see reference 5) form shown in Fig. 4(*b*). The latter form permits more direct plotting and utilization of the calibration data with the great

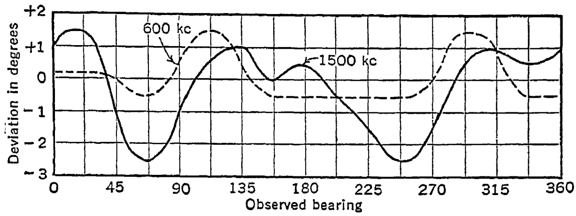

FIG. 4(*a*). Conventional Deviation Chart for Direction-finding Calibration

advantage that the corrected bearing of other than calibrated frequencies may be ascertained just as conveniently as that of the calibrated frequencies.

Polarization Effects. Radio waves propagated with their electric field vertical have become known as *vertically polarized* waves; those having their electric field horizontal

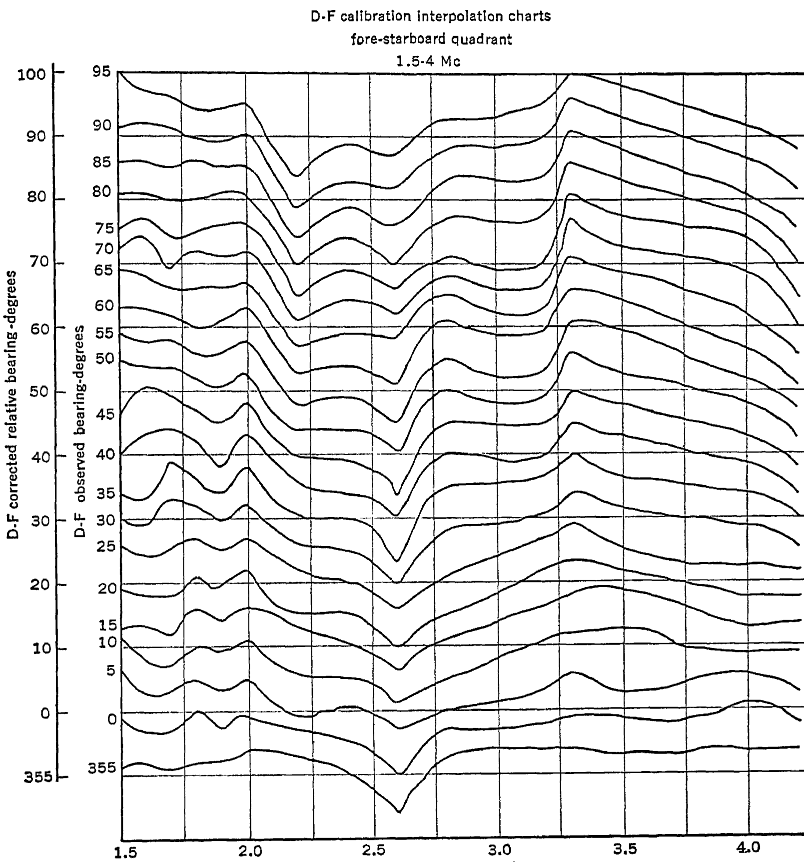

FIG. 4(*b*). Automatic Interpolation Chart for Direction-finding Calibration

have become known as *horizontally polarized* waves; those having their electric field inclined are a combination of both types. Experience shows that most direction finders are susceptible to appreciable unwanted polarized energy pickup, notwithstanding the care taken to exclude it from the antenna and feeder system. For a discussion of this effect and its cure see Section 6, article 32.

WEATHER AND TIME TRANSMISSIONS. Radio navigational warnings and standard time signals are available to all ships equipped with communication receivers. The navigational warnings include the local weather forecast plus any urgent information with regard to tidal waves, offshore winds, ice, and storms.

10. RECENTLY INTRODUCED NAVIGATIONAL AIDS

RADAR. (See references 7–12.) Present radar systems provide one of the few known, yet most reliable, methods for surface-obstacle detection under conditions of restricted visibility, whether these obstacles are other ships, icebergs, buoys, islands, landmarks, etc. Radar provides, in effect, an electronic searchlight aboard ship, capable of "seeing" through darkness or fog, in any weather condition, for ranges up to approximately 25–30 miles (line of sight), depending on the power of the "searchlight." The use of radar, therefore, will be most applicable to collision prevention at sea, iceberg detection, harbor navigation, coastal navigation, and harbor control from shore stations.

Table 2 lists minimum specifications for marine navigational radar. These specifications suggest the use of PPI (plan position indication) presentation of the echo information (see Section 15, article 24).

Table 2. Performance Factors for Some Marine Navigational Radars

Performance Factors	U.S.C.G. Class A Spec.*	Manufacturer A	Manufacturer B	U.S.C.G. Class B Spec.†	Manufacturer C	Manufacturer D
Maximum range	30 miles	32 miles	40 miles	30 miles	30 miles	50 miles

† Class B corresponds to U.S.C.G. Minimum Specifications, Brief No. 2, Nov. 14, 1945 (revised Aug. 1, 1946).

Principles. A short powerful burst of electromagnetic energy is emitted at a known spot and is narrowly beamed in a given known direction. Returning echoes from objects within an arbitrary range in that given direction are received at the known spot, detected, and visually displayed. For persistence and continuity of display, the emitted pulses are repeated periodically at a fixed rate with enough intervening time to allow the return of any echoes. If an echo from an object is received by the system after a time delay, T, from the initial burst, the distance of the object from the radar system is:

$$d = \frac{cT}{2} \tag{3}$$

where c is the velocity of light (or electromagnetic waves) in air and where the time T is measured from the beginning of the transmitted burst to the beginning of the received echo. Thus, the distance to the object is determined. If the antenna system is sufficiently directive, the pointed direction of the antenna at the time an echo is received is the direction of the echo, thus furnishing a bearing determination.

Unless the wavelength of the radiations used is small compared with the linear dimensions of the reflecting object, the phenomenon of diffraction takes place, making the echo amplitude inversely proportional to the square of the wavelength. If the wavelength is small compared with the reflecting object, the amplitude of the echo field does not sensibly depend upon the magnitude of the wavelength but rather upon the nature of the reflecting object. In the case of the free-space propagation between the radar system and the reflecting object, the following relationship holds:

$$P_r = \frac{A_0 G_0 P_t K}{(4\pi)^2 r^4} \quad \text{or} \quad r_{\text{max.}} = \sqrt[4]{\frac{A_0 G_0 P_t K}{P_{\text{min.}}(4\pi)^2}} \tag{4}$$

where P_r is the received power at the receiver input terminals (watts), A_0 is the effective absorption cross-section of the receiving antenna (square meters), G_0 is the overall power gain of the feeder and the radiating antenna, P_t is the transmitter peak power (watts), K is a complex reflection coefficient dependent on the nature of the target and is given as the effective echo area of the target in the direction of the radar (square meters), r is the distance in meters from the radar to the target. The second form of the equation is in terms of the maximum range, $r_{\text{max.}}$, and the minimum detectable power received, $P_{\text{min.}}$. These results for free space propagation must be modified for propagation over a spherical earth since, in the range of frequencies used, electromagnetic waves are propagated over approximately a "line of sight" path with small diffraction effects occurring at the lower radar frequencies. Thus, the antenna height above the sea, the target height above the sea, and the height of any intervening objects must be taken into account.

From these considerations, it is evident that, in order to utilize efficiently the principles of reflection with electromagnetic waves, a radar system must (1) generate a wave whose length is small compared with the objects from which the wave is to be reflected; (2) generate enough power at that frequency to be able to receive and detect the returning signal; (3) provide a means of measuring the time delay from the transmission to the reception of that signal.

Fundamental System Constants. Each radar system has associated with it certain constants whose choice depends upon the available components, the desired operational performance, and the intended use of the system. The normal variations of these constants are as indicated in the following:

(*a*) *Carrier Frequency.* The choice of carrier frequency depends on the permissible dimensions of the antenna system to be used and the directivity or beam sharpness desired, since the size of the antenna system reduces with increased frequency, and the directivity, as well as gain, improves with frequency for a given antenna size. Thus the lower frequency is limited by the practical antenna size; the upper frequency is limited by atmospheric reflection and absorption effects (pronounced near 3000 Mc or 10 cm wavelength for reflection and 30,000 Mc/s or 1 cm wavelength for absorption) and the availability of tubes capable of generating and amplifying enough radio-frequency energy to provide the necessary range. The lower frequency limit is about 100 Mc, though frequencies higher than 30,000 Mc have been successfully used experimentally.

(*b*) *Transmitter Pulse Width.* The minimum range at which an object can be detected by a radar system is determined largely by the width of the transmitted pulse (at the $^1/_2$ power point) since an echo returning while the transmitter is still operating will be masked by the transmitter pulse. This is even more true if the receiver is always blocked or desensitized for the duration of the transmitter pulse. The usual pulse widths range from 0.25 to 2.0 μs for navigational purposes.

(*c*) *Pulse Repetition Rate.* The pulse repetition rate must be slow enough to allow time for the maximum range echoes to return to the antenna before another pulse is transmitted, and it must be fast enough to provide enough traces while the antenna is rotating or pointing in a given direction to produce a lasting indication on an oscilloscope screen. Therefore the maximum range determines the highest pulse rate, and the rotational speed of the antenna determines the lowest pulse rate that can be used. In practice these rates vary from less than 60 to several thousand pulses per second.

(*d*) *Duty Cycle.* The duty cycle of a radar system is the ratio of the average power to the peak pulse power. It depends on the relation between pulse width and the pulse-repetition time. Thus a lower duty cycle permits higher peak power operation at the same average power. The maximum range of the system is dependent on the peak power for a given pulse width, while low average power means smaller tubes and components in the transmitter. The limit to peak power, however, for a given transmitter tube is the breakdown potentials between the various electrodes. In practice, radar duty cycles vary between 0.005 and 0.0001.

Fundamental System Components (General). Radar systems now in existence differ widely in detailed design and complexity, depending on their functional use and the accuracy and amount of information required. However, a single basic system can be visualized in which the functional requirements fit equally well almost all specific requirements.

The six primary components are shown in Fig. 5; they may be summarized as follows:

(*a*) *Timer or Synchronizer.* The timer determines the pulse-repetition rate of the radar and provides a zero reference point for time measurements and for operation of sequential functions in a definite time relationship. Such timing may be supplied by a separate unit such as a sine-wave oscillator, a multivibrator, or a blocking oscillator with the necessary pulse-shaping circuits. Another commonly used method of timing is to make the transmitter with its associated circuits establish its own repetition rate and provide the synchronizing pulses for the rest of the system. This action may be accomplished by a self-pulsing or blocking radio-frequency oscillator, or by a rotating spark gap. Self-timing eliminates a number of special timing circuits, but the pulse width and pulse-repetition rate are not usually as stable or rigidly controllable as is necessary for some applications.

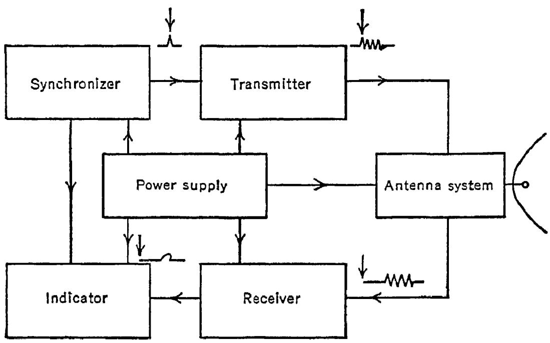

FIG. 5. Functional Block Diagram for Basic Radar System

(*b*) *Transmitters.* To generate pulses of high-frequency electromagnetic waves at high power levels a conventional pulse transmitter is used. Care must be taken that the tubes are suitable not only for the average power dissipation but also for the high powers and voltages during the pulse.

(*c*) *Antenna System.* The purposes of the antenna system are to beam and radiate the energy efficiently from the transmitter into space, to focus and pick up the returning echo and pass it on to the receiver. A transmit-receive switch (TR box) must be included to prevent the transmitter energy from harming the receiver.

(*d*) *Receiver.* A conventional wide-band receiver is used.

(*e*) *Indicator.* To display the detected pulses visually so that range, bearing, or elevation of any echo source, or combination of these, can be determined. See Section 15, article 24.

(*f*) *Power Supply.* A conventional well-regulated low-impedance power supply is used. Pulse-forming lines build up a charge during the inactive period to store energy to discharge in the pulse.

Performance Factors. (*a*) *Resolution.* The resolution of obstacles by a radar system will depend on the pulse width, the effective antenna beam width, the receiver band width, the frequency, and the stability of the entire system. For a typical commercial navigational radar in the 3-cm (10,000-Mc) band, having a receiver band width of 8 Mc/s, antenna beam width of 2° (to half power points), and a pulse width of $^1/_4$ μs, the resolution is 100 yards in range and 3° in azimuth. Above approximately 1000 Mc/s the frequency is not a major determining factor in itself, but only as it affects the other factors, since the wavelength is small enough to provide efficient reflection from the smallest objects ordinarily encountered.

(*b*) *Maximum and Minimum Range.* The maximum range will depend on the height of the antenna system above the sea, the power output of the transmitter, and the gain and efficiency of the antenna system. An average ship installation would have a maximum range of from 25–30 miles, which is, in general, great enough for the intended navigational use. The minimum range will depend directly on the pulse width and recovery time of the receiving system (including antenna switching mechanism); for the typical commercial system mentioned above, it is 100 yards. The radar indicator is usually provided with a range switch permitting any of several discrete ranges to be displayed on the screen. The accuracy of the range information depends on the initial accuracy and stability of the range markers; azimuthal accuracy usually depends on the accuracy of tracking between the antenna rotation and the sweep rotation on the cathode-ray tube face. Accuracies of 2 per cent in range and 2° in azimuth are not unusual.

(c) *Presentation.* The most usable form of the radar information for marine navigational purposes is the PPI type presentation on a screen of 5 to 9 in. in diameter, with provision for true or relative bearing stabilization, range markers, and range scale selector. The ratio between different range scales is often made the same.

(d) *Installation, Maintenance, and Operation.* The present radar systems are designed for operation by bridge personnel having little or no technical training. The indicator is mounted in the pilot house, and the antenna is properly located to provide 360° clearance to the horizon. To facilitate this arrangement on all types of vessels, the radio-frequency components, the antenna assembly, and the indicator are usually manufactured as separate units.

RADAR-BEACONS (RACON). (See references 10–12.) Radar piloting is beset by two important problems. First, targets for navigational purposes are sometimes small or poorly defined, resulting in small or weak echoes, especially near the maximum range of the radar system. Secondly, these weak echoes in the presence of sea return often leave the absolute identification of the navigational targets in doubt. These problems are greatly simplified, however, by providing a system of electronic beacons designed to serve as aids to navigation for ships equipped with the proper radar equipment. The term Racon, a contraction of *ra*dar-bea*con*, designates such a system. These beacons or racons are designed to emit or reflect a large amount of energy which will allow dependable target indication at a much greater distance than that obtainable when normal reflections alone are depended upon. There are three types of such beacons, and each is described below:

Radar Respondor-beacons (Transpondor). These racons consist of transpondors, or pulse-type receiver-transmitters, located at strategic ground sites such as coastal points and islands, which receive interrogating signals from a radar transmitter and automatically send back identifying reply pulses to the radar. The coded reply appears on the radar oscilloscope in such a way that both position and identification of the racon station are indicated. Reference to prepared code lists or charts then serves to associate that respondor-beacon with a fixed navigational point. Thus a navigator will be able to check his course, or even completely guide his craft, since range, bearing, and identification will be obtained from each respondor-beacon. A typical radar and fixed station microwave racon transpondor operation is shown in the block diagram in Fig. 6.

