FOURTH EDITION

WILEY ENGINEERING
HANDBOOK SERIES

NEW YORK : JOHN WILEY & SONS, INC.

LONDON : CHAPMAN & HALL, LIMITED

PRINTED IN THE UNITED STATES OF AMERICA

PREFACE

The first edition of Pender's *Handbook for Electrical Engineers*, compiled by a staff of specialists under the editorship of Harold Pender, appeared in 1914. The second edition, under the joint editorship of Pender and William A. Del Mar, was published in 1922. Both these editions covered all branches of electrical engineering as well as a large amount of material dealing with allied fields of interest to electrical engineers.

The third edition, published in 1936, was divided into two volumes: one on electric power under the editorship of Pender, Del Mar, and Knox McIlwain; the other on electrical communication and electronics under the editorship of Pender and McIlwain. Certain tables and fundamental theory were duplicated in the two volumes in order that each might be complete and independent of the other.

This plan met with such enthusiastic response that it has been continued in the fourth edition. The growth of knowledge and the greater degree of specialization in the various phases of electrical engineering have necessitated a considerable enlargement of both volumes. Careful selection and compression have been exercised in an effort to keep the books compact and readable. The treatment of subjects of decreased importance and those which are adequately treated by other handbooks of the Wiley Handbook Series has been either curtailed or left unchanged in length.

The bibliographies have been prepared with the idea of assisting the reader to further study of each subject; and they reflect each author's idea of this plan. The publications referred to are, in general, in the Engineering Societies Library, 29 West 39th Street, New York, N. Y. Most of them may be borrowed from the Library by members of its Founder Societies, the American Society of Civil Engineers, American Institute of Mining and Metallurgical Engineers, American Society of Mechanical Engineers, and American Institute of Electrical Engineers.

Seventy-eight specialists in their respective fields have contributed to this fourth and entirely rewritten edition of the Electronics and Communication portion of the *Electrical Engineers' Handbook*, as compared with twenty-seven, forty-five, and fifty-seven in previous editions. This reflects the rapid widening in the electronics field. In particular, frequency modulation and all the pulse techniques in both the communication and radar fields appear in the volume for the first time. The increased complexity and importance of radio aids to navigation are also of interest.

The editors' thanks are due to the many well-known and busy men who have contributed textual material, both for their unselfish efforts to make this a reliable reference work and for their continued patience with editorial vagaries. They are also due to Messrs. R. L. Jones, R. K. Honaman, and A. R. Thompson of the Bell Telephone Laboratories, Mr. Frank A. Cowan of the American Telephone and Telegraph Company, and Mr. E. W. Engstrom of RCA Laboratories for aid in the organization of the book.

Harold Pender, Consultant, Moore School of Electrical Engineering, University of Pennsylvania.

Dr. E. Peterson, Member Technical Staff, Bell Telephone Laboratories. *Wave Analysis.*

J. D. Phyfe, Product Engineer, Theatre Sound Equipment, Radio Corp. of America, RCA Victor Division. *Projection Practices.*

N. Y. Priessman, Member of Technical Staff, Bell Telephone Laboratories. *Varistors and Thermistors.*

Dr. G. L. Ragan, Research Associate, General Electric Company. *Wave-guide Components.*

Dr. E. G. Ramberg, Research Physicist, Radio Corp. of America, RCA Laboratories Division. *Television Pick-up Tubes.*

P. H. Richardson, Member of Technical Staff, Bell Telephone Laboratories. *Theory of Linear Passive Networks, Recurrent Networks.*

Arnold J. Rohner, Project Engineer, Bendix Radio Division. *Ferrous Cored Inductors, Transformers with Iron Cores.*

A. L. Samuel, Professor of Electrical Engineering, University of Illinois. *Klystrons.*

Arthur H. Schafer, Member of Technical Staff, Bell Telephone Laboratories. *Resistors and Rheostats.*

Dr. S. A. Schelkunoff, Member of Technical Staff, Bell Telephone Laboratories. *Wave-guide Theory.*

J. C. Schelleng, Radio Research Engineer, Bell Telephone Laboratories. *Radio Antennas, Transmission in Space.*

Dr. Theodore Soller, Professor of Physics, Amherst College. *Cathode-ray Tube Displays.*

F. J. Somers, Staff Engineer, National Broadcasting Company. *Television Broadcasting.*

Dr. John C. Steinberg, Member of Technical Staff, Bell Telephone Laboratories. *The Sense of Hearing, Speech and Music, Effects of Distortion.*

L. E. Swedlund, Sr. Engineer, Radio Corp. of America, RCA Victor Division. *Cathode-ray Tubes.*

W. O. Swinyard, Chief Engineer, Hazeltine Research, Inc. *Routine Measurement of A-m and F-m Broadcast Receivers.*

John D. Taylor, Consulting Engineer, American Telephone & Telegraph Company. *Telephony, Telegraphy, Coordination of Communication and Power Systems, Wire Transmission Lines, Mechanical Features of Transmission Lines.*

L. Vieth, Member of Technical Staff, Bell Telephone Laboratories. *Magnetic Recording and Reproducing of Sound, Mechanical Recording and Reproducing of Sound.*

Arthur H. Volz, Member of Technical Staff, Bell Telephone Laboratories. *Potentiometers and Rheostats.*

Dr. S. Reid Warren, Jr., Associate Professor, Moore School of Electrical Engineering, Associate Professor Radiologic Physics, Graduate School of Medicine, University of Pennsylvania. *X-ray Tubes, Medical Applications of Electricity.*

Charles Weyl, Professor, Moore School of Electrical Engineering, Associate Professor of Radiologic Physics, Graduate School of Medicine, University of Pennsylvania. *Medical Applications of Electricity.*

H. A. Wheeler, Consulting Radio Physicist, engaged for this work by Hazeltine Electronics Corp. *Pulse Techniques, Transient Networks.*

I. G. Wilson, Member of Technical Staff, Bell Telephone Laboratories. *Cavity Resonators.*

J. E. Young, Supervisor, Broadcast Engineering Section, Radio Corp. of America, RCA Victor Division. *Modulators, Power Supply, Radio Transmitters, F-m Transmitters.*

Dr. V. K. Zworykin, Vice President and Technical Consultant, Radio Corp. of America, RCA Laboratories Division. *Television Pick-up Tubes.*

GENERAL TABLE OF CONTENTS

Detailed tables of contents are given at the beginning of each section. An alphabetical index appears after Section 23.

SECTION 16. SOUND-REPRODUCTION SYSTEMS

SECTION 17. TELEPHONY

SECTION 18. TELEGRAPHY

SECTION 19. FACSIMILE TRANSMISSION AND RECEPTION

SECTION 20. TELEVISION

SECTION 21. ELECTRONIC CONTROL EQUIPMENT

SECTION 22. AIDS TO NAVIGATION

SECTION 23. MEDICAL APPLICATIONS OF ELECTRICITY

This book is divided into sections, each section carrying its independent sequence of page numbers. For example, 3-15 indicates Section 3, page 15.

1. ALGEBRAIC FORMULAS

MISCELLANEOUS FORMULAS

$$(a \pm b)^2 = a^2 \pm 2ab + b^2$$

$$(a \pm b)^3 = a^3 \pm 3a^2 b + 3ab^2 \pm b^3$$

$$(a \pm b)^n = \sum_{k=0}^{n} \frac{n!}{k!\,(n-k)!} a^k (\pm b)^{(n-k)}, \qquad n! = n(n-1)\ldots 3 \times 2 \times 1$$

$$a^2 - b^2 = (a+b)(a-b)$$

$$a^2 + b^2 = (a+jb)(a-jb), \quad j = \sqrt{-1}$$

$$a^x \times a^y = a^{(x+y)}, \quad a^\circ = 1 \text{ [for } a \neq 0], \quad (ab)^x = a^x b^x$$

$$\frac{a^x}{a^y} = a^{(x-y)}, \quad a^{-x} = \frac{1}{a^x}, \quad \left(\frac{a}{b}\right)^x = \frac{a^x}{b^x}$$

$$(a^x)^y = a^{xy}, \quad a^{1/x} = \sqrt[x]{a}, \quad \sqrt[x]{ab} = \sqrt[x]{a}\,\sqrt[x]{b}$$

$$\sqrt[x]{\sqrt[y]{a}} = \sqrt[xy]{a}, \quad a^{x/y} = \sqrt[y]{a^x}, \quad \sqrt[x]{\frac{a}{b}} = \frac{\sqrt[x]{a}}{\sqrt[x]{b}}$$

$$\log (a^x) = x \log a, \quad \log ab = \log a + \log b$$

$$\log \frac{a}{b} = \log a - \log b$$

$$\text{If } \frac{a}{b} = \frac{c}{d} \text{ then } \frac{a \pm b}{b} = \frac{c \pm d}{d} \text{ and } \frac{a-b}{a+b} = \frac{c-d}{c+d}$$

The sum of an arithmetical progression is given by

$$s = \frac{n}{2}(a + l) = \frac{n}{2}\{2a + (n-1)d\}$$

where $l = a + (n-1)d$ is the last term, a is the first term, d is the common difference, and s is the sum of the n terms.

The sum of a geometrical progression is given by

$$s = a\,\frac{(1 - r^n)}{1 - r} = \frac{lr - a}{r - 1}$$

where $l = ar^{n-1}$ is the last term, a is the first term, d is the common ratio, and s is the sum of the n terms. If n approaches infinity and r^2 is less than unity

$$s = \frac{a}{1 - r}$$

The multiple product represented by $n(n-1)(n-2)\ldots 3 \times 2 \times 1$ is designated by the symbol $n!$ or $\underline{|n}$ and is called " n factorial." The following list gives the value of $n!$ up to $n = 10$

1! =	1	6! =	720
2! =	2	7! =	5,040
3! =	6	8! =	40,320
4! =	24	9! =	362,880
5! =	120	10! =	3,628,800

For large values of n a good approximation for $n!$ is, from Stirling's formula,

$$n! = (2\pi n)^{1/2} \left(\frac{n}{e}\right)^n, \quad e = 2.7182818$$

This formula is accurate to about $2^1/_2$ per cent at $n = 10$ and becomes more accurate very rapidly as n is increased,

The number of permutations or arrangements of n things taken p at a time is

$$P_p^n = \frac{n!}{(n-p)!}$$

The number of combinations of n things taken p at a time is then

$$C_p^n = \frac{1}{p!} P_p^n$$

QUADRATIC EQUATION. The solution of

$$ax^2 + bx + c = 0$$

is

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

If a, b, and c are real, and the discriminant, $b^2 - 4ac$, is positive, the roots are real and unequal; if it is zero, the roots are real and equal; if it is negative, the roots are conjugate complex numbers.

CUBIC EQUATIONS. The solution of

$$ax^3 + 3bx^2 + 3cx + d = 0 \qquad (1)$$

is obtained as follows: Put $x = \frac{1}{a}(y - b)$; then (1) becomes

$$y^3 - 3Hy + G = 0$$

where

$$H = b^2 - ac$$
$$G = a^2 d - 3abc + 2b^3$$

For a solution let

$$A = \sqrt[3]{\frac{-G}{2} + \sqrt{\frac{G^2}{4} - H^3}}, \quad B = \sqrt[3]{\frac{-G}{2} - \sqrt{\frac{G^2}{4} - H^3}}$$

then the values of y will be given by

$$y = A + B, \quad -\frac{1}{2}(A + B) + j\frac{\sqrt{3}}{2}(A - B), \quad -\frac{1}{2}(A + B) - j\frac{\sqrt{3}}{2}(A - B)$$

If a, b, c, d are real and if $G^2 - 4H^3$, the discriminant, is positive there are one real root and two conjugate complex roots; if $G^2 - 4H^3$ is zero there are three real roots, at least two of which are equal; if $G^2 - 4H^3$ is negative there are three real and unequal roots.

The solution may be written in three other forms.