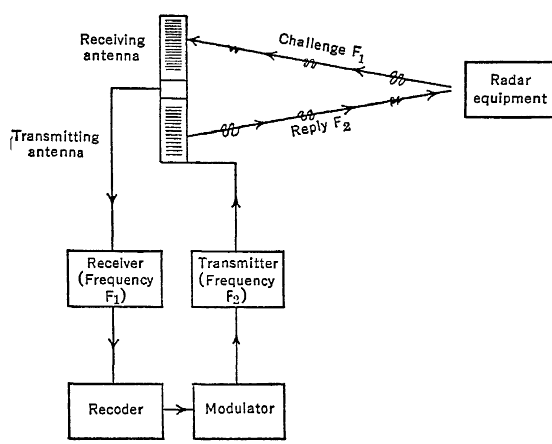

FIG. 6. Functional Block Diagram of Basic Racon System

To prevent racon signals from appearing on the radar screen all the time, and to avoid continual interrogation of the beacon by radar, the system is designed to operate under the following conditions: (1) the beacon responds only to pulses of 2-μs or greater duration within an appropriate frequency band; (2) the beacon replies at a fixed frequency which is common to the entire beacon system and which is just outside the radar system frequency band. Ten-centimeter band racons respond to 2-μs challenging pulses in the 3000–3246 Mc/s band and reply at 3256 Mc/s; 3-cm band beacons receive pulses in the 9320–9500 Mc/s band and reply at 9310 Mc/s. An additional band near 5 cm is being made available for radar and racon use. For racon system use, the radar equipment is designed to provide the necessary challenging pulse length and the correct receiver tuning upon activation of a special button or switch. The normal radar plot will then disappear and only radar-beacon responses will appear on the screen.

Three types of coding, to insure positive identification of a given respondor-beacon, have been devised: (1) Sequence coding is provided by emitting a number of half-second transmissions whenever the beacon is triggered. During the half second, pulses of a given duration appear as a pip of a certain width on the scope. However, the pulses making up the next transmission may all be of longer duration, thus giving a pip of greater width on the scope. The complete code is made up of the number and combination of widths of these pips. (2) Gap coding provides periodic interruption of a series of pulses. During each period of interruption, identification is given by a pulsed dot and dash transmission. Both sequence and gap coding are slow, requiring considerable time for complete identification. (3) Range coding gives an immediate identification as the complete code is produced on the oscilloscope at once. Each reply, caused by one interrogation pulse, consists of six pulses which appear on the PPI at different positions along a given bearing with the first pulse indicating the beacon position. Such coding is accomplished by changing the spacing of the pulses.

Separate broadside arrays serve as receiving and transmitting antennas for the transpondor. Both are non-directional in the horizontal plane in order to respond to interrogations from any point on the compass, but have a narrow low-angle vertical pattern to facilitate long-range operation. From the receiving antenna the received radar signals go to either a crystal-video or superheterodyne receiver which must satisfy the following requirements: (1) the radio- and intermediate-frequency stages must be broad-band in order to receive signals at any frequency within a given radar band (10-cm or 3-cm, but not both); (2) the video stages must not excessively widen 1-μs radar pulses; (3) the receiver must not be easily blocked; (4) the amplification must be adequate for the received radar signals. The output of the receiver goes to a recoder which consists of a discriminator, coder, and gate multivibrator. The discriminator accepts variable amplitude pulses of 2-μs or greater duration but rejects all pulses of shorter duration. The coder (in this case, a range coder) consists of six start-stop multivibrators whose outputs are combined in an amplifier to produce a series of pulses. The code may include a maximum of six pulses with 15- or 35-μs spacings between successive pulses. The gate consists of a 175-μs negative rectangular pulse that is fed back to the discriminator, where it prevents the coder from accepting other receiver video signals until after the completion of one range-coded transmission. The pulses from the coder are applied to a modulator where they are converted into very large amplitude rectangular pulses of $^1/_2$-μs duration. The modulator triggers a transmitting magnetron that oscillates at the proper reply frequency. To insure operation exactly on the radar transmission frequency, an automatic frequency control circuit is used to keep the magnetron in tune. Minimum peak powers of 10 kw are used, while some racons operate at peak powers as high as 40 kw.

Transpondor beacons of the type described, and radar equipments which use them, must be designed as "sister" equipments, as each is dependent upon the other. For this reason the Coast Guard's specifications for commercial radar equipment recommended that provisions be made for convenient future modifications of the radar for use with racons or microwave beacons. Considerable investigation and development work has been under way to permit adaptation of the wartime racon system to general marine navigational purposes.

RADAR MARKER BEACONS (RAMARK). A second type of radar beacon consists of a simple shore-based, continuously pulsed beacon operating on a single frequency. Rather than being interrogated by the radar pulses, this type continuously transmits, and the radar need have only a means for receiving the beacon frequency when it is desired to utilize the beacon. This eliminates the necessity for sending out 2-μs pulses and simplifies the ground equipment so that it acts in much the manner of the present low-frequency radiobeacons. The navigator sees, on his PPI, a line extending radially from the center to the periphery of the scope on the bearing of the beacon. Two beacons are needed to obtain a fix since no range information is provided. The means of identification is the location of the aid with respect to the naturally distinguishable land contours shown on the radar. Additional means of identification have been considered also, e.g., groups of pulses, known repetition rates, or modulation of the signal with an audio code, but these require additional modifications to the radar.

RADAR REFLECTOR BEACONS (CORNER REFLECTORS). A third type of beacon classed as a racon is the "corner reflector," which is merely a mechanical assembly of sheet-metal faces, designed to give the maximum reflection of energy received from any given direction over fairly wide angular limits. The reflector is inexpensive and easy to construct and maintain. These devices have no means of identification other than their prominent echoes on the radar screen and the fact that their positions can be plotted on charts. The great simplicity and economy of such a scheme suggest its use wherever feasible. In rough weather, however, it may be very difficult to distinguish its return through the ground clutter.

LORAN. (See references 11, 13, and 14.) The accelerated development of radar and other electronic equipments during World War II has reduced to relatively simple operational procedures the accurate measurement of radio transmission propagation time. This has resulted in the introduction and wide use of two important radio position-determining systems utilizing this propagation time principle, i.e., Loran and Gee. In these systems, a position fix is obtained from the intersection of two loci of position, each locus of position being determined by measuring the *propagation time difference* between two synchronized pulsed signal emissions arriving from two known but widely spaced radio transmitting sources. Since the velocity of propagation of radio waves over the earth's surface is essentially constant, propagation-time-difference measurement varies directly as the distance difference between a receiving station and two fixed transmitters. Therefore, the locus of points which are a given constant time difference from two fixed points is a hyperbola with the fixed points as foci. Thus the two transmitting stations or fixed points provide a family of hyperbolas about the stations, each hyperbola representing a constant value of propagation time difference. Position-fixing methods which use such a family of hyperbolas can be classed as hyperbolic systems, and, in addition to Loran and Gee, they include the Dingley system, Decca, and Popi. These last two systems utilize hyperbolas derived from constant propagation phase differences (identical in principle to optical interference phenomena) instead of constant propagation time difference, whereas the Dingley system utilizes hyperbolas derived from constant propagation frequency differences.

STANDARD LORAN. This system operates at approximately 2 Mc/s and utilizes ground wave and/or single hop *E* layer paths of transmission. Special charts are provided having Loran hyperbolas superimposed on geographical maps. Figure 7 shows a partial example of Loran hyperbolic charts. In practice, a master (or A) station transmits 40-μs pulses at a given repetition rate. These pulses serve to synchronize a slave (or B) station several hundred miles away so that the B station also transmits 40-μs pulses at the same repetition rate, but delayed in time by the travel-time between the two stations plus the B station's system delay. The reception and presentation of these transmitted pulses aboard ship by means of a special Loran receiver and indicator permit measurement of their time difference, and from that information the appropriate Loran chart will give the correct corresponding hyperbolic line of position. A separate operation on a second pair of Loran transmitting stations provides a second position curve, and the intersection of these hyperbolic curves on the special charts establishes a "fix." A block diagram of the Loran system is shown in Fig. 8.

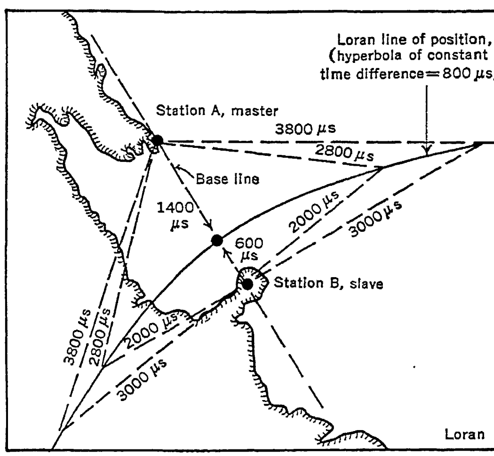

FIG. 7. Loran Hyperbolic Line of Position

Transmitting Equipment. The Loran transmitting stations generally operate as a group of four stations. Each station would normally consist of a timer and a transmitter. The timer establishes a very precise pulse rate by utilizing 50 kc/s or 100 kc/s crystal-controlled oscillations of very high accuracy, which are divided down to provide basic pulse rates of 25 pps and $33^1/_3$ pps. These timing pulses trigger an exciter which generates the 40-μs pulses for modulating the transmitter. The transmitter itself is a self-excited, tuned-grid, tuned-plate, push-pull unit, pulse modulated in the cathode circuit and oscillating from 1750 to 2000 kc/s. To provide precise synchronization, to conserve equipment, and to reduce maintenance, a single transmitter is usually employed as a master station which synchronizes two different slave stations, on the same frequency, but at different repetition rates. This is accomplished by providing, at the transmitter, two separate timers (each of which is independently referenced, for convenience, to the precise time signals from station WWV), two exciters, and a mixer stage preceding the modulator. The duty cycle of this double-pulsed transmitter system is approximately 80 μs in every 40,000 μs (25 pps), or 0.2 per cent. The transmitter, operating at about 100 kw peak power, feeds a 120-ft guyed radiator in the standard installation. In case of damage by windstorm, etc., an emergency T antenna is provided. The slave-station emitting equipment is identical to that of the master station, and suitable means are provided at the slave station for properly receiving the master station signals and for effecting the necessary precise synchronization of the slave-station pulses.

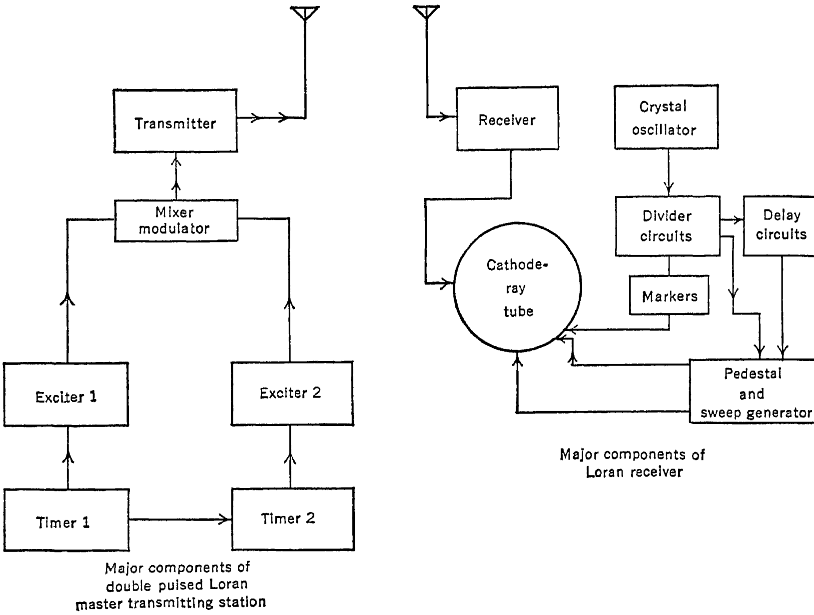

FIG. 8. Functional Block Diagram of Basic Loran System

RECEIVING EQUIPMENT. The craft's receiver-indicator equipment is usually furnished with a 50- to 60-ft vertical antenna leading to a medium-frequency receiver having a band width of 50 kc/s to pass the 40-μs pulses, and a 50-kc video output stage. To insure maximum range reception, the receiver must have enough sensitivity and gain to provide full screen deflection with 10 microvolts into the receiver. The indicator provides the necessary timing circuits to measure pulse separations with the required 1-μs precision. A 100 kc/s precision oscillator with associated dividers supplies a sequence of precise index timing markers at appropriate intervals, with a basic accuracy of ± 1 μs. It also contains the delay and deflection circuits for displaying the received pulses or the timing markers on the oscilloscope screen. The actual method of presentation is to provide separate paralleled sweep traces on the scope screen, one for the train of A station pulses and one for the train of B station pulses, with the index markers appearing simultaneously on the screen with the station pulses. Since more than one Loran transmitter may be operating on the same carrier frequency, pulses from all these stations will appear on the indicator screen. Therefore, the indicator includes timing and sweep circuits which provide precise repetition rates corresponding to the desired transmitter's repetition rates. This procedure synchronizes the indicator to the pulses of only one transmitting pair of Loran stations while the pulses of all others continuously drift across the screen and do not interfere with the desired stationary pair of pulses.

The exact amount of time delay between the slave and master pulses can be measured from manually incorporated time delay circuits required to make both these pulses coincide on the screen. The accuracy of measurement depends on the stability of the circuits which provide timing markers on the face of the oscilloscope. To facilitate this, an expanded or fast sweep is provided, enlarging the picture of the pulses and making the pulse-matching procedure accurate to approximately 1-μs, since the 10-μs marker spaces can be estimated to tenths. A typical presentation is shown in Figs. 9(*a*) and 9(*b*). A receiver refinement introduced by the Sperry Gyroscope Company permits the local time delay (equivalent to the time difference) to be read directly in microseconds on a Veeder-type counter. The currently available shipboard receiver-indicator equipment weighs between 125 and 235 lb, although the corresponding airborne equipment is a comparatively small unit weighing approximately 25 lb. Both types consume 200 to 300 watts from a 115-volt power source.

Performance. When used over water Loran can provide navigational fixes up to 750 nautical miles in the daytime and up to 1400 nautical miles at night. The daytime range is the limit of ground-wave propagation at the frequencies and power used. At night, pronounced reflection effects from the E layer of the ionosphere provides the additional range. Fortunately, this ionospheric reflection introduces only small errors which are compensated by known correction factors and allowed for in the Loran charts. When the ship is in a position to receive both ground- and sky-wave transmission, the indicator will show two or more sets of pulses where the first set is the ground-wave pair and the others are various sky-wave reflections as shown in Fig. 9(a). Such reception does not interfere with the fix determinations. The average operating accuracy of present systems is better than 0.5 per cent of the distance measured, e.g., less than $2^1/_3$ miles in 500 miles, but deteriorates somewhat along the base line of the transmitters. The accuracy depends on the location of the transmitting stations, the stability of the timing circuits, and the experience of the operator in matching pulses and estimating time between 10-μs markers.

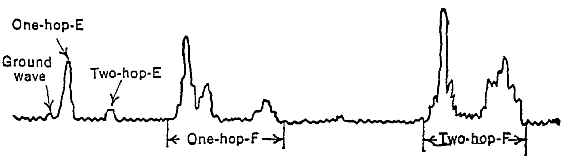

Fig. 9(a). Typical Ground Wave and Sky Wave Pulse Sequence from One Station. Signals to the right of the One-hop-E are generally disregarded.

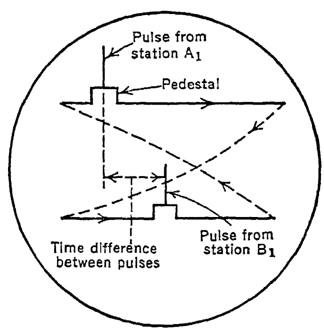

Fig. 9(b). Basic Loran Indicator Pattern. A calibrated time difference (or delay) mechanism and an expanded sweep are used to obtain 1 microsecond accuracy.

Since the system depends upon the measurement of time differences rather than upon direction of propagation, it is not subject to the usual errors encountered in direction-finder systems. Factors affecting the propagation from a master station will, in general, also affect the propagation from its slave station. This is especially true as the range *increases*, since the two paths then become approximately parallel. At the close of the war, the military Loran system comprised 40 transmitting stations located at strategic geographical points, with an additional 10 under construction; these systems supplied information to receiver-indicators installed on more than 3000 surface vessels. Among the improvements which are desired and may be expected in the near future are the following: (1) higher-power transmitting stations (about 1000 kw), (2) crystal-controlled oscillators to provide more stable carrier frequencies, (3) different methods of station synchronization and pulse-shaping circuits, and (4) a totally automatic receiver-indicator system requiring a minimum of technical operating skill and experience. These improvements are desired in order to overcome the present disadvantages of: (1) limited range, especially in the daytime, (2) the undesired synchronization upsets caused by ionospheric disturbances, (3) the need of a specially trained operator for interpretation and maintenance. In addition, experimental studies are being conducted (see below) on LF Loran which is an adaptation of standard Loran to the very low-frequency range.

SS LORAN. This system (*s*ky-wave *s*ynchronized Loran) is operable during the night only and is identical to standard Loran except that master and slave stations are separated by 1000 to 1200 nautical miles instead of the usual 200 to 300 nautical miles. Such a long base line requires synchronization of master and slave stations by sky waves, since, at the operating frequency of 2 Mc/s, the range of the ground-wave propagation is less than the base line itself, so that SS Loran can be used only at night, when sky waves are strong.

LOW-FREQUENCY LORAN. To provide greater daytime range, a modified Loran system has been designed which operates at about 180 kc/s and offers the following propagation advantages: (1) at these low frequencies the propagation range of ground waves is increased, especially over land; and (2) sky-wave reflections become much more stable, to such a degree that they can more readily be interpreted by a navigator. This stability results from the fact that radio-frequency energy at these frequencies does not penetrate the E layer of the ionosphere and thus the long trains of multiple night time sky waves, present at 2 Mc, are absent. Hence, the 180 kc/s sky-wave receptions are much more useful to the operation of the Loran system and it appears possible to obtain ranges of 1000 or more miles for satisfactory, stable operation for day or night over land or sea. However, resolution (separation) between the ground-wave and various sky-wave receptions deteriorates and affects the accuracy of the system. At very low frequencies (below 180 kc/s), ground waves are even less attenuated, and very reliable propagation over thousands of miles can be expected. However, because very wide-band antenna systems are not available at the very low frequencies in view of their prohibitive size and because of current limitations of wide-band and pulsed techniques, the pulse principles inherently required in Loran have not yet been adapted to the very low frequencies employed. In view of these factors it seems that 100–150 kc/s is about the lowest usable frequency range in which pulsed systems such as Loran can be employed, with the pulse length increasing to about 300 μs.

GEE SYSTEM. The British Gee system of navigation operates in the 20–85 Mc/s frequency range, on the pulse-propagation-time-difference principle. In nearly all respects it is the higher-frequency counterpart of the Loran system and was independently developed by the British. The essential differences of the Gee system are: (1) higher operating frequency and consequent reduction of range; (2) three-slave-station operation instead of two; and (3) simultaneous presentation of two propagation time differences in order that a position fix can be determined in one initial receiver operation.

CONSOL (BRITISH) AND SONNE (GERMAN). (See references 15 and 16.) Consol or Sonne is proposed as a medium-range navigational aid of the rotating beacon class. Radio navigational aids of this class operate in much the same manner as a directional searchlight which revolves at a known and constant rate with the addition of a non-directional visual light signal marking the instant that the revolving light passes through true north. The observer, at the point where the line of bearing to the beacon is to be determined, needs only to employ a stop watch to measure the time interval between the reception of the non-directional light signal and the searchlight signal, after which the desired azimuth angle is computed from the product of the known angular rotational speed and the time interval. In the Consol system dots and dashes are put into the rotating antenna pattern so that a stop watch is not needed. The observer simply counts the number of dots and dashes between the "north" pulse and the equisignal, and obtains his azimuth from the station thereby. A variation of this rotating-beacon principle consists of directly imparting the desired azimuthal information to the light beam proper via correlated modulation methods, e.g., by coding, intensity modulation, or frequency modulation. Completely analogous rotating *radio* beacon systems have also been used. For low and medium frequencies, large rotating antennas, or fixed antennas (e.g., Adcock type) with rotating goniometer arrangements transmitting a cosine-law or cardioid pattern, have been used. In other systems a cardioid or cosine-law modulation pattern has been transmitted, utilizing a receiver with a pattern synchronized cathode-ray sweep for an automatic indicator. Generally, radio frequencies in the VHF and UHF regions have been favored because rotating antennas of reasonable dimensions can be more conveniently built to give the desired sharpness of beam width to the predominantly single lobe radiation pattern usually employed. The necessarily high carrier frequency of these systems unfortunately limits them to line-of-sight ranges. Consol or Sonne, on the other hand, is a rotating-beacon system that operates in the 200–500 kc/s band and provides an accurate medium-range facility. Use is made of an ingeniously employed rotating multilobe radiation pattern such that sharp bearing resolutions are realized at these ranges.

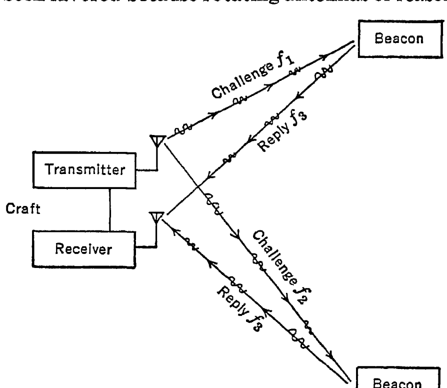

FIG. 10. Functional Block Diagram of Basic Shoran System

SHORAN. (See reference 17.) The Shoran, or *sho*rt *r*ange *n*avigation, system operates on the principle of echo ranging on two spaced beacons of the radar-respondor type. It combines the accuracy of propagation-time measurement with simplicity of operation and reliability of equipments.

Briefly, Shoran position "fixing" requires the measurement of the round-trip transmission times, in terms of range or distance, of two sets of short radio-frequency pulses transmitted by the craft, each set interrogating a known shore radar respondor-beacon station which retransmits the pulses back to the craft. Since each echo range defines an arc of fixed radius from each known radar respondor-beacon position, the intersection of these arcs determines the craft's location. The resulting double ambiguity, as in Loran and Gee, can usually be easily resolved. The two sets of pulses are transmitted from the craft on separate frequencies as shown in Fig. 10. Upon interrogation, both ground beacon stations retransmit on a common frequency that is different from either of the signal frequencies radiated by the craft. The returned pulses are then received and displayed by the craft's equipment. The crystal-controlled repetition rate is the precise yardstick in terms of which the craft to respondor-beacon distances are measured, and all interrogating transmitters use this same repetition rate.

DIRECTION-FINDER SYSTEMS (HF-VHF-UHF). (See references 18, 19, and 20.) Until recently direction-finder systems at these frequencies were quite unreliable. Primarily, this poor operation has been caused by resonant reradiation from structures near the DF collector. Since a grounded metallic structure will resonate approximately as follows:

$$f_{(\mathrm{Mc/s})} = \frac{246}{(h)_{\mathrm{ft}}} \tag{5}$$

structures between about 8 ft and 165 ft high will have a resonance somewhere in the 1.5 to 30 Mc/s frequency band. (See Environmental Effects, p. 22-39.) On the basis of these analyses shipboard HF/DF can now be installed with average errors of 5–10°.

In view of their poor accuracy compared to the 1° to 2° shipboard MF/DF accuracy, it is not likely that shipboard HF/DF will be widely employed for other than military intercept and location applications.

Shore stations (see reference 20) of 100 Mc/s direction finders employing a vertical spaced Adcock collector, a spinning goniometer, and a cathode-ray-type automatic indicator have given a 2–3° accuracy with line-of-sight range. At 8 Mc/s planes have been tracked from the United States to Northern Africa. For the ultra high frequencies 90 to 5000 Mc/s systems use a spinning reflector-type collector (dish) system in lieu of the fixed Adcock and goniometer arrangement. In general these are not too efficient in the 90 to, say, 200 Mc/s range but rapidly improve for the higher frequencies.

SONAR. (See references 21 and 22.) Sonar, or *so*und *na*vigation and *r*anging, which is the field of underwater sound navigation, has been applied in a manner similar, in principle and in electronic circuits, to radar in the field of radio navigation; the principal difference is the medium of propagation. The two main types of underwater sound aids in use are: (1) the vertical projectors called echo sounding or depth finding aids; and (2) the horizontal projectors known as echo ranging units.

Echo sounding equipment transmits sound pulses vertically downward from a projector placed in the bottom of the ship, or lowered from the side of the ship, and receives the reflected pulses from the bottom of the ocean or waterway, giving a direct and constant running record on graph paper of the depth of water beneath the boat's keel. Present commercial equipment has a range of 1000 fathoms or less and is used to navigate channels, rivers, and other waterways and to obtain data for charting the depths of these various waterways. Information necessary for the plotting of charts having contour lines of constant depth is gathered by the Coast and Geodetic Survey and is published by the Navy Hydrographic Office as an aid to marine navigation. This type of equipment has also been successfully used by fishing boats to locate schools of fish, as they also reflect sound pulses.

Echo ranging equipment transmits sound in a pattern which is conically beamed. It searches in the horizontal plane from a projector which can be rotated through 360°. Originally, the term Sonar implied the use of ranging equipment only, but it now designates almost any type of underwater sound equipment regardless of its use. This equipment was originally developed for the U. S. Navy for detecting submarines and surface ships, but it can obviously be used in the same manner for navigational and anticollision purposes. It presents the distance from the ship to an object, directly in yards, on a cathode-ray range indicator, and the bearing of the object with respect to the ship's position on a bearing indicator compass.

11. CONTEMPLATED AND PROPOSED NAVIGATIONAL AIDS

LANAC. The Lanac or *la*minar *na*vigation and *a*nti*c*ollision system is a method of electronic navigation, developed since the close of the war, which proposes a unified radar and identification navigational system for both marine and air use (see article 6), utilizing a minimum of equipments. The Lanac system provides target identification, coded radar beacon, and radar search operations from the same basic equipment. Essentially, the proposed system comprises a challenger and a replier, operating at approximately 1000 Mc/s, as shown in the block diagram Fig. 11. The challenger can also be operated as a low-power search radar, for auxiliary navigation and anticollision protection. The repliers are coded for identification and (in air use) for altitude discrimination. Thus the system provides the essential advantages of radar navigation, but the technical and operational emphasis is placed on the beacon operation, which provides positive point identification of all strategic locations and other ships, assuming that the ships are properly equipped. Thus, for maximum efficiency of operation, most other ships and prominent geographic locations would have to be marked by responder-beacons (repliers). The display of beacon replies on a PPI scope as a two-dimensional polar plot of the area surrounding the challenger is easier and more reliably interpreted than a corresponding radar display.

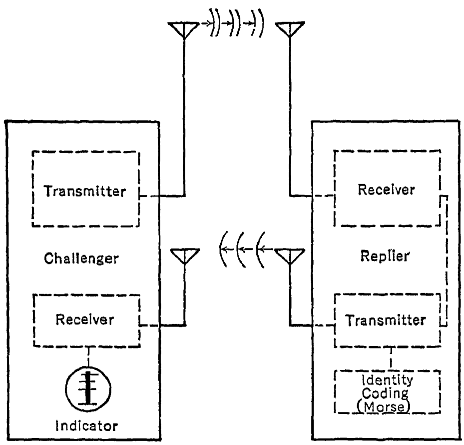

FIG. 11. Functional Block Diagram of Basic Lanac System

A chart of the marine services rendered by Lanac is shown in Fig. 12 with the addition of the auxiliary radar functions mentioned. Although not yet in general use, Lanac offers the advantages of a simple and very comprehensive navigational aid which combines the reliability of beacon operation with the versatility of radar.

DECCA. (See reference 16.) The British Decca system operates in the low- and medium-frequency ranges (i.e., 10–200 kc/s) on the propagation phase difference principle (e.g., similar to POPI). Operation is accomplished by transmitting CW signals from a master and a remote slave station accurately synchronized so that there is set up in space a stable interference pattern of radiations having distinct loci of constant phase difference.

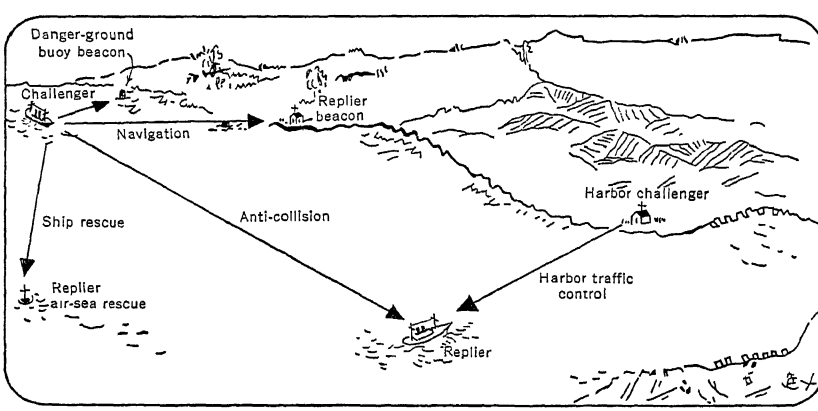

FIG. 12. Summary of Services Rendered by Lanac (Excluding Radar)

These Decca loci are hyperbolas of constant propagation phase difference, as compared to the Loran loci which are hyperbolas of constant propagation time difference. To facilitate the reception of the two distinct transmitted signals, and the practical measurement of their phase difference, the Decca master and slave CW emissions have a highly stabilized ratio of carrier frequencies; e.g., the master station may operate on $340/4 = 85$ kc/s, the slave station on $340/3 = 113.33$ kc/s. The received frequency ratio is converted to unity by suitable multipliers in two channels of the receiving equipment. The actual phase difference between the two signals is then measured by passing the two converted signals through phase discriminating and indicating circuits. An integrating phase-meter (called a decometer) numerically identifies each hyperbola of 0° phase difference as it is picked up by the receiver. These 0° phase difference hyperbolas are called "equiphase" lines and are used as a reference. All other hyperbolas within the "lanes" between the equiphase lines are then identified on the decometer as values of phase difference other than 0°. Since two such position lines are required for a "fix," another such phase comparison determination is necessary on a second pair of stations. The total equipment, therefore, comprises three shore transmitters (one master operating two slaves) together with their associated control circuits, and craft equipment consisting of three phase-stable amplifiers, four frequency-multipliers, and two integrating phase-meters.