(1) Put

$$\phi = \frac{1}{3}\sin^{-1}\left[\frac{G}{2H\sqrt{H}}\right]$$

then the roots are

$$y = 2\sqrt{H}\sin\phi, \quad 2\sqrt{H}\sin(\phi + 120°), \quad 2\sqrt{H}\sin(\phi - 120°)$$

Or (2) put

$$u = \frac{1}{3}\cosh^{-1}\left[\frac{G}{2H\sqrt{H}}\right]$$

then the roots are

$$y = -2\sqrt{H}\cosh u, \quad \sqrt{H}\cosh u + \sqrt{-3H}\sinh u, \quad \sqrt{H}\cosh u - \sqrt{-3H}\sinh u$$

Or (3) put

$$u = \frac{1}{3}\sinh^{-1}\left[\frac{G}{2H\sqrt{-H}}\right]$$

Then the roots are

$$y = 2\sqrt{-H}\sinh u, \quad -\sqrt{-H}\sinh u + \sqrt{3H}\cosh u$$
$$-\sqrt{-H}\sinh u - \sqrt{3H}\cosh u$$

SIMULTANEOUS EQUATIONS. Given n independent equations in n unknowns, these n equations usually fix one or more values for each of the n unknowns. To solve such a set of simultaneous equations in x, y, and z, say, solve each of the three equations for x in terms of y and z. Equating these three values for x gives two equations in y and z. Solving each of these two equations for y in terms of z and equating these two values of y gives a single equation in z. The solution of this last equation then gives the value of z. Then substitute this value of z in either of the equations in y and z, and solve for y. Then substitute these values of y and z in any one of the original equations and solve for x.

DETERMINANTS. In the case of linear simultaneous equations (i.e., when x, y, and z occur only to the first power), the equations may be solved by determinants. This method is a considerable time-saver when the number of unknowns is greater than three, but when the number of unknowns is three or less the straight substitution method is preferable.

The determinant of a set of simultaneous equations is formed by writing the equations one below the other with the same unknown in the same relative position in each. The block of numbers forming the coefficients of the unknowns is called the determinant. For example, the determinant of the equations

$$\begin{aligned} w + x + y + z &= 6 \\ w + y + 3z &= 4 \\ w + 2x + 3y &= 1 \\ w + 3x + z &= 3 \end{aligned}$$

is

$$D = \begin{vmatrix} 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 3 \\ 1 & 2 & 3 & 0 \\ 1 & 3 & 0 & 1 \end{vmatrix}$$

The values of any one of the unknowns, say y, is found by writing a second determinant, D_y, exactly like the determinant D, except that the constants forming the right-hand members of these equations are substituted for the coefficients of y in the determinant, that is

$$D_y = \begin{vmatrix} 1 & 1 & 6 & 1 \\ 1 & 0 & 4 & 3 \\ 1 & 2 & 1 & 0 \\ 1 & 3 & 3 & 1 \end{vmatrix}$$

Then

$$y = \frac{D_y}{D}$$

and similarly for the other unknowns.

The value of any determinant is found by making use of the following rules:

(1) If a determinant has two equal rows or columns, it is equal to zero.

(2) To any row or column one may add or subtract any number of times any other row or column without altering the value of the determinant.

(3) To multiply any row or column by a number is the same as multiplying the determinant by that number.

(4) If all the terms in a row or column except one are zero, the determinant reduces to one of a lower order which may be obtained by striking out the row and column which intersect at the element of the row or column which is not zero, and multiplying the whole by that element, changing the sign of this element, however, if it is removed by an odd number of elements from the principal diagonal. The principal diagonal is the line of elements beginning at the upper left-hand corner and ending at the lower right-hand corner. Thus,

$$\begin{vmatrix} 1 & 2 & 8 & 5 \\ 3 & 4 & 6 & 9 \\ 0 & 3 & 0 & 0 \\ 6 & 7 & 4 & 3 \end{vmatrix} = -3 \begin{vmatrix} 1 & 8 & 5 \\ 3 & 6 & 9 \\ 6 & 4 & 3 \end{vmatrix}$$

the principal diagonal being that with the figures 1, 4, 0, and 3. It is immaterial whether the distance from the diagonal is counted along a row or a column.

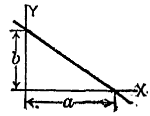
(5) The value of a determinant of the second order is

$$\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix} = a_1 b_2 - a_2 b_1$$

The reduction of determinants is effected by altering the terms according to the above rules until a row or column is obtained in which all terms but one are zero. This enables a reduction of order to be effected in accordance with rule 4. Reductions are continued until one of the second order is obtained.

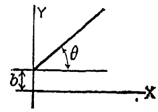
EQUATIONS OF COMMON CURVES. **Straight Line.**

$$\frac{x}{a} + \frac{y}{b} = 1$$



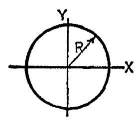
or

$$y = x \tan \theta + b.$$



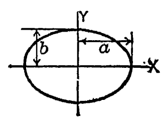
Circle.

$$x^2 + y^2 = R^2$$



Ellipse.

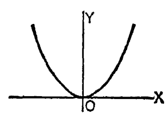
$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1.$$



Parabola (Vertical).

$$y = kx^2$$

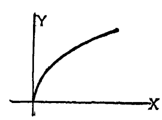
where k is a constant.



Parabola (Horizontal).

$$y = k\sqrt{x}$$

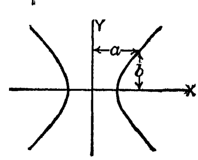
where k is a constant.



Hyperbola.

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1 \text{ (Horizontal)}$$

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = -1 \text{ (Vertical)}$$



Rectangular or Equilateral Hyperbola.

$$y = \frac{k}{x}$$

where k is a constant.

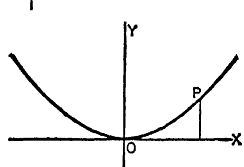
Catenary.

$$y = \frac{1}{k} \cosh kx - 1$$

where k is a constant. The length of arc from O to P is

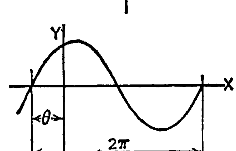
$$= \frac{1}{k} \sinh (kx)$$

See tables of hyperbolic functions.



Sinusoid.

$$y = A \sin (ax + \theta).$$



·2. COMPLEX QUANTITIES

The square root of a negative quantity is called an "imaginary" quantity, or a pure imaginary. A quantity consisting of the sum or difference of a real quantity and an imaginary quantity is called a "complex" quantity. All the rules of ordinary algebra apply to pure imaginaries and complex quantities. The square root of minus one is called the imaginary unit and is usually represented by the symbol j (writers on pure mathematics use the symbol i), that is,

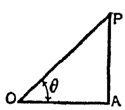
$$j = \sqrt{-1}$$

Any complex quantity may then be written

$$a + jb$$

where a and b are both real quantities.

GEOMETRICAL REPRESENTATION OF A COMPLEX QUANTITY. A positive real quantity may be represented by a line drawn on a plane in a given direction; a negative real quantity may be represented by a line drawn in the opposite direction. Multiplying a quantity by -1 then reverses its direction. Also, since multiplying a real quantity by $\sqrt{-1}$ twice is equivalent to multiplying it by -1, the operation of multiplying once by $\sqrt{-1}$ may be represented by turning the line representing the quantity through 90° in the positive direction of rotation. The positive direction of rotation is taken as the opposite direction to that in which the hands of a clock move. Hence, a complex quantity $a + jb$ may be represented by the line OP in the figure, where $OA = a$ and $AP = b$. The complex quantity $a + jb$ is then completely specified by a line of length $\sqrt{a^2 + b^2}$ making an angle θ, with the axis of reference OX where $\tan\theta = \frac{b}{a}$. The length $M = \sqrt{a^2 + b^2}$ is called the magnitude of the complex quantity, and the angle $\theta = \tan^{-1}\frac{b}{a}$ is called its angle. From the figure it is evident that the complex quantity $a + jb$ may also be written



$$a + jb = M(\cos\theta + j\sin\theta)$$

Expanding $\cos\theta$ and $\sin\theta$ into series (see Series, Article 9) and adding, the resultant series obtained is the series for $e^{j\theta}$; hence

$$a + jb = Me^{j\theta} \tag{1}$$

From the above definitions and equation (1) it is evident that complex numbers possess the following properties:

ADDITION OF TWO COMPLEX QUANTITIES.

$$(a + jb) + (a_1 + jb_1) = (a + a_1) + j(b + b_1)$$

SUBTRACTION OF TWO COMPLEX QUANTITIES.

$$(a + jb) - (a_1 + jb_1) = (a - a_1) + j(b - b_1)$$

MULTIPLICATION OF A COMPLEX QUANTITY BY A COMPLEX NUMBER.

$$(a + jb)(a_1 + jb_1) = aa_1 - bb_1 + j(ab_1 + a_1 b)$$

or, putting $\quad a + jb = Me^{j\theta}$ and $a_1 + jb_1 = M_1 e^{j\theta_1}$

where $\quad M = \sqrt{a^2 + b^2}, \qquad M_1 = \sqrt{a_1{}^2 + b_1{}^2}$

$$\tan\theta = \frac{b}{a}$$

and

$$\tan\theta_1 = \frac{b_1}{a_1}$$

we have $\quad (a + jb)(a_1 + jb_1) = Me^{j\theta} M_1 e^{j\theta_1} = MM_1 e^{j(\theta+\theta_1)}$

Hence the product of two complex quantities is in general a complex quantity which has a magnitude equal to the product of the magnitudes of the two quantities and an angle equal to the sum of the angles of the two quantities.

DIVISION OF A COMPLEX QUANTITY BY A COMPLEX NUMBER.

$$\frac{a + jb}{a_1 + jb_1} = \frac{(a + jb)(a_1 - jb_1)}{(a_1 + jb_1)(a_1 - jb_1)} = \frac{aa_1 + bb_1 - j(ab_1 - a_1 b)}{a_1{}^2 + b_1{}^2}$$

or

$$\frac{a + jb}{a_1 + jb_1} = \frac{Me^{j\theta}}{M_1 e^{j\theta_1}} = \frac{M}{M_1} e^{j(\theta-\theta_1)}$$

Hence the quotient of two complex quantities is in general a complex quantity which has a magnitude equal to the quotient of the magnitudes of the two quantities and an angle equal to the difference of the angles of the two quantities.

SQUARE ROOT OF A COMPLEX QUANTITY.

$$\sqrt{a + jb} = \pm \left[\sqrt{\frac{\sqrt{a^2 + b^2} + a}{2}} + j \sqrt{\frac{\sqrt{a^2 + b^2} - a}{2}} \right]$$

$$\sqrt{a - jb} = \pm \left[\sqrt{\frac{\sqrt{a^2 + b^2} + a}{2}} - j \sqrt{\frac{\sqrt{a^2 + b^2} - a}{2}} \right]$$

and in general

$$\sqrt[N]{a + jb} = M^{1/N} \epsilon^{j\theta/N}$$

Hence the nth root of a complex quantity is, in general, a complex quantity which has a magnitude equal to the nth root of the magnitude M of the quantity and an angle equal one-nth of the angle of the quantity.

EQUATIONS CONTAINING COMPLEX QUANTITIES. Since a real quantity cannot be equal to an imaginary quantity it follows that any equation of the form

$$A + jB = A_1 + jB_1$$

where A, B, A_1, and B_1 are all real quantities (which may, however, consist of any number of terms), is equivalent to the two equations

$$A = A_1$$

and

$$B = B_1$$

Also, if one member of an equation reduces to the form $A + jB$, then the other member of this equation must likewise contain an equal real and an equal imaginary part.

See K. S. Johnson, *Transmission Circuits for Telephonic Communication*, D. Van Nostrand.