In order to avoid ambiguities of fix in the Decca system, the decometers must be preset to a given reading at a known point which is within reception range of the Decca transmitters. Then, as long as the transmitters and the receiving equipments are operating, the decometer will read correctly as the receiver travels from one lane to another. If either the receiver or any of the transmitters fail to operate properly, or the receiver travels out of reception range, the absolute setting is lost and must be reset at a known position. To reduce these possibilities of ambiguity, means for positive lane identification are now being developed. A Decca facility (utilizing four stations centered near London, England) is in continuous 24-hour operation. Other Decca facilities are being planned including some for the European continent. The Decca system is easier to operate than the Loran system and appears capable of giving fix information with greater accuracy, but at decreased range. However, errors due to serious phase shifts may be introduced by ionosphere reflections of sky wave. It is to be noted that three carrier frequency channels are required for a position fix with the Decca system.

POPI. (See reference 16.) The British POPI or *p*ost *o*ffice *p*osition *i*ndicator system, operates in the medium-frequency range on the propagation-phase-difference principle (similar to Decca) with such a short base line that the hyperbolic lines of position are essentially straight lines or bearing lines of position to each POPI station. Two or more bearing lines of position from two or more POPI stations give the desired position fix. Each POPI station employs three outer antennas symmetrically disposed about a central antenna. If the antenna spacings are equal to or less than $\lambda/2$, there are no ambiguities, and at a distance exceeding five times the antenna spacing the hyperbolic lines may be considered as straight bearing lines of position. In operation, the central antenna transmits continuously at a radio frequency of f_3, the outer antennas transmit at a slightly lower radio frequency f_1, and they are sequentially keyed at some fraction, $1/n$, of the frequency difference f_2. For a typical POPI station, f_1 may be equal to 750.000 kc/s, $f_2 = 80$ cps, $f_3 = 750.080$ kc/s (obtained by mixing f_1 with f_2), and $n = 4$. With $n = 4$, the keying cycle would occur as follows:

First outer antenna on first $1/20$ sec
Second outer antenna on second $1/20$ sec
Third outer antenna on third $1/20$ sec
Space and reference on fourth $1/20$ sec

At the receiver, the audio beat frequency $f_2 = f_3 - f_1$ (e.g., 80 cps) is applied to a rotating switch with four contact sectors. In order to control this rotating switch so that the sequential transmissions will be correctly received, one of the 80-cps outputs from the rotating switch is used to synchronize an 80-cps oscillator which, in turn, drives a synchronous motor. This motor, through reduction gearing proportional to the factor $1/n$, permits $1/20$-sec intervals for receiving the sequential 80-cycle tones corresponding to the frequency difference of the transmissions from the outer and central antennas of the POPI station. Since each of the outer antennas has a separate distance or propagation time to the receiver, there is a correspondingly separate and distinct phase for each 80-cycle tone sector of the synchronous commutator's output.

It is planned to measure these phase differences as if they were coexistent even though they actually occur in alternate time sequence. One means proposed for accomplishing this measurement consists of a separate 80-cycle filter network for each synchronous commutator segment which is capable of ringing or sustaining 80-cycle oscillations after being energized for about $1/20$ sec without exhibiting adverse relative phase shifts between networks. No report is available at present on results obtained with this critical ringing network. The present British developments are in an experimental state, although full-scale trials are contemplated at an early date. It is to be noted that POPI may suffer the same errors, due to ionosphere phase shifts, that are expected in the Decca system.

TELERAN. (See reference 16.) Teleran, or *tele*vision *r*adar *a*nd *n*avigation, is a system that was originally proposed as an aid to air navigation and is discussed in detail in article 6.

It is believed, however, that it has considerable parallel usefulness as a harbor traffic control type of marine navigational aid, particularly during adverse weather conditions. Basically Teleran is a television system whereby the central control (shore) station transmits, by television, any essential information to nearby craft. In this manner pertinent PPI (plan position indication) information, weather warnings, and special instructions can be instantly presented via the television link to the navigator, using only a standard television receiver as the shipboard equipment.

FACSIMILE. Because of the increased speed with which navigational information will be available to the navigator in the future, it is expected that some storing and recording means will eventually be required in order properly to handle navigational information that cannot be too well interpreted via oscilloscopes, etc., under busy harbor and related conditions. Moreover, the need and desire for rapidly printed records of weather, warnings, and congested traffic conditions will serve as a powerful stimulus in the eventual adoption of such an aid. In view of the relative ease with which facsimile signals can be multiplexed with other transmissions to the craft being navigated, its introduction is not expected to be long delayed. In some respects, facsimile transmission becomes a desirable compromise between the systems of telephoto, television, and teletype transmissions. Details of the principles of facsimile are discussed in Section 19.

SOFAR. Sofar, or *so*und *f*ixing *a*nd *r*anging, is a proposed system for air-sea rescue service and is a possible long-range navigational aid in the field of underwater sound. It has been discovered that sound originating at certain depths (often 3000 to 4000 ft) will be refracted downward by the layers of water above the critical depth, owing mainly to the temperature gradient in the water, and upward by the layers of water below, owing largely to the hydrostatic pressure gradient, thus confining the sound energy to a horizontal channel. It has been found possible to use this channel for the transmission of a distress signal (e.g., by detonation of a suitable explosive charge) over a range exceeding 2500 miles. Reception of this signal by several coordinated and widely spaced hydrophone receivers allows an accurate position fix of the distressed craft. Special light-weight and properly armed charges have been designed for airplane and life-raft applications that are particularly efficient for air-sea rescue purposes. An initial network of four stations, at Hilo and Kaneoke in the Hawaiian Islands, and at Monterey and Point Arena on the California coast, principally for air-sea rescue purposes, cover the long air route from San Francisco to Hawaii.

REDAR. Redar, or *re*d (and infrared) *d*etection *a*nd *r*anging, is a proposed aid to marine navigation, similar in principle to radar. In redar, it is proposed to use a searchlight and telescope arrangement in the near-infrared band aboard the ship. The general techniques and procedures employed in radar are expected to be modified as necessary and applied to redar. For navigational applications, where rapid redar scanning is not necessary, a simplified infrared optical range finder operating on well-known optical range finding principles is proposed. At the present state of infrared investigations, ranges of 3 to 5 miles are predicted during average to clear weather and low humidity conditions, with accuracies comparable to radar accuracies. Because of the nearly equivalent attenuations of infrared radiations as compared to visible light radiations under fog conditions, infrared systems are not expected to become a general navigation system. If the need for very short-range target and obstacle detection becomes pronounced, it is possible that redar may adequately serve this need in a manner superior to that of most standard radar systems.

MISCELLANEOUS SYSTEMS. Dingley system (see reference 23) is a frequency-modulation type of radio navigation aid that basically operates on the propagation-time-difference principle, wherein the actual time difference is obtained in the form of a frequency difference (or audio beat). This is accomplished by the use of frequency-modulation emissions from two spaced antennas, whereby there is set up in space a stable pattern of frequency differences having distinct loci of constant frequency difference. Thus the Dingley loci are hyperbolas of constant frequency difference as compared to the Loran loci or hyperbolas of constant propagation time difference. In operation, a central antenna and at least one other outer antenna are energized with frequency-modulation signals. The signal received along a radial line from either antenna has a space distribution of frequencies when that antenna is emitting frequency f_0 at time t_0, f_1 at time t_1, f_2 at time t_2, etc. At time t_1 the signal of frequency f_0 has traveled to d_1, and signal of frequency f_1 is being emitted at antenna A or at d_0. The partial table shows the overall conditions responsible for the space distribution of frequencies. Since the table is also applied to give similar space distribution of frequencies for similar emissions from the second antenna, it can be seen that those points in space which maintain a constant distance difference to the two antennas will define a hyperbola along which will be found a constant frequency difference. Hence, a family of frequency-difference hyperbolas exists for the various differential distances to the two antennas, and their general similarity to Loran hyperbolas of constant propagation time difference is immediately apparent. If desired, the reference antenna, A, can be designated as master and any other antennas, B, C, etc., can be designated as slaves.

Instantaneous Time	Instantaneous Frequency at d_0	Instantaneous Frequency at d_1	Instantaneous Frequency at d_2	Instantaneous Frequency at d_3	Instantaneous Frequency at d_n
t_0	f_0	....	....	....	..
t_1	f_1	f_0	....	....	..
t_2	f_2	f_1	f_0	....	..
t_3	f_3	f_2	f_1	f_0	..
.	.	.	.	.	.
.	.	.	.	.	.
t_n	f_n	f_{n-1}	f_{n-2}	f_{n-3}	..

In view of the above, the Dingley system may be considered a simplified type of Loran system operating on an F-M basis. Because of the wide band factors generally associated with frequency modulators, it may be expected that the higher carrier frequencies may be required with their correspondingly reduced range.

Sonic direction finders have long been employed by the military particularly for anti-aircraft purposes. Similar sonic direction finders have been employed for underwater applications. In such applications, a pair of spaced sonic pickup devices (e.g., crystals acting as hydrophones or sound microphones) have their outputs differentially connected to yield a cosine law of coupling (i.e., similar to a pair of Adcock dipoles) and have their resultant output fed to a suitable receiver. When used with a system of underwater sound beacons the combined arrangement is similar to the radiobeacon system described under Established Navigational Aids, p. 22-36. Beacon stations are under investigation for automatically taking sonic bearings on a ship and transmitting by radio the range and direction of the ship with respect to the beacon's position.

Infrared systems have been proposed which are essentially similar to redar with an optional infrared beacon system on shore to provide a convenient navigational aid. The infrared systems, as pointed out previously, do not permit navigating during fog conditions owing to their inability to penetrate the fog without an attenuation almost as great as that experienced by visible light. Their chief value would appear to be a black light navigating system operating under blackout conditions and during the absence of fog. Such systems generally operate in the *near infrared* region (0.3 to 1.5 microns).

Far infrared (heat-ray) systems have been developed to distinguish targets from their backgrounds by operating on heat or temperature differences. These systems generally function in the 8- to 15-micron band and usually operate in a manner wherein the heat rays are detected by bolometers (see reference 24). One type of bolometer successfully developed by Johns Hopkins University operates as a superconductor at temperatures near absolute zero. This superconducting device may include scanning arrangements whereby target resolution, or definition, roughly comparable to radar definition, can be attained. Because of atmospheric absorption, ranges beyond a few miles are seldom obtained.

Microwave thermal detection has been reported by G. C. Southworth (reference 25) in an interesting series of measurements of microwave radiations from the sun. This phenomenon is to be expected since radio waves may be considered as infrared radiation of very long wavelength, and a hot body would be expected to radiate microwave energy thermally. Using such techniques, absorption bands of water vapor have been measured. It is to be further expected that targets casting a shadow by blanking out radiations over certain areas might be detected by such microwave thermal and similar techniques. Any radiation source or any radiation field arranged to cause target shadows is potentially a means for detecting these targets, whether the frequency of these radiations is sonic or extends to the cosmic-ray region, and whether or not the emitting source is under control of the local observer.

12. DETERMINATION OF OPTIMUM TRANSMISSION PARAMETERS FOR SOME LONG-RANGE RADIO NAVIGATION SYSTEMS

BASIC CONSIDERATIONS. A long-range transoceanic radio navigation system for global application must meet three essential requirements, namely, provide: (1) adequate signal reception with a sufficient number of coastal or island stations for world-wide coverage; (2) reliable signal reception at useful levels irrespective of weather, time of day, season, year, direction, and distance of reception; and (3) an economically feasible arrangement avoiding prohibitive installation and operating costs. P. R. Adams and R. I. Colin (reference 26) have studied these essential requirements and have arrived at the conclusion that, if the craft should at all times be within range of two ground stations (in order to obtain a cross fix), then these stations should have a minimum range of 1500 miles in order to insure world-wide double coverage. In addition, they have analyzed the relative suitability of the various transmission parameters for a reliable 1500-mile range of a long-range, essentially CW, radio navigation system. These analyses cover the optimum choice of frequency, band width, power, modulation, and radiation (antenna) efficiency, and comprehensively consider these transmission parameters with due respect to the following: (1) Quasi-minimum field strength (defined as the monthly average of signal strength measured at the worst hour of the day during the worst months of the worst year) that may be expected at different places, frequencies, direction of transmissions, etc. (2) Quasi-maximum significant static intensity (defined as the value of static which is rarely exceeded at any time and place where the useful signal is likely to have its quasi-minimum field strength) that may be expected at different places on different frequencies, etc. (3) Signal-to-noise ratio, based on the ratio of quasi-minimum field strength to quasi-maximum significant static intensity, in order to determine the ratio's minimum probable value, by giving proper regard to each factor in the ratio in order to avoid their extreme values when the time and place of their occurrence may never coincide (the time relationship for example, depends upon factors such as latitude, time of day, and direction of transmission). (4) Cost of reliability in the choice of a suitable transmitting frequency (aside from the normal merit factors determining a choice of transmitting frequency based on average reception conditions), the degree and frequency of occurrence of fadeouts, adverse polarization changes, static conditions, and susceptibility to magnetic storms. (5) Corona factors, since the size of antenna is partly determined by the required antenna capacitance that will prevent the antenna charging current from developing a peak voltage in excess of the critical corona voltage; the latter, in turn, is dependent upon the weather as well as the dimensional and electrical factors.

As a result of the above types of detailed investigation, employing compiled data and consideration of the pertinent factors including signal and static strength and fluctuations, and antenna efficiency, the conclusion is reached that, in an essentially CW type of transmitting system for navigational purposes up to a maximum distance of 1500 miles, adequate reception can be assured with least power input at a transmission frequency of 70 kc/s. These investigations show that the reduction in time lost through fading and fadeouts offsets the disadvantage of low-frequency transmission and its associated lower radiation efficiency and higher static intensity. Estimates of power requirements for several locations and antenna dimensions for handling such power without corona are also discussed in the above reference.