3. TRIGONOMETRIC FORMULAS

The trigonometric functions of an angle are the ratios to one another of the various sides of a right triangle having the given angle as one of its angles. Referring to Fig. 1, let B, P, and H be the three sides of a triangle. Then the trigonometric functions of the angle x are

sine of x, abbreviated	$\sin x = \frac{P}{H}$;	cotangent of x, abbreviated	$\cot x = \frac{B}{P}$
cosine of x, abbreviated	$\cos x = \frac{B}{H}$;	secant of x, abbreviated	$\sec x = \frac{H}{B}$
tangent of x, abbreviated	$\tan x = \frac{P}{B}$;	cosecant of x, abbreviated	$\csc x = \frac{H}{P}$

When B, P, and H are limited to the three sides of a right triangle, the above definitions are directly applicable only to angles lying between 0 and 90°. The definitions, however, may be extended by considering the point A (Fig. 2) as describing a circle of radius OA

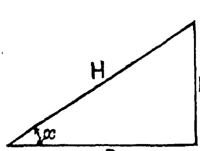


FIG. 1

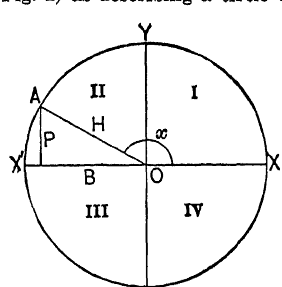

FIG. 2

with the center at O. Let XX' be the horizontal diameter and YY' the vertical diameter of this circle, and call P the perpendicular distance from A to the line XX' and B the horizontal distance from A to YY'. P is to be considered positive when A lies above XX', negative when below. B is considered positive when A is to the right of YY' and negative when to the left. The four quarters of the circle are called quadrants, and are designated as the first, second, third, and fourth quadrants as indicated. The angle is said to lie in the quadrant in which the point A lies. In Fig. 2 the angle x is in the second quadrant.

Algebraic Signs of the Functions

	Sine	Cosine	Tangent
Angle in first quadrant	+	+	+
Angle in second quadrant	+	−	−
Angle in third quadrant	−	−	+
Angle in fourth quadrant	−	+	−

Period. From the above definitions it is evident that adding 2π radians or 360° to an angle does not change the value of any of its functions; that is, these functions repeat themselves every time the angle increases by the 2π radians or 360°. They are therefore said to have a period equal to 2π radians or 360°.

Functions of Angles in Any Quadrant in Terms of Angles in First Quadrant.

$$\begin{aligned}
\sin(-x) &= -\sin x & \sin(90+x) &= \cos x\\
\cos(-x) &= \cos x & \cos(90+x) &= -\sin x\\
\tan(-x) &= -\tan x & \tan(90+x) &= -\cot x\\
\sin(180-x) &= \sin x & \sin(180+x) &= -\sin x\\
\cos(180-x) &= -\cos x & \cos(180+x) &= -\cos x\\
\tan(180-x) &= -\tan x & \tan(180+x) &= \tan x\\
\sin(270-x) &= -\cos x & \sin(270+x) &= -\cos x\\
\cos(270-x) &= -\sin x & \cos(270+x) &= \sin x\\
\tan(270-x) &= \cot x & \tan(270+x) &= -\cot x
\end{aligned}$$

Anti-functions. If $a = \sin x$, then x is the angle whose sine is a; this may be expressed symbolically $x = \sin^{-1} a$, which is read "x equals the angle whose sine is a." The angle x is also called the "anti-sine" or the "inverse sine" of a. Similar notation is used for the other functions; for example, $x = \cos^{-1} b$ is used to express the relation that x is the angle whose cosine is b. At least two "anti-functions" must be known to completely determine the quadrant in which an angle lies; for example, if $x = \sin^{-1} 0.5$ then x may be either 30° or 150°, but if we also have $x = \cos^{-1} 0.866$, then x must equal 30°, while if $x = \cos^{-1}(-0.866)$, then x must equal 150°.

Anti-functions may be taken from the Trigonometric Tables by finding the angle in the margin corresponding to the function in the table.

Example. $\sin^{-1} 0.319 = 18.6°$ or $180° - 18.6° = 161.4°$.

Versine. The expression $(1 - \cos x)$ is called the "versine" of x.

Relations among Functions of the Same Angle.

$$\begin{aligned}
\tan x &= \frac{\sin x}{\cos x} = \frac{1}{\cot x} & \sin^2 x + \cos^2 x &= 1\\
\sec x &= \frac{1}{\cos x} & 1 + \tan^2 x &= \frac{1}{\cos^2 x}\\
\csc x &= \frac{1}{\sin x} & 1 + \cot^2 x &= \frac{1}{\sin^2 x}\\
\sin(90-x) &= \cos x & \sin(-x) &= -\sin x\\
\cos(90-x) &= \sin x & \cos(-x) &= \cos x\\
\tan(90-x) &= \cot x & \tan(-x) &= -\tan x
\end{aligned}$$

Sum and Difference of Two Angles.

$$\begin{aligned}
\sin(x+y) &= \sin x \cos y + \cos x \sin y\\
\cos(x+y) &= \cos x \cos y - \sin x \sin y\\
\tan(x+y) &= \frac{\tan x + \tan y}{1 - \tan x \tan y}\\
\sin(x-y) &= \sin x \cos y - \cos x \sin y\\
\cos(x-y) &= \cos x \cos y + \sin x \sin y\\
\tan(x-y) &= \frac{\tan x - \tan y}{1 + \tan x \tan y}
\end{aligned}$$

Product of the Functions of Two Angles.

$$\sin x \sin y = \tfrac{1}{2}[\cos(x-y) - \cos(x+y)]$$
$$\sin x \cos y = \tfrac{1}{2}[\sin(x+y) + \sin(x-y)]$$
$$\cos x \sin y = \tfrac{1}{2}[\sin(x+y) - \sin(x-y)]$$
$$\cos x \cos y = \tfrac{1}{2}[\cos(x+y) + \cos(x-y)]$$

Functions of Twice an Angle.

$$\sin 2x = 2 \sin x \cos x \qquad \cos 2x = \cos^2 x - \sin^2 x = 2\cos^2 x - 1$$
$$\tan 2x = \frac{2 \tan x}{1 - \tan^2 x}$$

Functions of Half an Angle.

$$\sin\frac{x}{2} = \sqrt{\frac{1-\cos x}{2}} \qquad \cos\frac{x}{2} = \sqrt{\frac{1+\cos x}{2}} \qquad \tan\frac{x}{2} = \sqrt{\frac{1-\cos x}{1+\cos x}}$$

Functions of Three Times an Angle.

$$\sin 3x = 3\sin x - 4\sin^3 x \qquad \cos 3x = 4\cos^3 x - 3\cos x$$
$$\tan 3x = \frac{3\tan x - \tan^3 x}{1 - 3\tan^2 x}$$

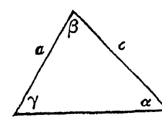

FIG. 3

TRIGONOMETRY. Any triangle is completely defined when (1) two sides and the included angle are known, (2) one side and two angles are known, (3) three sides are known. Let the sides and angles of a triangle be designated as in Fig. 3.

1. Given two sides a and b, and the included angle γ. Then

$$c = \sqrt{a^2 + b^2 - 2ab\cos\gamma}$$
$$\sin\alpha = \frac{a}{c}\sin\gamma$$
$$\beta = 180 - \alpha - \gamma$$

2. Given the side a and the two angles β and γ. Then

$$\alpha = 180 - \beta - \gamma$$
$$b = a\frac{\sin\beta}{\sin\alpha}$$
$$c = a\frac{\sin\gamma}{\sin\alpha}$$

3. Given the three sides a, b, and c. Put

$$s = \tfrac{1}{2}(a + b + c)$$

Then

$$\sin\alpha = \frac{2}{bc}\sqrt{s(s-a)(s-b)(s-c)}$$
$$\sin\beta = \frac{b}{a}\sin\alpha$$
$$\gamma = 180 - \alpha - \beta$$

Relations between Sides and Angles. The following relations between the sides and angles of a triangle are sometimes useful:

$$\frac{a}{\sin\alpha} = \frac{b}{\sin\beta} = \frac{c}{\sin\gamma}$$
$$\cos\alpha = \frac{b^2 + c^2 - a^2}{2bc}$$
$$\sin\frac{\alpha}{2} = \sqrt{\frac{(s-b)(s-c)}{bc}}$$
$$\cos\frac{\alpha}{2} = \sqrt{\frac{s(s-a)}{bc}}$$

and similar relations for the other two angles.

4. EXPONENTIAL AND HYPERBOLIC FORMULAS

When the relation between any variable y and another variable x is such that x occurs as an exponent of one or more terms, y is said to be an exponential function of x. Of particular importance in connection with electric circuits are the exponential functions e^x and e^{-x}, where e is the base of the natural logarithms. Since x is the natural logarithm of e^x, the value of e^x can be obtained from the table of common logarithms as shown at the beginning of that table. In addition the values of e^x and e^{-x} are given in a separate table.

Hyperbolic functions are an extension of the trigonometric functions to those cases where the use of the latter gives rise to imaginary or complex angles. From the relations

$$\cos x = \frac{e^{jx} + e^{-jx}}{2}$$

$$\sin x = \frac{e^{jx} - e^{-jx}}{2j}$$

where $j = \sqrt{-1}$, it follows that, putting $x = jz$:

$$\cos jz = \frac{e^z + e^{-z}}{2} \tag{1}$$

$$-j \sin jz = \frac{e^z - e^{-z}}{2} \tag{2}$$

Expressions (1) and (2) are both real quantities when z is real, that is, when the angle jz is imaginary. The first expression is called the hyperbolic cosine of z, abbreviated and pronounced "cosh"; the second expression is called the hyperbolic sine of z, abbreviated sinh and pronounced "shin." Hence, using x for the variable,

$$\sinh x = \frac{e^x - e^{-x}}{2}$$

$$\cosh x = \frac{e^x + e^{-x}}{2}$$

The hyperbolic tangent, cotangent, secant, and cosecant are defined as follows:

$$\tanh x = \frac{\sinh x}{\cosh x}$$

$$\coth x = \frac{\cosh x}{\sinh x}$$

$$\operatorname{sech} x = \frac{1}{\cosh x}$$

$$\operatorname{csch} x = \frac{1}{\sinh x}$$

The hyperbolic angle x is a number analogous to radians in circular measure; it is never expressed in degrees.

Adding 2π to an angle does not change the value of the trigonometric functions; they are therefore said to have a period equal to 2π radians. Hyperbolic functions, however, have no true period, but adding $2\pi j$ to the hyperbolic angle does not change the values of the functions; hence these functions have an imaginary period, $2\pi j$.

For the value of the hyperbolic functions see tables of exponential and hyperbolic functions, Article 13.

Approximate Formulas. Note that, for x less than 0.1,

$$\sinh x = x \text{ with an error of less than 0.2 per cent}$$

$$\cosh x = 1 + \frac{x^2}{2} \text{ with an error of less than 0.09 per cent}$$

For x greater than 6,

$$\sinh x = \cosh x = \frac{e^x}{2} = \frac{1}{2} \log_{10}^{-1} (0.43429x)$$

with an error of less than 0.01 per cent.

Anti-functions. If $a = \sinh x$, then x is the angle whose hyperbolic sine is a; this may be expressed symbolically

$$x = \sinh^{-1} a$$

which is read "x equals the angle whose hyperbolic sine is a." The angle x is also called the "anti-hyperbolic sine" or the "inverse hyperbolic sine" of a. Similarly for the other hyperbolic functions. The following relations exist between the anti-hyperbolic functions and the natural logarithms:

$$\sinh^{-1} x = \log (x + \sqrt{x^2 + 1})$$
$$\cosh^{-1} x = \log (x + \sqrt{x^2 - 1})$$
$$\tanh^{-1} x = \frac{1}{2} \log \left(\frac{1 + x}{1 - x}\right)$$

Relations among Functions of the Same Angle.

$$\cosh^2 x - \sinh^2 x = 1$$
$$1 - \tanh^2 x = \frac{1}{\cosh^2 x}$$
$$\coth^2 x - 1 = \frac{1}{\sinh^2 x}$$
$$\sinh (-x) = - \sinh x$$
$$\cosh (-x) = \cosh x$$
$$\tanh (-x) = - \tanh x$$

See also the definitions given above.

Sum and Difference of Two Angles.

$$\sinh (x + y) = \sinh x \cosh y + \cosh x \sinh y$$
$$\cosh (x + y) = \cosh x \cosh y + \sinh x \sinh y$$
$$\tanh (x + y) = \frac{\tanh x + \tanh y}{1 + \tanh x \tanh y}$$
$$\sinh (x - y) = \sinh x \cosh y - \cosh x \sinh y$$
$$\cosh (x - y) = \cosh x \cosh y - \sinh x \sinh y$$
$$\tanh (x - y) = \frac{\tanh x - \tanh y}{1 - \tanh x \tanh y}$$

Product of the Functions of Two Angles.

$$\sinh x \sinh y = {}^1/_2 [\cosh (x + y) - \cosh (x - y)]$$
$$\sinh x \cosh y = {}^1/_2 [\sinh (x + y) + \sinh (x - y)]$$
$$\cosh x \sinh y = {}^1/_2 [\sinh (x + y) - \sinh (x - y)]$$
$$\cosh x \cosh y = {}^1/_2 [\cosh (x + y) + \cosh (x - y)]$$

Functions of Twice an Angle.

$$\sinh 2x = 2 \sinh x \cosh x$$
$$\cosh 2x = \sinh^2 x + \cosh^2 x = 2 \sinh^2 x + 1 = 2 \cosh^2 x - 1$$
$$\tanh 2x = \frac{2 \tanh x}{1 + \tanh^2 x}$$

Functions of Half an Angle.

$$\sinh \frac{x}{2} = \sqrt{\frac{\cosh x - 1}{2}}$$
$$\cosh \frac{x}{2} = \sqrt{\frac{\cosh x + 1}{2}}$$
$$\tanh \frac{x}{2} = \sqrt{\frac{\cosh x - 1}{\cosh x + 1}}$$

Functions of Three Times an Angle.

$$\sinh 3x = 3 \sinh x + 4 \sinh^3 x$$
$$\cosh 3x = 4 \cosh^3 x - 3 \cosh x$$
$$\tanh 3x = \frac{3 \tanh x + \tanh^3 x}{1 + 3 \tanh^2 x}$$

Relations between Hyperbolic and Trigonometric Functions.

$$\sinh (jx) = j \sin x \qquad \sin (jx) = j \sinh x$$
$$\cosh (jx) = \cos x \qquad \cos (jx) = \cosh x$$
$$\tanh (jx) = j \tan x \qquad \tan (jx) = j \tanh x$$
$$\sinh^{-1} jx = j \sin^{-1} x \qquad \sin^{-1} jx = j \sinh^{-1} x$$
$$\tanh^{-1} jx = j \tan^{-1} x \qquad \tan^{-1} jx = j \tanh^{-1} x$$

$$\cosh^{-1} jx = j \cos^{-1} jx = \log (x + \sqrt{1 + x^2}) - j \frac{\pi}{2}$$

Hyperbolic Functions of a Complex Angle.

$$\sinh (x + jy) = \sinh x \cos y + j \cosh x \sin y = Me^{j\theta}$$

where $$M = \sqrt{\frac{\cosh 2x - \cos 2y}{2}} \quad \text{and} \quad \tan \theta = \frac{\tan y}{\tanh x}$$

$$\cosh (x + jy) = \cosh x \cos y + j \sinh x \sin y = Ne^{j\phi}$$

where $$N = \sqrt{\frac{\cosh 2x + \cos 2y}{2}} \quad \text{and} \quad \tan \phi = \tanh x \cdot \tan y$$

$$\tanh (x + jy) = \frac{\sinh x \cos y + j \cosh x \sin y}{\cosh x \cos y + j \sinh x \sin y} = Pe^{j\psi}$$

where $$P = \sqrt{\frac{\cosh 2x - \cos 2y}{\cosh 2x + \cos 2y}} \quad \text{and} \quad \psi = \tan^{-1} \left[\frac{\sin 2y}{\sinh 2x}\right]$$

$$\tanh^{-1} (Ae^{j\alpha}) = B_1 + jB_2$$

where $$B_1 = \frac{1}{2} \tanh^{-1} \left[\frac{2A \cos \alpha}{1 + A^2}\right] \quad \text{and} \quad B_2 = \frac{1}{2} \tan^{-1} \left[\frac{2A \sin \alpha}{1 - A^2}\right]$$

5. CALCULUS FORMULAS

The formula for the integration by parts is:

$$\int_a^b u\, dv = [uv]_a^b - \int_a^b v\, du$$

The following table is used in the formulas

$$\frac{df(x)}{dx} = f'(x)$$

$$\int f'(x)\, dx = f(x) + C$$

where C is an arbitrary constant.

$f'(x)$	$f(x)$	$f'(x)$	$f(x)$
x^m	$\frac{1}{m+1} x^{m+1}$	$\frac{1}{\cos^2 ax}$	$\frac{1}{a} \tan ax$
$\frac{1}{ax}$	$\frac{1}{a} \log_e x$	$\frac{1}{\sin^2 ax}$	$-\frac{1}{a} \cot ax$
e^{ax}	$\frac{1}{a} e^{ax}$	$\frac{1}{\sqrt{a^2 + bx^2}}$	$\frac{1}{\sqrt{-b}} \sin^{-1} \sqrt{-b}\, \frac{x}{a}$
a^{bx}	$\frac{1}{b \log a} a^{bx}$	$\frac{1}{x\sqrt{x^2 + a}}$	$\frac{1}{\sqrt{-a}} \cos^{-1} \sqrt{-a}\, \frac{1}{x}$
$\cos ax$	$\frac{1}{a} \sin ax$	$\frac{x}{\sqrt{a^2 \pm x^2}}$	$\pm\sqrt{a^2 \pm x^2}$
$\sin ax$	$-\frac{1}{a} \cos ax$	$\frac{x}{\sqrt{x^2 - a^2}}$	$\sqrt{x^2 - a^2}$
$\cosh ax$	$\frac{1}{a} \sinh ax$	$\frac{u \frac{dv}{dx} - v \frac{du}{dx}}{u^2}$	$\frac{v}{u}$
$\sinh ax$	$\frac{1}{a} \cosh ax$	$\log x$	$x \log x - x$
$\tan ax$	$-\frac{1}{a} \log (\cos ax)$	$\sin^2 x$	$-{}^1/_2(\cos x \sin x - x)$
$\tanh ax$	$\frac{1}{a} \log (\cosh ax)$	$\cos^2 x$	${}^1/_2(\sin x \cos x + x)$

MAXIMA AND MINIMA. Let y be any function of a variable x; then y will be a maximum or minimum for any value of x which satisfies

$$\frac{dy}{dx} = 0 \tag{1}$$

provided $\frac{d^2y}{dx^2}$ is not zero. If the second derivative $\frac{d^2y}{dx^2}$ is positive for this value of x, then the corresponding value of y is a minimum; if this second derivative is negative, the corresponding value of y is a maximum.

In case $\frac{d^2y}{dx^2}$ is also zero for the value of x which satisfies (1), the corresponding value of y is not a maximum or minimum unless $\frac{d^3y}{dx^3}$ is also zero and $\frac{d^4y}{dx^4}$ is not zero. When $\frac{d^3y}{dx^3} = 0$, y is a minimum if $\frac{d^4y}{dx^4}$ is positive and a maximum if $\frac{d^4y}{dx^4}$ is negative. In case $\frac{d^4y}{dx^4}$ is also zero, similar relations must hold for the fifth and sixth derivatives, etc.

6. DIFFERENTIAL EQUATIONS

Differential equations of the following forms are met with in the theory of alternating and transient currents.

The following notation is used: $e = 2.7183\cdots$ = base of natural system of logarithms; x, y, z are variables. A, ϕ, γ, and θ are constants of integration or arbitrary constants. Other letters represent known constants.

$$\frac{dy}{dx} = ay \tag{1}$$

Solution:

$$y = Ae^{ax}$$

$$\frac{dy}{dx} + ay = 0 \tag{2}$$

Solution:

$$y = Ae^{-ax}$$

$$\frac{dy}{dx} + ay = b \tag{3}$$

Solution:

$$y = \frac{b}{a}[1 - Ae^{-ax}]$$

$$\frac{d^2y}{dx^2} = -a^2y \tag{4}$$

Solution:

$$y = A \sin (ax + \phi)$$

$$\frac{d^2y}{dx^2} = a^2y \tag{5}$$

Solution:

$$y = A \sinh (ax + \phi)$$

$$\frac{d^2y}{dx^2} + 2u\frac{dy}{dx} + (u^2 + a^2)y = 0 \tag{6}$$

Solution:

Case I. a^2 positive: $y = Ae^{-ux} \sin (ax + \phi)$
Case II. a^2 negative: $y = Ae^{-ux} \sinh (ax + \phi)$
Case III. $a^2 = 0$: $y = A(x + \phi)e^{-ux}$

$$\frac{d^2y}{dx^2} + 2u\frac{dy}{dx} + (u^2 + a^2)y = B \sin (\omega x + \theta) \tag{7}$$

The complete solution of this equation consists of the solution of (6) plus the term

$$\left(\frac{B \sin \delta}{2u\omega}\right) \sin (\omega x + \theta - \delta) \tag{a}$$

where

$$\delta = \tan^{-1} \frac{2u\omega}{a^2 + u^2 - \omega^2}$$

For each additional sine term added to the right-hand member of the equation, there will be a corresponding term of the same form as (a) in the solution.

$$\frac{d^n y}{dx^n} + a_{n-1}\frac{d^{n-1}y}{dx^{n-1}} + \cdots a_1\frac{dy}{dx} + a_0 y = B\sin(\omega x + \theta) \tag{8}$$

Solution:

$$y = A_1 e^{m_1 x} + A_2 e^{m_2 x} + \cdots A_n e^{m_n x} + KB\sin(\omega X + \theta + \delta)$$

where m_1, m_2, etc , are the n roots of the equation

$$m^n + a_{n-1}m^{n-1} + \cdots a_1 m + a_0 = 0$$

and K and δ are found by substituting the $KB\sin(\omega x + \theta + \delta)$ by itself in the given differential equation and equating the coefficients of $\sin(\omega x + \theta)$ and $\cos(\omega x + \theta)$ respectively on the two sides of the resulting equation. When the second member of the differential equation is a constant, B, the sine term in the solution becomes simply $\frac{B}{a_0}$.

Note that all the preceding equations are merely special cases of the general equation (8)

$$\frac{d^2y}{dx^2} + 2u\frac{dy}{dx} + (u^2 - q^2)y = \frac{1}{c^2}\frac{d^2y}{dz^2} \tag{9}$$

The complete solution of this equation contains an infinite number of terms of the form

$$y = e^{-(u-s)x}\left[A_1 e^{mz}\sin(\omega x + nz + \phi_1) + A_2 e^{-mz}\sin(\omega x - nz + \phi_2)\right] \tag{a}$$

where A_1, ϕ_1, A_2, ϕ_2, and two of the four constants ω, s, m, and n are integration constants (fixed by the terminal conditions). The values of m and n in terms of ω and s are

$$m = c\sqrt{ab}\cos\frac{\eta + e}{2}$$

$$n = c\sqrt{ab}\sin\frac{\eta + e}{2}$$

where $a = \sqrt{(s+q)^2 + \omega^2}$, $\quad e = \tan^{-1}\left(\frac{\omega}{s+q}\right)$

$b = \sqrt{(s-q)^2 + \omega^2}$, $\quad \eta = \tan^{-1}\left(\frac{\omega}{s-q}\right)$

The values of ω and s in terms of m and n are

$$\omega = \frac{\sqrt{FG}}{c}\cos\frac{\alpha + \beta}{2}$$

$$s = \frac{\sqrt{FG}}{c}\sin\frac{\alpha + \beta}{2}$$

where $F = \sqrt{(n+cq)^2 + m^2}$, $\quad \alpha = \tan^{-1}\left(\frac{m}{n+cq}\right)$

$G = \sqrt{(n-cq)^2 + m^2}$, $\quad \beta = \tan^{-1}\left(\frac{m}{n-cq}\right)$

The solution of eq. (9) may also be written as a series of terms of the form

$$y = Me^{-(u-s)x}\sin(\omega x + \phi + \mu) \tag{b}$$

where

$$M = \frac{A}{\sqrt{2}}\sqrt{\cosh 2(mz + \gamma) + \cos 2(nz + \theta)}$$

$$\tan\mu = \tanh(mz + \gamma)\tan(nz + \theta)$$

where A, ϕ, γ, and θ are integration constants, and the relations between the other constants ω, s, m, and n are the same as above.