MODULATION AND BAND WIDTH. The above study makes little mention of the various methods of modulation by which intelligence may be transmitted at the chosen carrier frequency. Three paramount points must be considered: (1) the rate of transmission of intelligence on any one frequency is directly proportional to the band width used; (2) for a normal uniform energy distribution of noise over the frequency spectrum, the amount of noise energy received is directly proportional to the receiver band width; and (3) it has been operationally observed that present high-speed craft (including aircraft) can satisfactorily utilize navigational information furnished at a low rate of intelligence reception (e.g., 20-cycle modulation) by utilizing integration and average indication systems. Specifically, amplitude modulation may vary from CW through audio modulation to pulse modulation transmission. *CW transmission* provides no intelligence information except the direction of propagation of the wave; the latter information is extracted by the receiving station and is not a function of the type of modulation. The receiver band width required is extremely narrow, thereby reducing band-width noise to the minimum. Receiver-introduced modulation methods, as described on p. 22-42, may be used to discriminate further against noise and effectively increase the signal-to-noise ratio without affecting the receiver noise (which is determined by the input circuits). Large bearing errors may be experienced in pure CW systems at long range, where sky-wave transmission must be used. These bearing errors cannot be detected easily but may be reduced in certain cases by means of the receiver modulation methods mentioned. CW transmissions may be identified by their frequency or by means of very slow keying or on-off schedules which theoretically require a definite band width but can be reduced to a few cycles, effectively approaching zero.

AUDIO MODULATION can be taken to include modulation frequencies from a few cycles to several thousand cycles and does not impose prohibitive requirements on transmitter or receiver design. However, in view of the fact that the rate of intelligence transmission need not be high for most navigating systems, it would seem preferable to use band widths of the order of 10 to 100 cycles and utilize suitable receiving methods in order to reduce receiver band-width noise to the minimum. It has been operationally observed that modulated radio signals have a higher stability and accuracy performance beyond the ground-wave propagation range than do CW radio signals. This is apparently due to the operator's ability to distinguish single-path transmission from multiple-path transmission (either by aural or visual methods) when modulated signals are employed. With CW radio signals poorer performance results because it is practically impossible to distinguish the more stable single-path ray from the multiple-path rays with their larger instabilities and errors. Improved signal-to-noise ratios on desired signals can also be effected in audio modulated transmitting systems by employing receiver synchronizing procedures to match the transmitted modulation rate, thereby integrating or averaging out random noise. Furthermore, improvements in signal-to-noise ratios (e.g., bearing resolution and accuracy performance) can also be obtained in audio modulated systems by employing the same receiver-introduced-modulations technique discussed under CW systems and described on p. 22-42 under direction finders. Modulated systems also permit convenient means for positively effecting station identification either by keying, time scheduling, or variations of the modulation rates. It is important to note that modulation rates lend themselves to accurate synchronization between transmitters and receivers, not only for improving the signal-to-noise ratio but also for providing a highly effective means for efficiently employing the frequency spectrum. The spectrum can be conserved by permitting a number of stations to operate on a common carrier frequency with different known and stabilized modulation rates, allowing the receiver to select the desired station by synchronizing on the proper modulation. This procedure is already in use in various adaptations as in the Loran method of synchronized pulse modulation, where as many as 16 separate stations in a given area may share the common carrier frequency and are distinguishable at the receiver by the different synchronous repetition (i.e., modulation) rates. *Pulse modulation* systems require a greater band width, and, consequently, the inherent receiver noise is greater. However, methods of synchronous pulse gating are being developed which effectively reduce the noise and provide a higher sensitivity to pulse detection. The wide band required by one transmitter employing pulse modulation can be offset as in audio modulation by utilizing a number of precisely controlled repetition rates at the same carrier frequency (as mentioned above in the case of Loran), and by providing for differentiation between these various rates at the receiver. The greatest single advantage of pulse modulation is the very precise and highly convenient technique available for time synchronization, which permits effective time differentiation between the various transmission paths of the arriving wave. The improved signal-to-noise ratio advantage offered by modulation and pulse synchronization techniques constitutes another great advantage. However, pulsed techniques become more difficult to apply as the frequency decreases.

The efficiency of pulse synchronization techniques has been operationally proved in several instances, such as (1) in the India Theater during World War II where Loran operation was continuously maintained during the monsoon weather, when all communication links were erratic or inoperative; and (2) under conditions of severe precipitation static in Greenland when, again, Loran provided the only operative navigation link, whereas all communication circuits became unintelligible. The advantages of pulse techniques for maintaining continuous and reliable service must, therefore, be thoroughly investigated and included in any comprehensive analysis of the final choice of the operating parameters for a long-range world-wide navigation system.

Other modulations in addition to the various types of amplitude modulation exist, such as frequency modulation, phase modulation, and pulse-time modulation. Although no extensive study has been made of these for long-range navigational purposes it is well known that frequency and phase modulation possess considerable noise-reducing properties in addition to the modulation synchronization techniques previously described for improving signal-to-noise ratios. However, these advantages are partly offset by their usual wide-band transmission requirements and their general limitation to the higher frequencies (in order to achieve adequate depth of modulation) where line-of-sight range restrictions prevail. *Pulse-time modulation* (PTM) offers the advantage of increased intelligence on a pulse channel but decreases the number of simultaneous channels allowable at one frequency. It also makes the separation of single and multiple path transmissions more difficult and prevents use of the precise synchronization techniques necessary for effective improvements in signal-to-noise ratios. Lastly, hybrid or combination types of modulation and second and third derivative frequency modulation may play increasingly important roles as investigation continues into the techniques of such systems.

MEDICAL APPLICATIONS OF ELECTRICITY

By Charles Weyl and S. Reid Warren, Jr.

During the latter part of the eighteenth century Galvani and Volta discovered that the muscles of dead frogs' legs could be made to move by contact with metals. The descriptions of their experiments indicated that they were establishing a difference of electric potential between nerves and/or muscles of the frogs' legs and that this applied difference of potential caused a motion of the muscles. Since that time, many techniques have been devised for using electrical apparatus for studying physiological functions, for the diagnosis of disease, and for therapeusis. During the twentieth century the development of these medical applications of electricity has become accelerated and, particularly since 1925, new methods have been developed, tested, and applied to clinical practice. Although some of these techniques have become standardized by accurate experimental investigations, nevertheless, the biophysical explanations of many of the techniques are almost completely unknown. Although frequently the electrical apparatus and the techniques for their use are simple, an accurate knowledge of the results of the technique has been impeded by differences in individual patients, by lack of knowledge of the physiological factors involved, and by a lack of proper control of the apparatus and technique. Thus there exists a fertile field for investigation in which physicists and engineers are aiding physicians in problems of electromedical diagnosis and therapeusis.

With the accelerated development of the electromedical methods which were known before 1925, and also of the new methods which have been introduced since that time, there has been a great increase in the literature of the field. Furthermore, the applications of many of the newer devices and techniques to medicine are subsidiary to their applications in other scientific fields. This section is organized on the basis of these factors. Each article contains the following items: (1) a list of the fundamental components of the electrical apparatus required for a particular electromedical technique and an example of their combination into a practical, useful apparatus; (2) a brief description of the electromedical technique and examples of its use; (3) a list of references to papers and books in which the electromedical apparatus and technique are discussed in detail.

The literature of the medical applications of electricity uses terms quite different from those employed by physicists and engineers, and some of them are extremely confusing. For example, the term *electrotherapy* is sometimes used as a generic to represent nearly all the electromedical techniques except those involving x-rays; it also often represents solely those techniques described in the next article involving the conduction through parts of the body of direct, pulsating, and alternating currents.

ELECTROTHERAPY AND SHOCK THERAPY

1. APPARATUS

The apparatus employed for generating direct and alternating currents for electrotherapy has many forms, all of which are fundamentally of simple design from the engineering point of view. The requirements are as follows: (1) direct current, 0 to 80 volts, 0 to 50 ma, with a continuous resistance control; (2) alternating current at commercial frequencies from 0 to 50 volts rms, 0 to 25 ma; (3) a method for periodically surging or modulating the alternating currents mentioned in (2); (4) an induction coil operated by direct current with a mechanical interrupter; (5) a device for providing pulsating current at frequencies from 10 to 100 pulses per second.

Occasionally an attempt is made to construct an apparatus which will supply all these wave forms. Usually, however, the physician purchases different pieces of apparatus for each purpose. At present, the trend is toward the construction of apparatus which operates from an a-c source of 110 volts, 60 cycles. For example, the d-c generator may take the form of a small 1:1 ratio transformer with the secondary connected to a full-wave rectifier and filter system. Across the filter system is connected a potentiometer, and the electrodes are connected to two terminals of the potentiometer. The surging devices are generally motor-driven variable resistances. The apparatus used for these purposes has not been standardized and therefore it is not possible to give typical wiring diagrams.

The arrangements for protection of the patient from excessive electric shock are, in many installations, inadequate.

A number of accessory parts comprising, for example, specially designed electrodes and a timer for controlling the length of treatment are required.

The development of technique in electrotherapy is based entirely on empirical results frequently acquired from doubtful interpretations of meager data. Since remarkably little attention has been paid to the precise measurement of voltage and current, many of the accumulated data are of doubtful value.

Treatments usually have a duration of 1 to 15 min. In general the physician specifies his technique by a measurement of the current which flows through the patient, and the duration of the treatment.

2. ELECTROTHERAPY

It has been known for many years that passage of electric currents through the human body may cause important physical and physiochemical changes within the tissue. The following results form the basis of methods of diagnosis and treatment by the passage of electrical currents through the body: (1) the transfer of ions from outside the body into the treated part; (2) the transfer of ions from within the body to an electrode outside; (3) the production of heat within the living tissue; (4) the stimulation of nerve and muscle fibers.

To accomplish these purposes, direct currents, pulsating currents, and alternating currents are used. The following paragraphs describe the applications of each of these several forms of current.

ELECTROCHEMICAL CAUTERIZATION. A flow of direct current (called galvanic current in electrotherapy) through the body generally serves its therapeutic purpose by destroying diseased tissue. If platinum electrodes are applied to a diseased part which is near the surface of the body, and a direct current is made to flow between the electrodes, an acid tends to form by electrolytic action at the anode, and an alkali at the cathode. The destructive action of such chemicals is well known, and frequently it is possible to control the destruction of tissue by means of the electrical method for the production of these chemicals. Such a procedure is called electrochemical cauterization. Usually only one metallic electrode is placed in contact with the tissue. The other electrode, called the indifferent electrode, consists of a metal disk several inches in diameter held against a pad of cotton soaked in a solution of sodium chloride and placed against the skin of the patient. The transfer of ions from the salt solution apparently has negligible effect on the human body. Electrochemical cauterization is used for removing superfluous hair, warts, and small rodent ulcers, and also in the treatment of certain skin diseases.

IONTOPHORESIS. If one hand of the patient is placed in a liquid electrolyte, and this electrolyte is used as an electrode, it is possible by the application of direct current to transfer ions from the solution into the body. This process is called iontophoresis. The physiological results of treatment by this method have not been adequately explained. Some work has been done for the purpose of effecting local anesthesia by the transfer of ions from cocaine into the body at chosen places. Metallic ions have been introduced, and it is claimed that the recombinations that occur within the body provide small quantities of atomic metal or of metallic salts at the site of disease. Other chemicals such as acetylbetamethylcholine chloride and histamine have been used for the treatment of specific disorders.

CATAPHORESIS. If a semi-solid electrolytic gelatin is formed in the shape of a cylinder and two metal plates are placed at the ends of the cylinder, a direct current may be made to flow through the gelatin. After a few minutes have elapsed, there is an increase of water at the cathode and a decrease of water at the anode. This phenomenon is apparently caused by changes in osmotic pressure due in turn to the current flow. This procedure is sometimes used to remove undesired liquids from skin lesions. It is called cataphoresis.

MISCELLANEOUS. It has been found that muscles which are in a state of fatigue become considerably strengthened after treatment with direct current. It has also been claimed by many workers that the passage of current causes exhilaration of some patients, and, on the other hand, with a slightly different technical procedure, the same type of treatment may produce drowsiness. The causes of these effects are unknown.

The passage of small direct currents through the body causes no pain. However, a sudden change in the amplitude of the current produces muscular twitching and pain. Normally, d-c treatments require a source capable of adjustment from 0 to 80 volts. The current passing through the body may be from $^1/_2$ to 50 ma. Because of the muscular twitching described above, it is particularly important that the current be adjusted slowly to the desired value. Quantitatively, it is usual to increase the current linearly with time at the rate of 1 ma per min. The d-c resistance of the two arms and the trunk of the average adult is approximately 1400 ohms. This resistance is measured by suspending the hands in salt solutions, thereby overcoming the high resistance of dry skins.

The passage of alternating current of frequency less than a few thousand cycles per second involves a sensation of pain and twitching of the muscles. The intensity of muscular reaction and pain increases with the amplitude of the current and with the frequency up to an indefinite limiting value of several thousand cycles per second. When the frequency is raised above this value, the sensation decreases and finally disappears unless the amplitude of the current is sufficient to produce appreciable heat.

The steady application of alternating currents of a few milliamperes of commercial frequencies is extremely painful and dangerous. Therefore a device is required to produce a surging sinusoidal current which may be described in the following manner. At the beginning of the treatment the alternating current is zero amplitude. Over a period of the order of 2 sec it is increased to a maximum and decreased to zero. There follows a rest period of about 2 sec, and then the surge is repeated. Apparently the application of 60-cycle alternating currents causes contraction and extension of the muscles. Treatment by this method has been recommended for paralyzed muscles or muscles damaged by disease.

FARADIC AND MISCELLANEOUS WAVE FORMS. Various other types of alternating and pulsating currents have been recommended for therapeutic use. It will suffice to list a few of these: (1) the secondary current from an induction coil, called faradic current in electrotherapy; (2) currents produced by the periodic charge and discharge of condensers; (3) pulsating current of various wave forms produced by mechanical interrupters; (4) high-frequency brush discharge by means of a Tesla coil. Standardization of such methods will require a careful oscillographic analysis of the electrical parameters combined with a statistical analysis of the clinical results.

3. SHOCK THERAPY

In certain mental disorders it has been found that if a convulsive shock is produced in the patient by means of drugs, or by electric currents passing through the brain, improvement in the condition of the patient is often observed. The techniques of shock therapy are still based chiefly on empirical data. It is to be noted that the threshold at which electric shock of the brain will cause convulsion is relatively close to the higher lethal threshold. It is, therefore, necessary to control the shock precisely. Shock treatments are usually given in a series of from six to twelve treatments during periods of a few weeks.

It is found that, using electrodes placed approximately over the two temples, currents of the order of 1 amp, adequate to produce convulsion, are caused to flow by a 60-cycle alternating voltage of approximately 100 volts. Thus, the apparatus for shock therapy consists essentially of a transformer, the output of which can be continuously varied, and a timer capable of producing exposures from 0.1 sec to 0.6 sec in steps of 0.1 sec. Motor-driven timers, time-delay relays, and electronic timers have been used to produce the desired intervals of shock. In order to avoid fatal accidents, it is important in these devices to use circuits such that the failure of a component will result in a great decrease in the output voltage.

DIATHERMY AND HIGH-FREQUENCY SURGERY

4. APPARATUS

Generators of high-frequency alternating current, from 750 kc per sec to 3000 Mc per sec, have been used to raise the temperature of parts of the human body in the techniques known as *diathermy* and *high-frequency surgery*.

There are two general types of diathermy apparatus. In the first type, a high-voltage transformer is connected to an oscillatory discharge circuit consisting of a spark gap, condensers, and an inductance. Loosely coupled to this oscillatory circuit is a secondary circuit to which the patient is connected. A high-frequency ammeter is connected in series with the patient to measure the magnitude of the treatment current. Figure 1 is a diagram of such a generator. More recently vacuum-tube oscillators (see Section 7) have

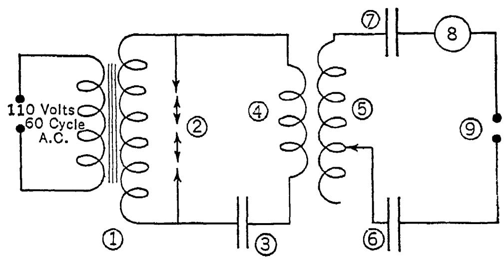

FIG. 1. Diathermy Apparatus Using Spark-gap High-frequency Generator

1, Step-up transformer; 2, spark gaps; 3, condenser, and 4, inductance forming oscillatory circuit which resonates at 500–1000 kc; 5, coil coupled to oscillatory circuit; 6, 7, condensers; 8, high-frequency a-c ammeter; 9, leads to electrodes.

been designed for this purpose. They are connected in a manner similar to that shown in Fig. 2. It will be noted that the two circuits are identical in all essential features with the two types of radio transmitters known respectively as spark and continuous-wave transmitters.

Various techniques are used for producing a high-frequency electromagnetic field within the part that is to be treated. Thus, the output of the oscillator is sometimes applied to two metallic plates between which the part of the body to be treated is placed. Alternatively the output of the oscillator may be fed to a cable which can be wrapped in the

form of a solenoid around a body part or shaped into a spiral coil (the technical term is pancake) which can then be fixed against one side of the part to be treated. The special electrodes required for surgery are described in article 6.

Apparatus using a magnetron operating at 2450 Mc is now available. Radiation is emitted by one of several parabolic reflectors 6 to 10 cm in diameter excited by a dipole. The radiation is thus confined to a relatively sharp beam.

Because of the very important danger of interference with communication facilities, the F.C.C. has prescribed the frequencies permitted for diathermy and the frequency stability that is required. The frequencies so assigned are: 13,560 kc ± 6.78 kc; 27,120 kc ± 160.00 kc; 40,680 kc ± 20.00 kc; 2450 Mc ± 50 Mc, available for experimental work.

5. DIATHERMY TECHNIQUE

If the frequency of the alternating current applied to the human body is indefinitely increased, an ill-defined point can be found (order of magnitude of 10,000 cycles per second) beyond which no sensation other than warmth is felt. The minimum amplitude of alternating current which produces pain by passage through the human body varies with the frequency of the alternating current and with the subject. Average values obtained by a number of workers are as follows:

Frequency, cycles per second		Average Tolerance, milliamperes
60	....	3– 8
10,000	tolerance current, increasing gradually to.......	25– 30
100,000	tolerance current, increasing quickly to.........	250–600

Heating effects, only, are noted above 100,000 cycles per second. As a result it is possible to increase the current flowing through the body to values as high as 5 amp. This causes a sensible dissipation of heat within the tissue. For this purpose frequencies above 750 kc per sec are used. It has been discovered that heat produced internally is effectual in the treatment of certain diseases. The name *diathermy* has been given to the treatments characterized by the internal heating effect of high-frequency alternating currents. Electrodes several square centimeters in area are used in order that the current may be distributed approximately uniformly over a large area. Other machines in which the patient is not in contact with electrodes, but is placed in a strong high-frequency electromagnetic field (between "condenser" electrodes), have been constructed for the purpose of heating the entire body or, more commonly, large portions of the body. It is possible to raise the body temperature as much as 3 or 4 deg C by this means. The method has proved useful in the treatment of syphilis, pleurisy, neuritis, and other diseases. The currents normally used range from 0.5 to 5.0 amp.

6. HIGH-FREQUENCY SURGERY

If one large electrode is applied to a part of the body and a second electrode consisting of a large platinum needle is brought in contact with any other part of the body, the resultant current density is so high at the point of application of the needle that the tissue may be completely destroyed by heat. This method, which is called electrosurgery, is a relatively recent development. The small blood vessels severed by means of the high-frequency knife are normally sealed by the heating action, and bleeding is therefore considerably reduced. Basically, there is no difference between the equipment used for diathermy and for high-frequency surgery.

THE MEDICAL USES OF ULTRAVIOLET AND INFRARED RADIATIONS

7. APPARATUS

Apparatus for the production of ultraviolet radiation includes the carbon-arc generator, the quartz-enclosed mercury-arc generator, and the mercury glow-discharge lamp enclosed in quartz or Corex, a glass which transmits a useful amount of ultraviolet radiation. One of the chief objections to the carbon-arc generator is its production of relatively high-intensity visible and infrared radiations. In addition to the above-mentioned lamps, which have relatively high outputs, several special lamps have been developed for home use under medical supervision.

One of these—the Mazda RS lamp—is rated at 110 volts 275 watts. At a distance of 24 in. this lamp will produce a mild reddening (erythema) of the skin in about 5 min. The lamp is strong in those radiations that produce sunburn (2800 to 3200 angstrom units). There is also a relatively strong infrared beam produced chiefly by a tungsten filament in an atmosphere of argon and nitrogen.

The outer envelope of the Mazda RS lamp is made of special glass that transmits infrared and visible radiation, and ultraviolet radiation of wavelengths greater than 2800 A. A reflecting surface is deposited on the interior surface of this envelope; the radiation is emitted through the circular (12-cm diameter) end of the lamp opposite the screwplug. A tungsten filament, which operates as a series ballast after the initial preheating period, is mounted in the outer envelope; the space is filled with argon and nitrogen.

Within the larger outer envelope, there is a quartz capsule containing an oxide-coated filament and a second, initially cold, electrode; this capsule contains mercury.

When the lamp is initially connected to 110-volt 60-cycle alternating current, the outer (tungsten) filament and the inner (oxide-coated) filament are connected in series. After approximately 30 sec, when the oxide-coated filament acquires a sufficiently high temperature for copious emission of electrons, a thermal delay switch within the tube operates to connect the initially cold electrode of the quartz capsule to the terminal of the supply opposite from the terminal connected, through the tungsten filament, to the oxide-coated filament and disconnects the oxide-coated filament. The mercury arc then strikes, becoming stable as the initially cold electrode becomes heated by bombardment. The arc in the mercury vapor at a pressure of approximately 1.1 atmospheres then operates in series with the tungsten filament; the filament and arc emit ultraviolet, visible, and infrared radiation. The manufacturer recommends a 1-min. "warm-up" period before use.

Glow-discharge mercury tubes operating at voltages as high as 5000 volts and currents of the order of 15 ma produce radiation almost entirely of the emission frequency line of mercury having a wavelength of 2537 A. This radiation is strongly bactericidal. Since it also requires low-power input, this type of lamp is often used to irradiate the area in operating rooms and in other places where air-borne bacteria are to be minimized. Experiments using these devices in schoolrooms are being conducted.

Since the mercury-arc lamp enclosed in quartz produces a relatively high-intensity radiation at wavelengths from 2483 to 4047 A, and since this apparatus is relatively stable in operation after a few minutes of operation, it is now the most common source for medical purposes. The total power input to such a device is from 250 to 400 watts, and its output of ultraviolet radiation is of the order of 225 microwatts per square centimeter at a distance of 1 meter without a reflector.

Special photoelectric cells connected to integrating circuits and counters have been devised to measure the outputs of ultraviolet generators throughout various bands of wavelengths. However, such standardizing measurements have not been very often applied to clinical use.

Infrared radiation is produced chiefly by electrically heated wire operating at temperatures from 800 to 1600 deg C or by means of incandescent tungsten lamps with or without filters.

8. THERAPEUTIC USE OF ULTRAVIOLET RADIATION

It has been known for many years that sunlight has a definitely beneficial effect upon the human body. Since 1800 the spectra of light emitted by the sun and by electric arcs have been analyzed and more attention has been directed to the specific photochemical effects of the various parts of the spectrum. More or less arbitrarily, ultraviolet radiation has been defined as radiation with a range of wavelengths from approximately 4000 to about 40 A (1 angstrom unit = 10^{-8} cm). The solar spectrum extends down to approximately 2900 A but under average atmospheric conditions at sea level there is negligible radiation below 3000 A. It has been shown that most of the ultraviolet radiation incident upon the human body from the sun or from artificial sources is absorbed in the surface tissues. The penetration is 0.1 mm or less.

There has been much speculation as to the biological processes produced by ultraviolet radiation, which has so far resulted largely in contradictions and disagreements among authorities on the subject.

The first noticeable effects of ultraviolet radiation are erythema, or reddening of the skin, usually followed by pigmentation. Each individual has a different tolerance to ultraviolet radiation. What may cause a pronounced erythema in one may produce no effect upon another. It has been discovered that certain non-soluble fats, particularly ergosterol, form vitamin D when irradiated by ultraviolet rays. This substance is present in the human body, and normal exposure to sunlight is one method for supplying the definite need of the body for vitamin D. Although there is no question as to the beneficial effects of sunlight and artificial sources of ultraviolet radiation when exposures are carefully controlled, enthusiasm on the part both of physicians and of laymen has led to dangerous overexposures to both natural and artificial sources of this form of energy. It has not been proved that exposure to direct sunlight is essential to the physical well-being of the normal healthy human.

Treatment by ultraviolet radiation is useful in cases of rickets, high blood pressure, and some skin diseases. It has been shown definitely that ultraviolet radiation produces directly and indirectly a substantial rise in the amount of calcium and phosphorus in the blood. The treatment is in general use for rickets in infants and has been remarkably successful. Certain experimenters believe that the effect of ultraviolet rays on the nervous system is stimulating. A number of psychiatrists have recommended the treatment for neurasthenia and some of the psychoses.

After Pasteur's discovery that small living organisms are the cause of many diseases and also of fermentation, experiments were performed to find the effects of various types of radiation upon these organisms. It was found that ultraviolet rays were potent in bactericidal action, particularly in the 2600 A region.

Different parts of the body vary considerably in sensitivity. For example, twenty to thirty times as much ultraviolet radiation is required to produce an erythema of the soles of the feet than of the face, which is the most sensitive part. Even small doses which penetrate to the eyeball can cause serious damage; therefore all patients receiving ultraviolet treatment are required to wear goggles made of glass which absorbs practically all the ultraviolet radiation. Practically no ultraviolet radiation is transmitted through window glass and very little through smoky atmosphere. Therefore sunlight may be used as a source of therapeutic ultraviolet rays to the best advantage in special regions—for example, in high mountains where there are generally very few clouds and practically no dust or smoke. Since the ultraviolet content of sunlight varies with latitude, season, time of day, and atmospheric conditions (such as ozone, water vapor, dust, and smoke) it is important to measure the intensity in the region of 2900–3200 A during treatment.

9. THERAPEUTIC USE OF INFRARED RADIATION

Infrared radiation is used for surface heating, either of a small circumscribed area or for the surface of an entire leg or arm. One of the chief effects is the production of increased blood flow near the surface, and this may, in turn, cause more deep-seated changes.

It is possible also to change the temperature of the entire body. Thus the body may be placed in a heat-insulated housing inside of which incandescent lamps or other heating elements raise the temperature of the body and of the area surrounding it. Since there is no way for this heat to be entirely radiated, the temperature of the body is caused to rise. Such whole-body heating may also be accomplished by means of diathermy.

ELECTROCARDIOGRAPHY AND ELECTROENCEPHALOGRAPHY

10. APPARATUS

Muscular contractions and the functioning of nerves are accompanied by measurable differences of electric potential at the surface of the body. Thus the time-varying differences of potential between the right arm and the left arm, the right arm and the left leg, the left arm and the left leg are used by cardiologists to interpret the action of the heart; these differences of potential are called respectively the potentials of Lead I, Lead II, and Lead III. The measured differences of potential are of the order of a few millivolts. An electrocardiogram for Lead II for a normal patient and a heart sound record made simultaneously are shown in Fig. 1. For the electrocardiogram, a vertical deflection of one small division corresponds to a difference of potential of 0.2 mv.

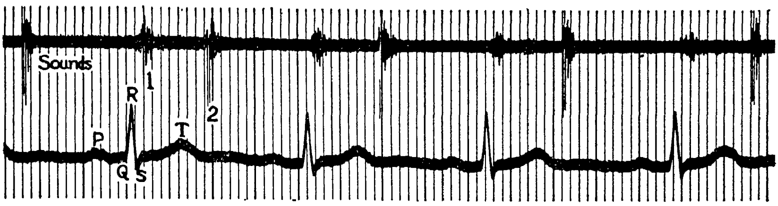

Fig. 1. Electrocardiogram

Lower.—Electrocardiogram, Lead II, normal patient. The letters P, Q, R, S, and T are standard symbols for designating the waves thus marked.
Upper.—Heart sound record made simultaneously with the electrocardiogram above.

Electrocardiographic apparatus requires the following component parts: (1) a device for transforming the electromotive force generated by the heart into the motion of a light beam or of a shadow; (2) a camera with moving film or paper to record the deflections of the light beam or shadow; (3) devices for calibrating the abscissa (time) and the ordinate (electromotive force) on the electrocardiogram.

Einthoven developed a system similar to that shown in Fig. 2. A silvered quartz string with variable tension is held perpendicular to an intense constant magnetic field produced by an electromagnet. A calibrated external source of electromotive force is used as standardizer. A variable resistance and associated battery are used to compensate for skin currents (described below under technique). A specially adapted camera, with a tuning fork or other timing device, is used to record the deflection of the string produced by the heart action.

It has been shown that the Einthoven string galvanometer produces distortion due to the change in its response with frequency; furthermore, as is described below, it requires, for an adjustment of sensitivity, a change in the string tension which produces further distortion. Therefore, efforts were made to use galvanometers with more uniform frequency response. It was found that the use of carefully constructed thermionic amplifiers in association with these new galvanometers provided instruments of great flexibility and stability. The cardiographic paper or film can be driven by a synchronous motor, so that the time abscissas are the same for all cardiograms.

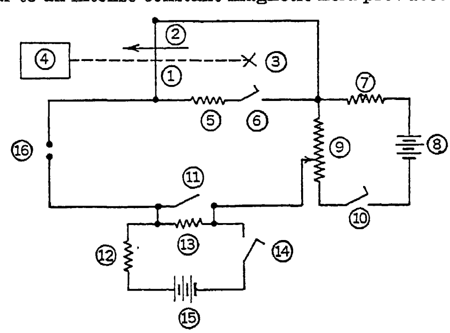

Fig. 2. Outline Diagram of Einthoven String Electrocardiograph

1, galvanometer conducting string of silvered quartz, suspended with controllable tension between the poles of an electromagnet (not shown) which produces a magnetic field in the direction of the arrow 2; 3, light source to obtain, with system of lenses not shown, an image of the string upon the moving photographic film in the camera 4; 5, 6, a shunt, of about one-tenth the resistance of the string, and a switch; 7, 8, 9, 10, the compensator, a series circuit which introduces an adjustable electromotive force in series with the string to compensate for skin current; 11, 12, 13, 14, 15, a circuit for introducing a calibrating emf of 1 mv in series with the string; 16, leads to the patient.