In the special case when $q = 0$, the solution of eq. (9) is

$$y = e^{-ux}\left[f_1(\omega x + nz) + f_2(\omega x - nz)\right] \tag{c}$$

where f_1 and f_2 are any two arbitrary functions and ω and n are connected by the relation

$$\frac{\omega}{n} = \frac{1}{c}$$

$$\frac{d^2y}{dx^2} + \frac{1}{x}\frac{dy}{dx} + \left(1 - \frac{n^2}{x^2}\right) y = 0 \tag{10}$$

This is known as Bessel's equation of order n. $J_n(x)$, Bessel's function of the first kind of order n, is a particular solution of this equation. It may be computed from the infinite series:

$$J_n(x) = \frac{x^n}{2^n\Gamma(n+1)}\left[1 - \frac{x^2}{2^2(n+1)} + \frac{x^4}{2^4 2!(n+1)(n+2)} - \frac{x^6}{2^6 3!(n+1)(n+2)(n+3)} + \cdots\right] \tag{a}$$

where $\Gamma(n + 1)$ is the gamma function which reduces to unity for $n = 0$ and to $n!$ for n equal to any positive integer. In general, the function $J_n(x)$ is an oscillatory function of x having the value zero for $x = 0$, except for the case where $n = 0$. For values of n larger than 1, the slope of $J_n(x)$ is zero for $x = 0$ and the first maximum and the first zero occurs at successively higher values of x as n takes on larger values. For small values of n, the values of x for which $J_n(x)$ is a maximum or zero can be gotten from tables of Bessel functions. For large values of n, the first maximum, that is, the smallest x for which $J_n'(x) = 0$, is given by

$$n + 0.809\sqrt[3]{n} \tag{b}$$

with an error not larger than $1/\sqrt[3]{n}$, and the first zero, that is, the smallest x for which $J_n(x) = 0$, is given by

$$n + 1.856\sqrt[3]{n} \tag{c}$$

again with an error of the order of $1/\sqrt[3]{n}$.

For integral values of n greater than zero,

$$J_{n+1}(x) = \frac{2n}{x} J_n(x) - J_{n-1}(x) \tag{d}$$

which permits one to compute Bessel functions for successively higher order from tables of $J_0(x)$ and $J_1(x)$.

When n is an integer,

$$J_{-n}(x) = (-1)^n J_n(x) \tag{e}$$

7. ERRORS OF OBSERVATION

When a quantity is measured with all possible accuracy many times in succession, the numbers expressing the results are found to differ by amounts which, although generally small, are occasionally considerable in comparison with the quantity measured. Though these differences may be decreased by improved methods, better instruments, or greater skill, they can never be entirely removed. They are known as the errors of observation. The following formulas, which are derived from the theory of least squares, apply to such errors and not to errors which can be eliminated by correcting mistakes of the observer or defects of instruments or methods of observation. That is, they apply only to errors which may be either positive or negative, the chance of a positive error occurring being exactly the same as the chance of a negative error occurring.

WEIGHTED OBSERVATIONS. Sometimes, in spite of the care with which observations are taken, there are reasons for believing that some observations are better than others. In this case the observations are given different "weights" or numbers expressing their relative practical worth. A weighted observation is an observation multiplied by its weight.

PROBABLE VALUE OF SEVERAL OBSERVATIONS. The most probable value of a quantity which is observed directly several times with equal care is the arithmetical mean of the measurements.

The most probable value of a quantity which is observed directly several times, but the observations of which have different weights, is equal to the sum of the weighted observations divided by the sum of the weights.

PROBABLE ERROR OF ANY ONE OF SEVERAL OBSERVATIONS. The probable error or dispersion of a number of direct observations made with equal care is given by the following formula:

$$r = 0.6745\sqrt{\frac{\Sigma v^2}{n-1}}$$

where n = number of observations.
r = probable error of a single observation.
v = residual found by subtracting the arithmetical mean from each measurement.

The probable error of each of a number of direct observations, where the observations have different weight, is found by the following formula, in which p represents the per unit weight of an observation.

$$r_1 = 0.6745\sqrt{\frac{\Sigma pv^2}{n-1}}$$

PROBABLE ERROR OF THE ARITHMETICAL MEAN. If

r = probable error of a single observation,
n = number of observations,
r_0 = probable error of the arithmetical mean,

$$r_0 = \frac{r}{\sqrt{n}} \text{ for observations of equal weight}$$

or

$$r_0 = \frac{r_1}{\sqrt{\Sigma p}} \text{ for unequal weight}$$

It should be noted that the probable error of the mean decreases inversely as the square root of the number of observations.

PROBABLE ERROR IN A RESULT CALCULATED FROM THE MEANS OF SEVERAL OBSERVED QUANTITIES. Let Z = a sum or difference of several independent quantities.

Let r_1, r_2, r_3, etc., be the probable errors in these quantities. Then the probable error of Z is equal to

$$\sqrt{r_1^2 + r_2^2 + r_3^2 + \text{etc.}}$$

Let $Z = Az$, where z is an observed quantity, and A, a known number. Let r be the probable error in z. Then the probable error in Z is Ar.

Let Z be the product of two independently observed quantities z_1 and z_2 whose probable errors are r_1 and r_2 respectively. Then the error in Z is equal to

$$\sqrt{z_1^2 r_2^2 + z_2^2 r_1^2}$$

Let Z be any function of the independently observed quantities z_1, z_2, z_3, etc., whose probable errors are r_1, r_2, r_3, etc. Then the probable error in Z is equal to

$$\sqrt{\left(\frac{\partial Z}{\partial z_1}\right)^2 r_1^2 + \left(\frac{\partial Z}{\partial z_2}\right)^2 r_2^2 + \left(\frac{\partial Z}{\partial z_3}\right)^3 r_3^2 + \text{etc.}}$$

8. APPROXIMATIONS

If a is small

$$(1 \pm a)^m = 1 \pm ma$$

If m is nearly equal to n

$$\sqrt{mn} = \frac{m+n}{2}$$

If θ, expressed in radians, is small compared to a radian

$$\sin\theta = \tan\theta = \theta \text{ radians}$$

9. SERIES

Taylor's series is written

$$f(x+h) = f(x) + \frac{h}{1!}f'(x) + \frac{h^2}{2!}f''(x) + \cdots$$
$$= f(h) + \frac{x}{1!}f'(h) + \frac{x^2}{2!}f''(h) + \cdots$$

where the prime on the function means the derivative with respect to the argument.

The following series are frequently useful.

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \cdots$$

$$a^x = 1 + x\log a + \frac{(x\log a)^2}{2!} + \frac{(x\log a)^3}{3!} + \cdots$$

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \cdots$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \cdots$$

$$\cos(x\sin\theta) = J_0(x) + 2\{J_2(x)\cos 2\theta + J_4(x)\cos 4\theta + \cdots$$

where $J_n(x)$ is Bessel's function of order n,

$$\sin(x\sin\theta) = 2\{J_1(x)\sin\theta + J_3(x)\sin 3\theta + \cdots$$

$$\cos(x\cos\theta) = J_0(x) - 2J_2(x)\cos 2\theta + 2J_4(x)\cos 4\theta + \cdots$$

$$\sin(x\cos\theta) = 2J_1(x)\cos\theta - 2J_3(x)\cos 3\theta + 2J_5(x)\cos 5\theta + \cdots$$

$$\begin{aligned}\sin(A + x\sin\theta) = {} & J_0(x)\sin A + J_1(x)[\sin(A+\theta) - \sin(A-\theta)] \\ & + J_2(x)[\sin(A+2\theta) + \sin(A-2\theta)] \\ & + J_3(x)[\sin(A+3\theta) - \sin(A-3\theta)] \\ & + J_4(x)[\sin(A+4\theta) + \sin(A-4\theta)] + \cdots\end{aligned}$$

10. MENSURATION

The term mensuration is used in this article to include the relations between the areas and volumes of geometric figures and their linear dimensions.

Triangle.

$$\text{Area} = {}^1/_2\,(\text{Base}) \times (\text{Perpendicular height})$$
$$= \sqrt{s(s-a)(s-b)(s-c)}$$

where a, b, and c are the lengths of the three sides respectively, and $s = {}^1/_2\,(a+b+c)$.

Trapezoid.

$$\text{Area} = \left(\frac{a+b}{2}\right)d$$

where a and b are the lengths of the parallel sides respectively, and d their distance apart.

Parallelogram.

$$\text{Area} = (\text{Base}) \times (\text{Perpendicular height})$$

Parabola.

$$\text{Area} = {}^2/_3\,(\text{Area of circumscribing rectangle})$$

Cycloid.

$$\text{Area} = {}^3/_4\,\pi x(\text{Altitude})^2$$

the altitude being the diameter of the rolling circle.

Circle.

$$\text{Circumference} = 2\pi r = \pi d$$

$$\text{Area} = \pi r^2 = \frac{\pi}{4} d^2$$

where r is the radius and d the diameter.

$$\text{Area of segment} = \frac{r^2}{2} (\theta - \sin \theta)$$

where θ is the angle in radians (see Angles) subtended by the arc of the segment. If n is the height of the segment, measured along the radius perpendicular to the chord,

$$\text{Area of segment} = \pi r^2 M - A(r - n)$$

where $$A = \sqrt{n(2r - n)} \quad \text{and} \quad M = \frac{1}{180} \sin^{-1} \left(\frac{A}{r}\right)$$

Ellipse.

$$\text{Area} = \pi ab$$

where a and b are the principal semi-axes.

Prism with Parallel Sides and Parallel Ends.

$$\text{Volume} = (\text{Area of end}) \times (\text{Perpendicular distance between ends})$$

Right Circular Cylinder.

$$\text{Volume} = \frac{\pi}{4} d^2 l$$

where d is the diameter and l the length.

$$\text{Total surface of right cylinder} = \pi d(l + {}^1\!/_2 d)$$

Right Circular Cone.

$$\text{Volume} = {}^1\!/_3 \,(\text{Area of base}) \times (\text{Height})$$

$$= {}^1\!/_3 \,(\text{Volume of circumscribing cylinder})$$

where r is the radius of base and h the height of the cone.

$$\text{Area of curved surface of a right circular cone} = \pi r \sqrt{h^2 + r^2}$$

Right Pyramid.

$$\text{Volume} = {}^1\!/_3 \,(\text{Area of base}) \times (\text{Height}).$$

$$\text{Volume of frustum of pyramid} = {}^1\!/_3 \,(\text{Height}) \,(A + \sqrt{aA})$$

where A and a are the areas of the ends respectively.

Sphere.

$$r = \text{radius}$$

$$\text{Area of surface} = 4\pi r^2 = {}^2\!/_3 \,(\text{total area of circumscribing cylinder})$$

Area of the surface of a zone of a sphere = area of zone of the same height as this zone projected on to a cylinder.

$$\text{Volume} = {}^4\!/_3 \,\pi r^3 = {}^2\!/_3 \,(\text{volume of circumscribing cylinder})$$

Volume of a frustum of a sphere $= \pi r^2(k \pm h) - \frac{\pi}{3} (k^3 \pm h^3)$, where k is the distance of its outer face from center and h the distance of its inner face from the center, the negative signs in the brackets to be used if both faces are on the same side of the center and the positive signs if on opposite sides of the center.

Ellipsoid.

$$\text{Volume} = {}^4\!/_3 \,\pi abc$$

where a, b, and c are the three principal semi-axes, respectively.

Paraboloid. Volume of a paraboloid of revolution equals one-half that of the circumscribing cylinder.

MATHEMATICAL TABLES AND CHARTS

11. COMMON AND NATURAL LOGARITHMS OF NUMBERS

The common logarithm of a number is the index of the power to which the base 10 must be raised in order to equal the number.

The common logarithm of every positive number not an integral power of 10 consists of an *integral* and a *decimal part.* The integral part or whole number is called the *characteristic* and may be either *positive or negative.* The decimal or fractional part is a *positive* number called the *mantissa* and is the same for all numbers which have the same sequential digits.

The characteristic of the logarithm of any positive number greater than one is positive and is one less than the number of digits before the decimal point.

The characteristic of the logarithm of any positive number less than one is negative and is one more than the number of ciphers immediately after the decimal point.

A negative number or number less than zero has no real logarithm.

EXAMPLES: $\text{Log}_{10}\,25400. = 4.404834$ $\text{Log}_{10}\,0.0254 = \bar{2}.404834$ or $8.404834 - 10$

The two systems of logarithms in general use are the common or Briggsian logarithms, introduced in 1615 by Henry Briggs, a contemporary of John Napier, the inventor of logarithms, and the natural or less appropriately termed Napierian or hyperbolic logarithms, which developed somewhat accidentally from Napier's original work. The latter have a base denoted by e, an irrational number, which is:

$$e = \text{Lim}_{u \to \infty} \left(1 + \frac{1}{u}\right)^u = 1 + 1 + \frac{1}{2!} + \frac{1}{3!} + \frac{1}{4!} + \ldots = 2.7182818$$

To obtain the natural logarithm, the common logarithm given below is multiplied by $\log_e 10$ which is 2.302585, or $\log_e N = 2.302585 \log_{10} N$.

12. TRIGONOMETRIC TABLES

The following tables give the values of sin x, cos x, and tan x for values of x from 0 to 90° in intervals of 0.1 degree. By making use of the periodic character of these functions, the values can be determined from these tables for all values of x to an accuracy of 0.1 degree. (See Trigonometric Formulas.)

If the angle is given in radians multiply the number of radians by $\frac{180}{\pi}$ (57.295) to obtain the number of degrees.

13. EXPONENTIAL AND HYPERBOLIC TABLES

The following tables give values of e^x, e^{-x}, $\sinh x$, $\cosh x$ and $\tanh x$ for values of x from 0.00 to 6.00 in intervals of 0.01.

To facilitate computations involving multiplication, the common logarithms of e^x, $\sinh x$, $\cosh x$, and $\tanh x$ are also given.

For values of x greater than 6, e^x may be computed from the relationship $e^x = \log^{-1} (x \log_{10} e) = \log^{-1} 0.43429x$; e^{-x} approaches zero; $\sinh x$ and $\cosh x$ are approximately equal and become $0.5\,e^x$; and $\tanh x$ and $\coth x$ have values approximately equal to unity.

Where more accurate values of the exponentials and functions are required they may be computed from the following relationships.

$$e = 2.71828\ 18285 \qquad \frac{1}{e} = 0.36787\ 94412$$

$$M = \log_{10} e = 0.43429\ 44819 \qquad \frac{1}{M} = \log_e 10 = 2.30258\ 50930$$

$$e^x = \log^{-1} Mx \qquad e^{-x} = \log^{-1} - Mx$$

$$\sinh x = \frac{e^x - e^{-x}}{2} \qquad \cosh x = \frac{e^x + e^{-x}}{2} \qquad \tanh x = \frac{e^x - e^{-x}}{e^x + e^{-x}}$$

$$\operatorname{csch} x = \frac{1}{\sinh x} \qquad \operatorname{sech} x = \frac{1}{\cosh x} \qquad \coth x = \frac{1}{\tanh x}$$

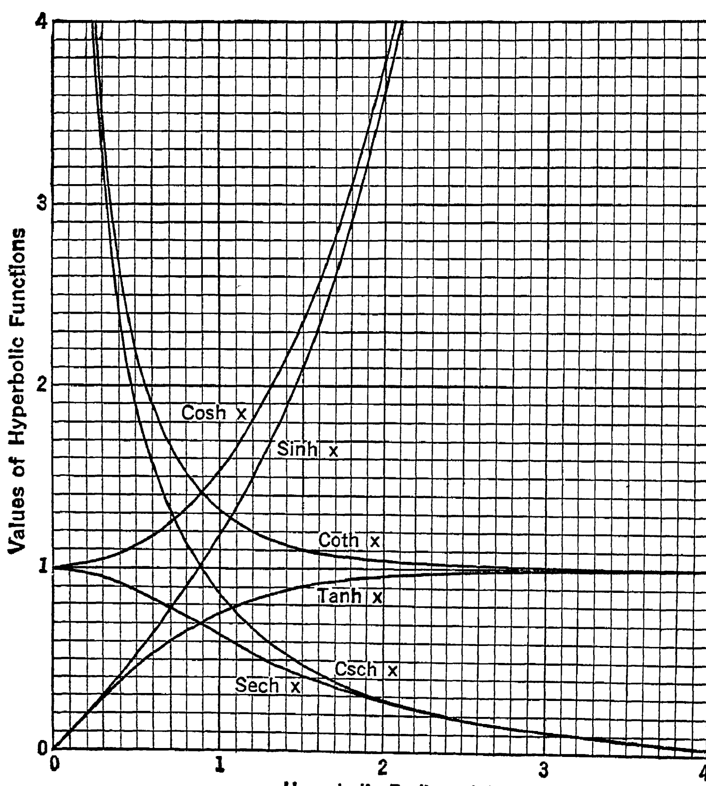

Chart of the Hyperbolic Functions.

14. BESSEL FUNCTIONS

The chart below shows approximate values for some representative Bessel functions of the first kind. Values for higher-order Bessel functions can be computed by successive application of the recurrence formula

$$J_{n+1}(x) = \frac{2n}{x} J_n(x) - J_{n-1}(x)$$

starting with the values of $J_0(x)$ and $J_1(x)$.

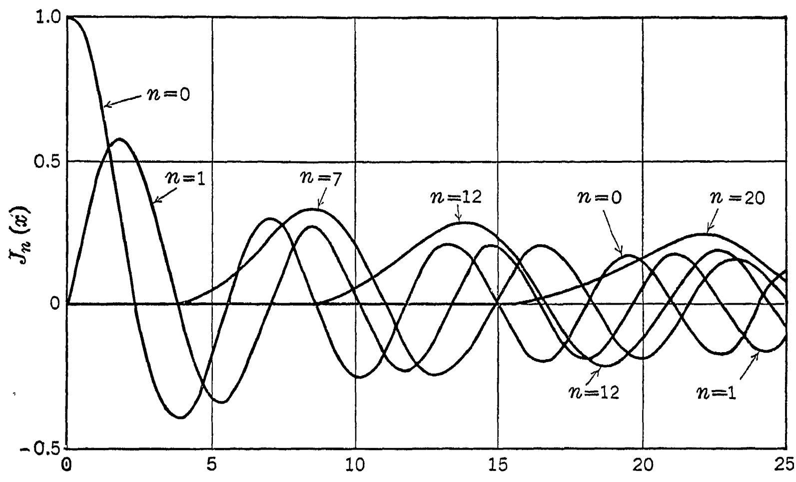

FIG. 1. Chart of Bessel Functions.

15. TRANSMISSION UNIT AND POWER REFERENCE LEVELS.—DECIBELS

Power losses occur in all parts of an electric circuit; in many circuits, which are built up of a number of components, the easiest method of predicting overall efficiencies is to determine individual efficiencies and combine them. When amplifiers are used, power gains exist (*as far as the alternating signal current is concerned*) and must be considered. For, although the useful power is less than the total power input, the output signal power may be greater than the input signal power, so that, using the conventional definition of efficiency, values greater than 100 per cent can be obtained.

THE DECIBEL AND THE NEPER. In order to avoid the multiplication of the individual efficiencies recourse has been had to logarithms of the efficiencies, giving measures of efficiency which can be added and subtracted directly.

Many units have been proposed and several have at various times been adopted in different localities. At the present time two such units are in general use in Europe and this country, one based on the napierian system of logarithms, the other based on the decimal system of logarithms. The International Advisory Committee on Long Distance Telephony of Europe has recommended that both these units be standardized and defined as follows:

The **unit of transmission** *expresses the ratio of apparent or real power in transmission systems. In practice, the number of units of transmission in a given case is expressed in terms of a logarithm.*

In the case of two powers P_1 and P_2 the number of units is:

$$\textit{in the napierian system,}\quad {}^1/_2 \log_\epsilon \frac{P_1}{P_2}$$

$$\textit{in the decimal system,}\quad \log_{10} \frac{P_1}{P_2}$$

The napierian unit is called the **neper.** The decimal unit is called the **bel.** A decimal submultiple of these units may be used, as **decineper** and **decibel.**

The unit generally used in this country is the decibel, which is exactly equivalent to and was first standardized as the "transmission unit"; it is also exactly equivalent to the "sensation unit" used in acoustic work. The decibel is abbreviated db, the transmission unit TU, and the sensation unit SU. The neper is called the βl unit. The comparative sizes of the two units is given by the fact that

$$\log_\epsilon \frac{P_1}{P_2} = 2.3026 \log_{10} \frac{P_1}{P_2},$$

so that 0.8686 neper is equal to 1 bel. Also 1 neper = 11.51 decibels.

From the above definition the number of decibels which expresses the ratio between any two powers is

$$N = 10 \log_{10} \frac{P_1}{P_2}$$

The quantity N is called the *transmission equivalent* of the element considered. It may be readily evaluated for a particular ratio by multiplying the common logarithm of this ratio by 10. If P_1 represents the delivered power and P_2 the input power, N will be negative for power losses and positive for power gains, since the logarithms of numbers less than unity are negative.

The use of the decibel may be seen from the following. If two circuit elements, with a ratio of power output to power input of $\frac{P_1}{P_2}$ and $\frac{P_3}{P_4}$, respectively, are connected in series, the power ratio of the combination is

$$\frac{P \text{ out}}{P \text{ in}} = \frac{P_1}{P_2} \times \frac{P_3}{P_4} = 10^{N_1(0.1)} \times 10^{N_2(0.1)} = 10^{(N_1+N_2)0.1}$$

where N_1 and N_2 are the transmission equivalents of the first and second elements, respectively. Taking the logarithms of both sides and multiplying through by 10,

$$10 \log \frac{P \text{ out}}{P \text{ in}} = N_1 + N_2 = N_T$$

It is thus seen that any number of transmission equivalents can be added (losses with their associated minus sign) to obtain the transmission equivalent of a complete circuit.

In making measurements of circuit efficiency the current ratio, or the voltage ratio, is usually more readily obtainable than the power ratio. Either of these ratios may be used to specify the efficiency of the circuit *when conditions are such that it is the square root of the power ratio.*

In this case

$$\frac{I_1^2}{I_2^2} = \frac{P_1}{P_2} = 10^{N(0.1)}$$

and taking the square root of both sides

$$\frac{I_1}{I_2} = 10^{N(0.05)}$$

By the method used above in the case of power ratios, the transmission equivalent is

$$N = 20 \log_{10} \frac{I_1}{I_2} = 20 \log_{10} \frac{E_1}{E_2}.$$

It must be remembered that this is true only when the current or voltage ratio is the square root of the power ratio, the simplest case being where the currents through, or voltages across, equal impedances are measured.

LOGARITHMIC VOLTAGE RATIO. In measuring electron-tube amplifiers, it is frequently useful to measure the voltage gain of each stage and compare the sum with the overall gain of the complete amplifier. Such measurements are in many cases conveniently made in terms of voltage and are made only with great difficulty in terms of power. The habit has grown up of using the advantages of logarithmic addition and calibrating amplifiers in terms of comparison voltages without any regard for the impedance relations. Furthermore in some instances the overall sensitivity of amplifiers and complete radio sets has frequently been expressed in terms of "decibels below 1 volt" with no thought of impedance. According to the above discussion this, of course, is a misuse of the term. Since it is so convenient, however, it is a practice which is likely to continue. Confusion can be avoided by the association of a new term to this measurement. It has been suggested that the abbreviation **dbv** be used to indicate that the logarithmic ratios are in terms of volts and not in terms of power. It has furthermore been suggested that the dbv also carry the implication where appropriate that it is below the level of 1 volt. A

Decibels Versus Power, Voltage, and Current Ratios

db	Current and Voltage Ratio		Power Ratio		db	Current and Voltage Ratio		Power Ratio

sensitivity of 100 μv could be expressed as -80 dbv, and a sensitivity of 10 μv as -100 dbv, with this system.

A table is appended giving values of transmission equivalents in terms of both power and current, or voltage, ratios in tenths of a decibel up to 20 db. For values above 20 db the tables may be used as described below.

Example. To find the current and power ratios for a loss of 57.6 db.