It is most convenient to describe the technique of electrocardiography by reference to the Einthoven instrument shown in Fig. 2. A resistance 5 is connected in parallel with the string, reducing its sensitivity by a ratio of 10 to 1. One area on each arm of the patient is rubbed with a contact paste and a metal electrode is applied. This corresponds to the designation described above as Lead I. A switch is closed connecting the patient to the electrocardiograph. The galvanometer deflects, owing to what is called skin current. The slide of 9 is then moved until the galvanometer string is returned to its zero position. This operation balances out the skin current, which is constant and plays no part in the interpretation of the electrocardiogram. After the compensator is adjusted, the shunt 5 across the galvanometer string is disconnected. This increases the amplitude of swing of the fiber. The standardizing circuit is then connected by closing switch 14 and opening switch 11. The circuit 12, 13, 15 is designed to produce a potential drop of 1 mv across the resistance 13. This throws the image of the string across the screen. An adjustment of the mechanical tension of the string is made so that the application of the 1-mv standardizing voltage produces a deflection of exactly 1 cm. The standardizing voltage is then removed by opening switch 14 and closing switch 11, and the electrocardiogram for Lead I is taken by means of a paper moving at constant speed past the beam of light through the galvanometer. For each centimeter deflection of this record an electrocardiographic impulse of 1 mv is necessary. The same procedure is followed for Leads II and III. The moving photographic paper passes before a glass screen upon which lines 1 mm apart are ruled in the direction of motion of the paper, while a synchronous motor turns a bladed wheel through the light beam at right angles to the direction of motion of the paper, producing a series of time-marking lines spaced at 0.04-sec intervals.

The procedure described can be accomplished quickly in practice. The entire operation is illustrated in Fig. 3. This description applies to the older type of electrocardiograph, from which the underlying principles can be clearly understood. The routine use of a modern electrocardiograph is characterized by practical simplicity, although a description of this procedure would not illustrate so clearly the fundamental characteristics.

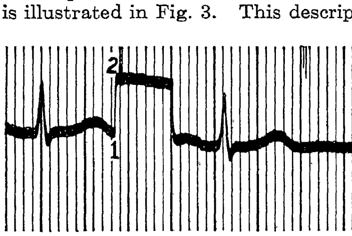

FIG. 3. Calibration of Electrocardiograph

The calibration record which is made at the end of the electrocardiogram of each patient. At (1) the standardizing voltage of 1 mv is connected in series with the galvanometer, causing a deflection of 1 cm to (2). The electrocardiogram is of Lead II, normal patient.

The modern electrocardiograph may be battery operated or it may operate from a 110-volt 60-cycle source. It is usually a self-contained portable device, and the records may be produced on film or photographic paper or—more recently—may be directly recorded on paper that may be examined as soon as it is produced. These devices are equipped with stabilized audio-frequency amplifiers feeding into specially designed galvanometers. The frequency characteristic of these electrocardiographs results in the reproduction, at nearly constant levels, of frequencies from 0.5 to 50 or 100 cycles per second. Because of the susceptibility of these high-impedance amplifiers to hum pickup, special hum-bucking input circuits are incorporated.

An electroencephalograph is used to record time-varying changes of potential between pairs of electrodes in contact with various parts of the scalp; the magnitudes of these differences of potential are from a few microvolts to approximately 100 mv. The component frequencies of the electroencephalographic signals are less than 1000 cycles per second. It follows, therefore, that an electroencephalograph can be a device similar to an electrocardiograph except that (1) the amplification must be about 100 times greater in the electroencephalograph, and (2) it is considered essential to provide fourteen-channel input (and two- to six-channel output) for the electroencephalograph instead of four-channel input which is used in the electrocardiograph.

11. TECHNIQUES

Since the middle of the nineteenth century it has been known that an electromotive force is generated within the heart during the period of contraction of this muscular organ. The precise causes of this effect are unknown. Nevertheless, the methods for measuring the variations of this electromotive force with time have been carefully standardized, and statistical records have been made for many years. By associating these records with case histories, a technique has been evolved for diagnosing certain diseases of the heart which is, in many instances, remarkably valuable. The development of electrocardiography has shown the benefits of carefully standardized scientific methods more than most other special fields of medicine in which electrical equipment has been used.

When the so-called "brain waves" are recorded by means of an electroencephalograph the wave forms are found to vary with age, with the somatic state of the individual, with the state of mental health of the individual, and with many other factors. Thus the development of this field of investigation has been based upon the recording of many electroencephalograms, their analysis and intercomparison, and finally attempts at diagnosis based upon these analyses. The electroencephalograph now finds clinical use in the corroborative diagnosis of epilepsy and, in many cases, in the localization of brain tumors.

ELECTROACOUSTIC DEVICES

12. AIDS TO THE DEAF

Those whose hearing is deficient require aids designed upon the basis of a quantitative study of their relative deafness. For this study a device called the audiometer is used; this instrument consists essentially of a vacuum-tube oscillator capable of producing practically pure tones accurately controllable as to pitch and intensity in head receivers. The pitch proceeds by octaves from 32 double vibrations per second to 16,384, with an intensity range of 10^9. Charts called audiograms have been made, showing the thresholds in sensation units, of hearing and of pain, for thousands of subjects with normal hearing. By comparing the audiograms, both the type and degree of deafness may be estimated. This constitutes a valuable aid in diagnosis and also is a useful adjunct for the prescription of hearing aids.

Many who are deaf learn to read lips. Care must be taken, therefore, to eliminate this source of error from tests of hearing aids, even though lip-reading may become a part of the method of understanding speech after the hearing aid is adopted. Some who have been deaf for a period of years require a considerable amount of time to learn to understand sounds heard with the aid of an electric device.

Hearing aids usually consist of a small microphone, a battery, and a special light-weight electromagnetic or crystal receiver. The system is designed to produce at the ear, as nearly as possible, an amplified replica of the sounds incident upon the microphone. If such a simple device does not amplify sufficiently, an amplifier using vacuum tubes may be added.

In recent years, the development of so-called "miniature" and "hearing-aid" tubes and of small batteries and printed circuits has considerably reduced the size and weight of such equipment.

More elaborate devices have been made for those whose hearing is especially deficient, in some instances the apparatus being designed to suit the individual requirements as determined from studies of the audiograms and the personal characteristics of the subject. Among the more elaborate examples of this type of hearing aid is the two-channel system in which two high-fidelity, velocity microphones are connected individually to two high-quality amplifiers, equipped with filters especially designed to compensate for the auditory deficiencies of the subject. The outputs of these two systems are then connected to individual headphones so that each ear of the subject has an entirely separate channel, separately connected, and affording corrected binaural (two-ear) hearing.

13. THE STETHOPHONE

About 1924 a device for picking up human heart sounds by means of a microphone and amplifying these sounds was developed and given the name "stethophone." The original purpose of the device was to make it possible for students in the amphitheater of the heart clinic to listen simultaneously with the demonstrator to the heart sounds of the patient under examination. The device had the additional advantage over the ordinary stethoscope of producing louder sounds in the listener's ear. It was further shown that by the insertion of electrical filters it was possible to eliminate portions of the audible frequency spectrum in order to concentrate upon certain specific sounds. This means of selective listening proved an aid in the diagnosis of murmers and other cardiac abnormalities. More recently this device has been used by physicians who are somewhat hard of hearing.

RECORDING OF HEART SOUNDS. Heart specialists have also shown that it is of value to record the heart sounds on a moving strip of paper or film simultaneously with an electrocardiographic record. This dual record has proved an aid in the diagnosis of certain cardiac disorders, and also for purposes of research into the mechanism of the heart.

ROENTGEN THERAPY

14. PURPOSE AND GENERAL TECHNICAL REQUIREMENTS

A short time after the announcement by Roentgen of the discovery of x-rays in 1895, a number of physicians began to use the new radiation for the treatment of certain diseases. It has been only since 1920, however, that important detailed data have been recorded and correlated. It has been definitely determined that the absorption of x-rays by living tissue can cause the destruction of that tissue. Destruction of a given type of tissue is dependent upon the dose rate (in roentgens per minute; see below), the duration and frequency of treatments, the area of the irradiated skin surface (portal), the total dose, and probably other factors as well. The destructive action is radically different with different kinds of tissue. The reproductive cells of the human body are most sensitive, and the bones are least affected. The treatment of malignant tumors, such as cancer, is based upon the fact that, to a certain extent, it is possible to cause destruction of the diseased tissue without permanently damaging normal surrounding tissue.

X-rays generated by means of a hot-cathode tube have continuous spectra characterized by a minimum wavelength dependent upon the maximum x-ray tube voltage. The shorter the wavelength, the more penetrating is the radiation (see also Section 4, x-ray tubes). For these reasons the kind of x-ray equipment chosen for therapeutic use depends upon the site of the diseased portion which it is intended to treat. If, for example, it is desired to treat the skin, it may prove desirable to use radiation of a wavelength of the order of 1 A. Such radiations are sometimes called Grenz rays. The most generally used x-ray therapy apparatus is operated at x-ray tube voltages of 50 to 400 kvp (peak kilovolts). A filter consisting of a few millimeters of aluminum, a few tenths of a millimeter of copper, or a combination of the two, is inserted between the x-ray tube and the patient. This filter absorbs a large part of the low-frequency radiation which would otherwise be absorbed by the skin. The filtered x-ray energy penetrates to the site of disease, and a reasonable proportion is absorbed and helps to produce the desired effect. Treatments by x-ray therapy have been apparently beneficial in some cases, particularly if the diseased part is properly diagnosed early in its development.

The gamma rays of radium have been valuable in treating cancer. It has therefore been assumed that x-ray apparatus capable of generating radiation comparable in frequency to gamma rays might prove useful. Experiments in this direction have led to the construction of tubes and apparatus capable of operating at 600 kvp to 2 Mev.

APPARATUS. The high-voltage generator (50–400 kvp) required for exciting an x-ray therapy tube is usually constructed with one of the following typical circuits as a basis (see also Section 7, Power Supply): (1) half-wave thermionic rectification; (2) special half-wave rectified voltage-doubling circuits with condensers (see Fig. 1); (3) full-wave thermionic rectification with condensers (nearly constant potential).

Two kinds of apparatus have been devised and put into relatively common use for operation at 1 and 2 Mev.

In one of these devices a van de Graaff generator and an x-ray tube are assembled in a steel tank into which air is introduced at a pressure of several atmospheres, the spark-over potential gradient of gases at high pressures being considerably greater than at normal atmospheric pressure. The van de Graaff generator consists of a continuous belt of insulating material mounted on two pulleys, one of which is at ground potential and is driven by a motor. Near the bottom pulley electrodes are mounted in front of and in back of the belt. A difference of potential is applied to these electrodes so that negative charges (electrons) are deposited on the belt. Thus the moving belt effectively carries a negative charge toward the top pulley. Surrounding this upper pulley there is mounted a hollow metal electrode to which a brush near the belt is connected. Electrons from the belt are conducted to the exterior surface of the hollow electrode, which thus acquires a negative charge. The cathode of the x-ray tube is connected to this upper electrode of the generator; the anode of the tube is grounded. In order to maintain uniform potential gradient throughout the length of the tube, cylindrical accelerating anodes are sealed into the glass column of the tube and connected to taps on a resistor which in turn is connected in parallel with the generator. The potential of the upper electrode with respect to ground increases at the beginning of operation until the sum of the resistor current, the x-ray tube current, and the leakage currents is equal to the rate at which charge is carried up on the belt. Thus, the tube operates at constant potential at voltages from 1 to 2 Mev, and currents of the order of a few tenths milliampere are obtained.

The second type of equipment used for voltages above 1 Mev employs the same kind of x-ray tube as the device described above but a different kind of high-voltage generator. The generator consists of an auto transformer (air core) operating at 180 cycles per second.

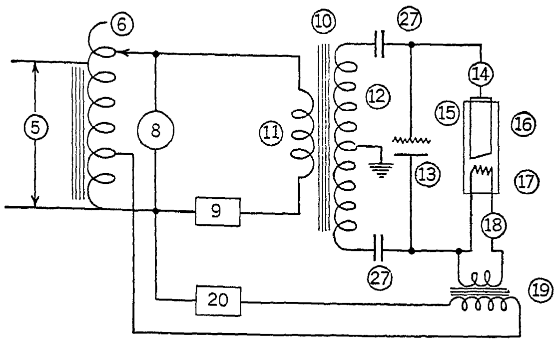

FIG. 1. X-ray Therapy Apparatus, with Half-wave, Voltage-doubling Circuit

5, a-c leads; 6, auto-transformer; 8, a-c voltmeter; 9, exposure timer; 10, high-tension transformer; 13, thermionic valve; 14, d-c milliammeter; 15, x-ray tube of which 16 is the anode, 17, the cathode; 18, cathode a-c ammeter; 19, the cathode heating transformer; 20, the cathode current regulator; and 27, the condenser.

The primary consists of a few turns of wire near the anode end of the tube wound coaxially with the axis of the tube. The secondary consists of a series of coils (each connected to an accelerating anode in the tube) mounted one above the other along the tube so that the top coil is approximately at the level of the cathode of the tube. This apparatus is enclosed in a steel tank into which "Freon" gas is pumped at a pressure of approximately 3 atmospheres.

15. TECHNIQUE

The x-ray tube mountings are arranged so that the patient may recline in a comfortable position during treatment. A lead-lined cone protects the patient and operator from scattered radiation. The radiation coming through the filter upon the patient is thus confined to an area of 10–400 sq cm called a *portal.* Investigations have been made to determine how much radiation is absorbed at various depths within the tissue. Sometimes in order to get the desired absorption within a deeply seated tumor it is necessary to turn the patient and to give several exposures through different portals, the central x-ray beam passing, in each case, through the tumor. This method of *cross-firing* prevents the absorption in any particular skin area from exceeding a tolerable dose. The distance from the tube to the patient is generally 50 to 100 cm. Tubes operate at currents of 5 to 30 ma, and the time of exposure may be from 5 to 45 min.

Just as with ultraviolet treatment, the individual tolerance must be investigated to prevent x-ray burn. In general a large factor of safety is allowed to prevent such a possibility.

The unit of x-ray dosage is called the roentgen. It is defined in terms of measurement by means of an ionization chamber. The roentgen is the quantity of x- or gamma-radiation such that the associated corpuscular emission per 0.001293 gram of air produces (in air) ions carrying 1 esu of quantity of electricity of either sign. It is assumed and apparently justified by empirical results that this measurement parallels the biologic effect of x-rays. The unit is an international standard. In some laboratories an ionization chamber is connected at all times; and in a few, the chamber operates an electric counter which integrates the total dose and turns off the power supply to the x-ray tube after the desired exposure. In other laboratories the x-ray machine is calibrated by means of a sphere gap and a milliammeter which measure respectively the peak kilovoltage supply to the x-ray tube and the average current through the x-ray tube. This calibration in turn is referred to the results of ionization-chamber measurements made several times each year.

ROENTGENOGRAPHY AND ROENTGENOSCOPY

16. PURPOSE, GENERAL TECHNICAL REQUIREMENTS, AND TECHNIQUE

In the first group of experiments performed by Roentgen the following x-ray phenomena were observed.

1. X-rays, incident upon photographically sensitive emulsions, produced a latent image similarly to visible light. Development of the emulsion produced a darkening of the film or plate throughout the area traversed by x-rays.