1. The power ratio of 50 db is 10^{-5} (this being the first power ratio which is an even submultiple of 10 and corresponds to less than 57.6 db).
2. The power ratio of 7.6 ($57.6 - 50 = 7.6$) db is 0.1738.
3. To add decibels, power ratios must be multiplied, hence:

$$\textit{Power ratio of } 57.6 \textit{ db} = 0.1738 \times 10^{-5}$$

4. The current ratio of 40 db is 0.01 (first current ratio which is an even submultiple of 10 and corresponds to less than 57.6 db).
5. The current ratio of 17.6 ($57.6 - 40 = 17.6$) db is 0.1318.
6. Multiplying these ratios:

$$\textit{Current ratio of } 57.6 \textit{ db} = 0.001318$$

POWER REFERENCE LEVELS. When the efficiency of a device or system is expressed in decibels there is in general no indication of the actual amount of power in the device. In comparing devices it is frequently desirable to know the actual overall efficiency. In such a case this can readily be expressed in decibels, 100 per cent efficiency being represented by zero decibels. In many cases, however, it is more desirable that the relative efficiencies at different frequencies be known; in some such cases it is also desirable that the normal power capacity of the device be specified in such form as to be readily comparable with similar devices.

For such a specification to be made when the ordinates of a characteristic are in decibels, it is only necessary to specify some arbitrary amount of power as corresponding to zero decibels; then every value of decibels represents a definite amount of power (or volume level). The amount of power chosen as the reference level is completely arbitrary; hence it has been customary to choose some average value of power as zero level, for a particular type of work.

Attempts at standardization have been made, with the result that the American Standards Association (and IRE) has recommended 1 milliwatt in 600 ohms in connection with a particular meter to measure levels in radio program transmission (see ASA "American Recommended Practice for Volume Measurements of Electrical Speech and Program Waves," Nov. 6, 1942) and has introduced the term vu (vee-you) to represent the number of decibels above or below this level. Also it has become customary to specify power in *dbm* which is used to mean decibels above or below 1 milliwatt.

However, some other groups are still using other levels. For instance, in sound-motion pictures the reference level is 6 milliwatts. Also certain radar engineers use decibels below or above 1 watt.

It will apparently require further action by the American Standards Association to bring order out of the present chaos. The desirability of such a standard is shown by the experience in the acoustic field where 10^{-16} watt per sq cm was universally adopted, so that measurements made anywhere are everywhere intelligible. Until the adoption of such a standard, great care must be exercised in comparing curves and statements of levels to insure that correction is made for differences in reference levels. Also a statement of the reference used should always be included as a part of any publication of results.

UNITS AND CONVERSION FACTORS

By J. G. Brainerd and Carl C. Chambers

16. SYSTEMS OF UNITS

The magnitude of a physical quantity has no tangible meaning except as the relative magnitude of that quantity as compared with some other quantity of the same nature. Thus, 50 ohms is a resistance having a magnitude 50 times the resistance of 1 ohm. Therefore, whenever it is necessary or desirable to talk about the magnitude of a physical quantity, it is necessary to have a basis for comparison. This basis for a quantity is called the *unit* of magnitude of that quantity. In order to communicate the idea of magnitude between different people, it is necessary that they at least know the relative magnitudes of their units. It is the purpose of this section to act as tool for the specification of the relative magnitudes of the more commonly used systems of units for physical quantities.

Because of the relations defining physical laws, there are relations between the magnitudes of physical quantities. It is desirable that these physical relations be expressed alike in the different systems of units. For instance, the relation mass × acceleration = force should be independent of the system of units. Therefore, unit mass times unit acceleration should equal unit force. This gives a relation among these three units.

Because of such physical relations, all the mechanical units can be derived from the units for three fundamental quantities. The three quantities ordinarily taken as fundamental are mass, length, and time. Thermal quantities are conveniently derived from these three quantities together with another fundamental quantity, temperature. Photometric quantities are derived from the three fundamental mechanical quantities together with luminous intensity as a fourth fundamental quantity.

Similarly, electrical and magnetic quantities are derived from the three fundamental mechanical quantities and one fundamental electrical or magnetic quantity.

Two systems of mechanical units are in use in English-speaking countries, the English and the metric systems. The metric system is used universally by physicists and to a great extent by engineers, although the English system is still very common in engineering. The English system uses the foot, the pound, and the second as the units for length, mass, and time, respectively. The metric system (as used in the current literature—see MKS system below) employs the meter, the kilogram, and the second as the units for length, mass, and time, respectively.

STANDARDS OF THE FUNDAMENTAL UNITS. The physical units upon which these fundamental units are based and the legalized standards of the United States and Great Britain are described below.

Standard of Length. The standard meter (100 cm) is the distance between two lines on a platinum-iridium bar carefully preserved at the Bureau of Weights and Measures, at Sèvres, France, when the bar is kept at a uniform temperature of 0 deg cent throughout. In the United States the yard (3 ft) was defined by Act of Congress, July 28, 1866, as

$$1 \text{ U. S. yard} = \frac{3600}{3937} \text{ meter}$$

and similarly the British imperial yard is defined by law as

$$1 \text{ British imperial yard} = \frac{3600}{3937.079} \text{ meter}$$

For engineering purposes the U. S. and British yards may be considered identical.

Standard of Mass and Force. The standard kilogram (1000 grams) is the mass of a cylinder of platinum preserved at the Bureau of Weights and Measures, at Sèvres, France. The U. S. pound avoirdupois is defined by law (Act of Congress, 1866) as $\frac{1}{2.2046}$ kg, but in 1893, the Superintendent of Weights and Measures, with the approval of the Secretary of the Treasury, declared the pound to be

$$1 \text{ U. S. lb} = \frac{1}{2.204622} \text{ kg}$$

The British imperial pound has the same value.

The same relations between the pound and kilogram hold whether these units be taken as units of mass or as units of force, the unit of force being defined in both cases as the pull of the earth on unit mass at 45 deg latitude and sea level.

Standard of Time. The standard second universally adopted is the $\frac{1}{86{,}400}$ part of a mean solar day. The solar day is the interval of time between two successive transits of the sun across a meridian of the earth at the point of observation; this interval varies in length at different times during the year, but the average length of the interval for one year is constant as far as can be determined by any known methods of observation.

Temperature Scales. Two units of temperature, or temperature scales, are commonly employed, viz., the centigrade and the fahrenheit units. The relation between these two units results solely from the manner in which they are defined. One degree centigrade $= {}^9/_5$ degree fahrenheit. Owing to the difference in the zeros of the two scales, a temperature of t_f degrees fahrenheit corresponds to a temperature of $t_c = {}^5/_9(t_f - 32)$ degrees centigrade, and vice versa, $t_f = {}^9/_5\,t_c + 32$ degrees fahrenheit.

Standard of Luminous Intensity. Before Jan. 1, 1948, the standard of luminous intensity was the mean intensity in the horizontal plane from a group of incandescent lamps maintained by the National Bureau of Standards (U. S.), in cooperation with similar custodians in France, Great Britain, and Germany. The International candle was a point source of light having an intensity of a definite fraction of this standard intensity.

The National Bureau of Standards, in pursuance of decisions of the International Committee on Weights and Measures, decided that, beginning Jan. 1, 1948, it would take as the primary standard for the system of photometric units a black-body radiator operated at the temperature of freezing platinum. The "candle," unit of intensity, is defined as one-sixtieth of the intensity of one square centimeter of such a radiator. Other units are derived from the candle, with the provision that when differences of color are involved the evaluation shall be made by means of standard spectral luminosity factors which have been adopted by the International Commission on Illumination and the International Committee on Weights and Measures.

ELECTRIC UNITS. Three systems of electric and magnetic units are in general use, viz., (1) the cgs electrostatic system, (2) the cgs electromagnetic system, and (3) the practical system. In the cgs electrostatic system the dielectric coefficient, ϵ, of air * at 0 deg cent and 760 mm mercury pressure is arbitrarily chosen as unity. In the cgs electromagnetic system the magnetic permeability of air under the same standard conditions is arbitrarily chosen as unity. In the practical system a concrete standard of the unit of resistance (called the ohm) and of the unit of current (ampere) is arbitrarily chosen (it was stated above that only one electric or magnetic unit need be chosen; the choice of two leads to inconsistencies; see below); the unit of resistance is closely equal to 10^9 times the unit of resistance in the cgs electromagnetic system and the unit current is approximately 0.1 that in the latter system. Occasionally other (special) systems are used, most of which are designed to get rid of a factor 4π which frequently appears in the usual systems. The most popular of these others is the Heaviside–Lorentz system in which the unit of electric charge is $1/\sqrt{4\pi}$ of the unit in the electrostatic system. (See MKS system.)

Use of the Prefixes "Stat" and "Ab." To designate the electric and magnetic units in the electrostatic and electromagnetic systems of units respectively, the prefixes "stat" and "ab" may be used with the name of the corresponding practical unit. For example, the cgs electrostatic unit of electric charge may be called the statcoulomb and the cgs electromagnetic unit of electric charge may be called the abcoulomb, etc.†

Relations among the Three Systems of Electrical Units. The fundamental relations, experimentally determined, between the cgs electrostatic and the cgs electromagnetic system is that 1 abfarad $= 8.9878 \times 10^{20}$ statfarads, which may be approximated for engineering purposes to

$$1 \text{ abfarad} = 9 \times 10^{20} \text{ statfarads}$$

which, as a consequence of the definition of the various terms, is equivalent to

$$1 \text{ abcoulomb} = 3 \times 10^{10} \text{ statcoulombs}$$

the erg being the unit of energy in both systems. Rigorously,

$$1 \text{ abcoulomb} = 2.9979 \times 10^{10} \text{ statcoulombs}$$

(See the article by Birge, *Rev. of Mod. Phys.*, Vol. 1, 1 [July 1929].)

---

* Rigorously, ϵ_0 of free or empty space is chosen unity; for air at 0 deg cent and 76 cm mercury pressure $\epsilon_0 = 1.000585$; see *International Critical Tables*, Vol. 6, 77, for the value of ϵ for air under various conditions.

† This abcoulomb, the unit of quantity of electricity in the electromagnetic system, should not be confused with an "absolute coulomb," which is a unit closely equal to the coulomb and is what the latter would be if 1 international or practical ohm equaled *exactly* 10^9 abohms and 1 ampere equaled *exactly* 0.1 abamp. For engineering purposes, the difference between an absolute coulomb and a coulomb is negligible.

The fundamental relations between the cgs electromagnetic system and the practical system are

$$1 \text{ abcoulomb} = 10 \text{ coulombs}$$

$$1 \text{ erg} = 10^{-7} \text{ watt-second or joule}$$

the erg being the unit of energy in the cgs electromagnetic system and the joule (or watt-second) that in the practical system.

Practical Electrical Units. The former (see below) legal units of electrical measure in the United States are given in an Act of Congress, July 12, 1894. Unfortunately, the units there defined are not consistent with one another; for example, the unit of power (watt) there given is not equal to the unit of power derived from the units of current (ampere) and voltage (volt) as defined in the Act. The practical units (the so-called international units) in use before Jan. 1, 1948, are based on the following two definitions:

The unit of resistance is the (international) ohm and is equal to the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice, 14.4521 grams in mass, of a constant cross-sectional area and 106.300 cm in length.

The unit of current is the (international) ampere and is equal to the unvarying electric current which, when passed through a solution of nitrate of silver in accordance with certain specifications, deposits silver at the rate of 0.00111800 gram per second.

The unit of electromotive force, the (international) volt, is derived from the above by Ohm's law. Other international units are derived from these.

The National Bureau of Standards, in agreement with decisions of the International Committee on Weights and Measures, decided to use as standard, beginning Jan. 1, 1948, the electrical units "derived from the fundamental mechanical units of length, mass, and time by use of accepted principles of electromagnetism, with the value of the permeability of space taken as unity in the centimeter-gram-second system or as 10^{-7} in the corresponding meter-kilogram-second system." The reference is to the unrationalized MKS system; in the rationalized MKS system, the permeability of space is $4\pi \times 10^{-7}$ henry per meter.