2. X-rays, incident upon barium platino cyanide, produced a visible (fluorescent) radiation.

3. X-ray absorption was greater for a given thickness of absorbing material in materials of high density than in materials of low density. For a given absorbing material x-ray absorption was found to be greater as the thickness increased.

These three facts form the bases of modern roentgenography.

The physically measurable characteristics of a roentgenogram of a part of the human body which are most important for medical diagnostic purposes are: (1) roentgenographic density; (2) roentgenographic contrast; (3) roentgenographic sharpness. Roentgenographic density and photographic density are identically defined as the logarithm to the base 10 of the ratio of light incident upon a particular area of film to the intensity of light transmitted through this area. Density is a function of x-ray intensity, therefore of x-ray tube voltage, distance of the plate from the x-ray tube, current through the x-ray tube, time of exposure, and of several less important factors, and also of the type of photographic material and of the method of development and the fixing and drying of this material. Density is, of course, a function of the physical characteristics of the object which is roentgenographed. Roentgenographic density may be measured with a polarization photometer or a photoelectric densitometer, or, for rougher approximation, densities may be compared by eye. This last method is most unsatisfactory. Roentgenographic contrast is the difference between the two densities of two areas of the roentgenogram and is therefore a function of the same variables as roentgenographic density. If it is desired to perceive the difference produced roentgenographically by tissue of nearly similar x-ray absorption characteristics in the object roentgenographed, then it is important to control the technique of roentgenography so as to make this difference clearly visible to the eye. Roentgenographic sharpness is the ability of a particular roentgenographic equipment to reproduce precisely borderlines between contiguous but definitely different densities. Information deduced from the physical measurements of these characteristics is influenced greatly by physiological and psychological factors associated with the viewing of roentgenograms, which factors have not as yet been completely investigated.

In order to roentgenograph any particular part of the human body a tube having a very small focal spot is necessary. It is also advisable to remove the film and object from the tube as far as possible in order to decrease distortion due to magnification of those parts of the object not in contact with the film. Since the focal spot of the x-ray tube is not a point there will be some loss in roentgenographic sharpness due to its finite size. If the object to be roentgenographed may be kept stationary for a moderately long period of exposure, the focal spot may be made correspondingly small. This method is employed for roentgenography of teeth and bones. If the part to be roentgenographed is continuously in motion a relatively short exposure is necessary, in order to arrest this motion sufficiently. Therefore, to roentgenograph parts such as the human chest the x-ray tube focal spot must be made correspondingly larger in order to dissipate rapidly the energy necessary for short exposure time. For roentgenography of the chest and heart, exposures of $^1/_{30}$ to $^1/_5$ sec are used. For roentgenography of other parts of the body the exposure time may be from $^1/_2$ to 20 sec.

To control the contrast in the roentgenograms the voltage of the x-ray tube is varied. The x-rays produced by high voltages are more penetrating than those produced by lower voltages. The voltage of the x-ray tube is generally measured by means of a sphere gap and is calibrated, for the particular current used, against the primary voltmeter reading. The x-ray-tube current for exposures longer than 3 sec is measured by a d-c d'Arsonval milliammeter. For very short exposures a ballistic milliampere-second meter is used to measure the total quantity of electricity passing through the x-ray tube. The timer for short exposures is arranged to make and interrupt the primary current at zero points of the first and last half cycle of the exposure. The target-film distance is varied, depending upon all the other factors involved; it generally has a value between 0.5 meter and 2 meters.

Secondary radiation from the heavier parts of the human body emanates in all directions, causing a general fogging effect over the whole area of the film and therefore reducing the contrast so important for accurate diagnosis. To minimize this, the Potter-Bucky diaphragm, consisting of a series of parallel lead strips perpendicular to the film and separated from each other by non-absorbing strips, is made to move over the surface of the film during exposure. The lead strips effectively absorb cross-radiation (secondary radiation) and therefore make better diagnostic results possible. Table 1 gives approximately the techniques required for making roentgenograms of various parts of the human body.

Table 1. Technique for Roentgenography and Roentgenoscopy

Purpose	Focal Spot-film Distance, meters	X-ray Tube Peak Voltage, kvp	X-ray Tube Current Average, ma	Exposure Time, seconds	Intensifying Screens
General roentgenoscopy..........	0.5–1.0	60–90	2–10	20–60	....
Roentgenography					
Hand........................	0.7–1.0	50–60	50	1.5	No
Elbow........................	0.7–1.0	40–60	50	1.5	No
Skull........................	0.7–1.0	60–75	100	1	Yes
Spine (use Bucky diaphragm)...	1.0	60–90	200	1	Yes
Colon (use Bucky diaphragm)...	1.0	60–90	100	1	Yes
Chest........................	1.25–2.0	45–85	30–500	0.4–0.033	Yes

17. APPARATUS

Roentgenoscopic apparatus comprises simply a high-tension transformer with the secondary connected directly to the x-ray tube (*self-rectification*) and a control apparatus for adjusting the x-ray-tube voltage and current to predetermined values from 60 to 90 kvp and from 2 to 10 ma. Portable roentgenographic machines are usually self-rectified. In order to avoid excessive voltage on the x-ray tube during the inverse half cycles, roentgenographic apparatus for use at 30 to 500 ma makes use of thermionic rectifiers. Up to 100 ma, a single thermionic rectifier is connected in series with the x-ray tube, resulting in half-wave rectification. At higher x-ray-tube currents (the usual ratings are 200 and 500 ma), four thermionic rectifiers are connected in a bridge circuit to produce full-wave rectifiers. In addition there are a few roentgenographic machines using three-phase rectifiers; there are also roentgenographic machines in which a high-voltage condenser with a capacitance of 0.25 to 1.0 μf is charged and subsequently discharged through the tube with effective exposure times of less than $^1/_{10}$ sec.

Several pieces of auxiliary equipment are essential for the production of good roentgenograms. Generally the film is contained in a light-tight cassette having a front plate of thin Bakelite or thin aluminum. Inside the cassette two intensifying screens, one on either side of the film, are arranged to maintain close contact with the film when the cassette is loaded. The x-rays passing through the screens excite fluorescence in the calcium tungstate or zinc sulfide contained therein, and this fluorescent light radiation records upon the film. Screens now used produce about 95 per cent of the total roentgenographic density, the other 5 per cent being caused by the direct absorption of x-rays in the film itself.

Conventional techniques require the use of 14-in. by 17-in. films for a roentgenogram of a chest. If it is desired to make chest films of many individuals, the cost is extremely high. This has led to the development of *photofluorographic* equipment for making x-ray surveys of the chest to discover early lesions of tuberculosis and other abnormalities. In this apparatus the x-rays which have traversed the patient impinge upon a fluorescent screen mounted in a light-tight box, opposite which a photographic camera is focused upon the screen. The camera records the image from the screen on 35-mm or 70-mm roll film, or on 4-in. by 5-in. flat film. Although the sharpness of the images of such photofluorograms is inferior to the sharpness of a roentgenogram, the results are believed by many radiologists to be accurate enough for surveys.

In order to standardize photofluorographic techniques, an automatic timing device has been developed. Light from a part of the screen is focused upon an electron multiplier tube, the output of which is integrated and used to operate a switch to discontinue the exposure at the end of the time required for producing the proper density on the film. This automatic timing device is now being tested for possible application to standard roentgenographic procedures.

The techniques of medical roentgenography have been increasingly used and further developed in the examination of industrial products. Thus the equipment operating at 2 Mev is capable of producing a satisfactory record on x-ray film of steel as thick as 12 in. The gamma rays from radium are also utilized to make films of metal parts. These are extremely valuable methods of inspecting the industrial products in order to detect faults within the product without destroying the product.

18. MISCELLANEOUS DEVICES

Of the many electrical devices used in medicine that are not mentioned in the sections above, three pieces of apparatus are briefly described in this section.

The *electron microscope* is a device in which a beam of electrons traverses a thin sample of tissue or other material and impinges upon a fluorescent screen or film to produce an enlarged image representing a pattern of the specimen. The electron beam is controlled by means of electrostatic or electromagnetic lenses. The RCA type EMU is a recently developed commercially available electron microscope. The magnification can be varied from 100 to 20,000; the resolving power is somewhat less than 100 A. The device operates with a maximum difference of potential of 50 kvp. Films made on the electron microscope can be photographically enlarged so that the overall magnification may exceed 100,000. Among the limitations of the device are: (1) it is extremely difficult properly to prepare specimens; and (2) the specimen may be destroyed or seriously modified in structure by the electron beam.

The *betatron* is a device for accelerating electrons to velocities closely approaching the speed of light. It consists of a laminated iron core with an air gap. Between the poles of the gap there is mounted a doughnut-shaped vacuum tube into which pulses of electrons with a duration of about 2 μsec and velocities corresponding to approximately 80 kvp can be injected into the evacuated space. A winding on the core is fed from a source of 180-cycle alternating current in order to produce across the air gap a magnetic field in which the flux density varies sinusoidally with time; the first rising one-quarter cycle of the flux ($^1/_{720}$ sec) actuates the device. The pulse of electrons is injected into the doughnut a few microseconds after the magnetic flux has passed through zero and is increasing. Subsequently, the increasing magnetic field causes the electrons to be accelerated; they traverse the circular path within the tube several hundred thousand times in $^1/_{720}$ sec. It is possible so to shape the pole pieces that these electrons will remain in a stable circular orbit during their acceleration. At the end of the period ($^1/_{720}$ sec) they are caused to spiral outward from the stable orbit and to impinge upon a target, causing the production of x-rays. Betatrons for producing electron velocities corresponding to 20 Mev have been in use for several years, and an experimental model of a 100 Mev betatron has been announced by the General Electric Company. At high equivalent voltages, some of the phenomena observed in cosmic-ray studies have been produced in the laboratory for the first time.

A *cyclotron* is a device for accelerating protons and heavier positive ions. Its operation depends upon two facts: (1) charged particles traveling at right angles to a constant magnetic field traverse a circular path with constant linear velocity in the absence of an electric field; (2) charged particles are accelerated in the presence of an electric field in the direction of their motion. Near the center of a shallow, cylindrical evacuated cavity, positive ions are emitted from a suitable source at very low velocities. The cylindrical space is surrounded by two semicircular *dees*, and the source of ions is located in the gap between the dees. A source of high-frequency alternating voltage is applied to the dees so that those positive ions that are emitted during the peak of a particular half cycle are accelerated toward the dee which, at that instant, is negatively charged. Upon entering the dee the effect of the electrostatic field becomes negligibly small, and the electrons would continue in a straight line except that the dees are mounted in the gap between the poles of an electromagnet excited by direct current. Thus the ions that have been initially accelerated by their first traverse of the gap between the dees travel in a semicircle inside the dees until they again reach the gap. The high-frequency source of potential between the dees is adjusted so that the ion will be again accelerated as it crosses the gap the second time.

This process is repeated, and the radius of the semicircle increases each time the ions are accelerated by the electric field. Thus the ions spiral outward and are subjected to two increases in acceleration during each revolution. After several hundred revolutions the ions spiral outward to the maximum diameter of the dees and are then emitted tangentially through a window. By placing various materials in the path of the beam outside the cyclotron, important nuclear experiments can be carried out. For example, when protons are accelerated in the cyclotron and permitted to impinge on beryllium, neutrons are produced in relatively large quantities. The largest of these devices, 184 in. in diameter, was constructed at the University of California under the direction of Dr. E. O. Lawrence, the inventor of the apparatus. The cyclotron has been used for many important experiments in the phenomenal developments of nuclear physics. Note that the operation of the cyclotron in its simplest form depends upon the following fact: The time required for ions to move through one semicircle remains constant regardless of the linear velocity as long as the velocity is not comparable with the velocity of light. Ions in cyclotrons with equivalent voltages of 20 Mev or less satisfy the condition.

Several suggestions have been made of methods for accelerating both electrons and positive ions to velocities corresponding to voltages of 10^8 or 10^9 volts, and development of these methods is now proceeding.

HIGH-VOLTAGE SHOCK AND X-RAY BURN

19. HIGH-VOLTAGE SHOCK

The physiological effects of a high-voltage electric shock may be classified in two groups: the major effects, such as cessation of respiration or heart action; and the less serious effects, such as fractures and internal injuries due to falls, and also burns.

The first necessary action is to remove the victim from the circuit *without touching him with bare hands*. If it is not possible to open the circuit by means of a switch near at hand, then it is usually effective to move the conductor, or the victim, with a non-conductor. A physician should be summoned immediately, and it is important to administer first aid or artificial respiration immediately while awaiting his arrival. If the victim is breathing, heart stimulants may be administered hypodermically. The body should be rubbed to produce external warmth, and the clothing should be loosened in order to excite consciousness.

If the victim does not breathe, artificial respiration should be applied as follows: Lay the subject face down with arms and legs extended, and turn the face one side so that the mouth and nose are free for breathing. Remove foreign bodies such as tobacco, gum, and false teeth from the mouth, and have an assistant draw the subject's tongue forward. Kneel, straddling the subject's thighs, facing his head; rest the palms of the hands on the muscles of the small of the back with fingers spread over the lowest ribs. With arms held straight, swing forward slowly so that weight is gradually brought to bear upon the subject. This operation should take 2 or 3 sec. Immediately swing backward, removing the pressure. Repeat this procedure 12 or 15 times a minute, a complete respiration in 4 or 5 sec. Continue artificial respiration at least an hour without interruption or until the physician arrives. Do not give any liquid by mouth until the subject is fully conscious. After the victim breathes again, shock treatment may be administered as outlined above. If any bones have been fractured or if the victim appears to have received internal injury do not move him any more than is necessary and prepare for removal to the nearest hospital.

If the victim has received burns the surface of the skin should be protected from the air. Cut around any clothing that sticks to the burns and saturate adhering cloth or cotton dressing with $^1/_2$ per cent solution of picric acid or a solution of baking soda, about 1 teaspoonful to a pint of water.

20. X-RAY BURN

As noted under the section on roentgen therapy the effect of x-rays on living tissue is always destructive. This effect is cumulative; that is, the successive application of small doses may cause destruction of living tissues. Workers in x-ray laboratories should be properly protected from exposure by the installation of lead or lead glass protective shields about the x-ray tube. If the worker must be in the field of the x-rays, he should wear a protective lead rubber apron, hood, and gloves. X-rays produced by low x-ray-tube voltages are absorbed almost completely by the skin. To eliminate these x-rays, which have normally no useful effect in treatment or roentgenography, a filter of $^1/_2$ mm or 1 mm of aluminum is placed between the x-ray tube and the patient.

The first effects of x-ray burn are reddening and itching of the skin and falling hair. Later, open sores may develop, which may subsequently cause the destruction of large areas.

Standards of x-ray protection have been set up and internationally accepted. *These standards should always be observed rigorously.* It is necessary to make periodic tests by having workers carry small pieces of light-protected film with a narrow lead strip covering part of the outer casing. These films are carried over a period of several working days and are then developed to discover whether any fogging has occurred on those portions of the film not protected by the lead strip. Such fogging indicates the need of more effective protective measures. Ionization chambers, similar in shape and size to fountain pens, may be charged and worn by a worker for several hours, and the exposure in fractions of a roentgen may be measured by means of a calibrated electrometer. Although there is some controversy concerning the magnitude of the safe daily tolerance dose, a commonly accepted value is 0.05 roentgen per day.