In explanation of the legal status of the new standard, the Bureau states, "When the electrical units were defined by law (Public Law No. 105, 53rd Congress) in 1894 it was supposed that the international units were practically identical with the corresponding multiples of the centimeter-gram-second electromagnetic system. Alternative definitions were given for most of the units, and those definitions which appear to be legally controlling were taken partly from one system and partly from the other. The joule and the watt, for example, are clearly defined as multiples of the cgs units. In brief, the absolute units have as good a legal basis under the terms of that act as do the present international units. New legislation is being proposed to remove the ambiguities of the old act, but there should be no objection on legal grounds to the general adoption of the absolute units even in advance of Congressional action."

Using "international" to refer to the previous standard, and "absolute" to refer to the new, the relations accepted by the International Committee on Weights and Measures at its meeting in Paris in October, 1946, are as follows:

$$1 \text{ mean international ohm} = 1.00049 \text{ absolute ohms}$$

$$1 \text{ mean international volt} = 1.00034 \text{ absolute volts}$$

The mean international units to which the above equations refer are the averages of units as maintained in the national laboratories of the six countries (France, Germany, Great Britain, Japan, U.S.S.R., and the United States) which took part in this work before the war. The units maintained by the National Bureau of Standards differ from these average units by a few parts in a million, so that the conversion factors for adjusting values of standards in this country will be as follows:

$$1 \text{ international ohm (U. S.)} = 1.000495 \text{ absolute ohms}$$

$$1 \text{ international volt (U. S.)} = 1.00033 \text{ absolute volts.}$$

Other electrical units will be changed by amounts shown in the following table:

$$1 \text{ international ampere} = 0.999835 \text{ absolute ampere}$$

$$1 \text{ international coulomb} = 0.999835 \text{ absolute coulomb}$$

$$1 \text{ international henry} = 1.000495 \text{ absolute henrys}$$

$$1 \text{ international farad} = 0.999505 \text{ absolute farad}$$

$$1 \text{ international watt} = 1.000165 \text{ absolute watts}$$

$$1 \text{ international joule} = 1.000165 \text{ absolute joules}$$

The Act of 1894 defined the international ohm as previously stated, but defined the ampere as 0.1 abampere. These units give rise to the so-called "semiabsolute" system, which is seldom used.

THE MKS SYSTEM OF UNITS. In 1904 Giorgi proposed a system of units in which the fundamental units were the meter, the kilogram, the second, and the ohm. Using this system of fundamental units, the permeability of free space is $\mu_0 = 4\pi \times 10^{-7}$ henry per meter, and the equations of electricity and magnetism, using the practical units, become equations without factors such as 10^8, etc. Such a system is similar to the so-called absolute systems such as the cgs electromagnetic and the cgs electrostatic systems. It follows from the theory of radiation of electromagnetic waves that the dielectric coefficient $\epsilon_0 = \dfrac{1}{\mu_0 c^2}$, where c is the ratio of electromagnetic to electrostatic units, which can be taken as the velocity of light in free space.

The International Committee of Weights and Measures, at its meeting in October 1946, decided that the actual substitution of this absolute system of electrical units for the international system should take place on January 1, 1948.

The units are then defined by a set of definitions such as follows:

(a) **Ampere.** The ampere is the constant current which, maintained in two parallel rectilinear conductors of infinite length separated by a distance of 1 meter, produces between these conductors a force equal to 2×10^{-7} mks (meter-kilogram-second) units of force per meter of length.

(b) **Volt.** The volt is the difference of electrical potential between two points of a conductor carrying a constant current of 1 ampere when the power dissipated between these points is equal to 1 mks unit of power (watt).

(c) **Coulomb.** The coulomb is the quantity of electricity transported each second by a current of 1 ampere.

(d) **Ohm.** The ohm is the electrical resistance between two points of a conductor when a constant difference of potential of 1 volt, applied between these points, produces in the conductor a current of 1 ampere, the conductor not being the seat of an electromotive force.

(e) **Weber.** The weber is the magnetic flux which, traversing a circuit of a single turn, would produce an electromotive force of 1 volt, if brought to zero in 1 second with uniform diminution.

(f) **Henry.** The henry is the inductance of a closed circuit in which an electromotive force of 1 volt is produced when the electric current traversing the circuit varies uniformly at the rate of 1 ampere per second.

(g) **Farad.** The farad is the electrical capacitance of a capacitor between the plates of which appears an electrical difference of potential of 1 volt, when charged with 1 coulomb of electric charge.

The original Giorgi MKS system chose the ohm as the fourth fundamental unit. This choice has not been confirmed. The electrical fundamental unit could be almost any of the electrical units. No particular unit has as yet been chosen as fundamental. The preferences seem to be divided between the ampere, the ohm, the permeability, and the coulomb.

The original Giorgi MKS system chose $\mu_0 = 4\pi 10^{-7}$ henry per meter, the 4π factor causing the electromagnetic formulas expressing rectilinear symmetry, such as the Maxwell equations, to be free of the factor 4π, and the electromagnetic formulas expressing circular symmetry, such as Coulomb's law, to contain the factor 4π. Such a system is called a rationalized system as contrasted with a non-rationalized system, examples of which are the electromagnetic and the electrostatic cgs systems. The non-rationalized MKS system corresponding to the original Giorgi system is defined by the choice of $\mu_0 = 10^{-7}$. This changes the values of some of the units as shown in the table below.

Metric Multiples

10^6 microns = 10^3 millimeters = 10^2 centimeters = 10 decimeters = 1 meter = 10^{-1} dekameter = 10^{-2} hectometer = 10^{-3} kilometer = 10^{-4} myriameter = 10^{-6} megameter = 10^{10} Angstrom Units.

Land Measure

7.92 inches = 1 link
25 links = 1 rod = 16.5 feet = 5.5 yards (1 rod = 1 pole = 1 perch)
4 rods = 1 chain (Gunther's) = 66 feet = 22 yards = 100 links
10 chains = 1 furlong = 660 feet = 220 yards = 1000 links = 40 rods
8 furlongs = 1 mile = 5280 feet = 1760 yards = 8000 links = 320 rods = 80 chains

Ropes and Cables

2 yards = 1 fathom   120 fathoms = 1 cable's length

Nautical Measure

6080.27 feet = 1 knot = 1 nautical mile = 1.15156 statute miles
3 nautical miles = 1 league (U. S.)   3 statute miles = 1 league (Gr. Britain)

(NOTE.—A knot, or nautical mile, is the length of a minute of longitude of the earth at the equator at sea level. The British Admiralty uses the round figure of 6080 feet. The word "knot" is frequently used also to denote "nautical miles per hour.")

Miscellaneous

3 inches = 1 palm   9 inches = 1 span
4 inches = 1 hand $2\,^1/_2$ feet = 1 military pace

Acre-feet: multiply number of acre-feet by 4.356×10^4 to obtain number of cubic feet; multiply by 3.259×10^5 to obtain number of gallons.

Metric Multiples

10 milliliters	= 1 centiliter	= 0.338 fluid ounce
10 centiliters	= 1 deciliter	= 0.845 liquid gill
10 deciliters	= 1 liter	= 1.0567 liquid quarts
10 liters	= 1 dekaliter	= 2.6417 liquid gallons
10 dekaliters	= 1 hectoliter	= 2.8375 U. S. bushels
10 hectoliters	= 1 kiloliter (or stere)	= 28.375 U. S. bushels

Cubic Measure

1 cord of wood = a pile cut 4 feet long, piled 4 feet high and 8 feet on the ground = 128 cubic feet

1 perch of stone = a quantity 1 1/2 feet thick, 1 foot high and 16 1/2 feet long = 24 3/4 cubic feet

(NOTE.—A perch of stone is, however, often computed differently in different localities; thus, in most if not all of the States and Territories west of the Mississippi, stonemasons figure rubble by the perch of 16 1/2 cubic feet. In Philadelphia, 22 cubic feet are called a perch. In Chicago, stone is measured by the cord of 100 cubic feet. Check should be made against local practice.)

Board Measure

In board measure, boards are assumed to be one inch in thickness. Therefore, feet board measure of a stick of square timber = length in feet × breadth in feet × thickness in inches.

Shipping Measure

For register tonnage or measurement of the entire internal capacity of a vessel, it is arbitrarily assumed, to facilitate computation, that:

100 cubic feet = 1 register ton

For the measurement of cargo:

40 cubic feet = 1 U. S. shipping ton = 32.143 U. S. bushels

42 cubic feet = 1 British shipping ton = 32.703 Imperial bushels

Dry Measure

One U. S. Winchester bushel contains 1.2445 cubic feet or 2150.42 cubic inches. It holds 77.601 pounds distilled water at 62 deg fahr.

(NOTE.—The above is a *struck* bushel. A *heaped* bushel in general equals 1 1/4 struck bushels, although for apples and pears it contains 1.2731 struck bushels = 2737.72 cubic inches.)

One U. S. gallon (dry measure) = 1/8 bushel and contains 268.8 cubic inches.

(NOTE.—This is not a legal U. S. *dry measure* and therefore is given for comparison only.)

One British Imperial bushel contains 1.2843 cubic feet or 2219.36 cubic inches. It holds 80 pounds distilled water at 62 deg fahr.

One British Imperial gallon = 1/8 Imperial bushel and contains 277.42 cubic inches.

1 Winchester bushel = 0.9694 Imperial bushel

1 Imperial bushel = 1.032 Winchester bushels

Same relations as above maintain for gallons (dry measure)

[NOTE.—1 U. S. gallon (dry) = 1.164 U. S. gallons (liquid).]

U. S. Units

2 pints	= 1 quart	=	67.2 cubic inches
4 quarts	= 1 gallon * = 8 pints	=	268.8 cubic inches
2 gallons *	= 1 peck = 16 pints = 8 quarts	=	537.6 cubic inches
4 pecks	= 1 bushel = 64 pints = 32 quarts = 8 gallons *	=	2150.42 cubic inches

1 cubic foot contains 6.428 gallons (dry measure) *

Liquid Measure

One U. S. gallon (liquid measure) contains 231 cubic inches. It holds 8.336 pounds distilled water at 62 deg fahr.

One British Imperial gallon contains 277.42 cubic inches. It holds 10 pounds distilled water at 62 deg fahr.

1 U. S. gallon (liquid) = 0.8327 Imperial gallon

1 Imperial gallon = 1.201 U. S. gallons (liquid)

[NOTE.—1 U. S. gallon (liquid) = 0.8594 U. S. gallon (dry).]

U. S. Units

4 gills	= 1 pint	=	16 fluid ounces
2 pints	= 1 quart = 8 gills	=	32 fluid ounces
4 quarts	= 1 gallon = 32 gills = 8 pints	=	128 fluid ounces

1 cubic foot contains 7.4805 gallons (liquid measure)

Apothecaries' Fluid Measure

60 minims = 1 fluid drachm. 8 drachms = 1 fluid ounce

In the U. S. a fluid ounce is the 128th part of a U. S. gallon, or 1.805 cu in. or 29.58 cu cm. It contains 455.8 grains of water at 62 deg fahr. In Great Britain the fluid ounce is 1.732 cu in. and contains 1 ounce avoirdupois (or 437.5 grains) of water at 62 deg. fahr.

* The *gallon* is not a U. S. legal dry measure.

Table 4. Plane Angle [*No Dimensions*]

* Nautical miles per hour.

The Miner's Inch

(Used in Measuring Flow of Water)

An Act of the California legislature, May 23, 1901, makes the standard miner's inch 1.5 cu ft per minute, measured through any aperture or orifice.

The term miner's inch is more or less indefinite, for the reason that California water companies do not all use the same head above the center of the aperture, and the inch varies from 1.36 to 1.73 cu ft per minute, but the most common measurement is through an aperture 2 in. high and whatever length is required, and through a plank 1 1/4 in. thick. The lower edge of the aperture should be 2 in. above the bottom of the measuring-box, and the plank 5 in. high above the aperture, thus making a 6-in. head above the center of the stream. Each square inch of this opening represents a miner's inch, which is equal to a flow of 1.5 cu ft per minute.

* These same conversion factors apply to the *gravitational* units of force having the corresponding names. The dimensions of these units when used as gravitational units of force are MLT^{-2}; see table for *Force*.

† Avoirdupois pounds and ounces.

Metric Multiples

10^6 micrograms = 10^3 milligrams = 10^2 centigrams = 10 decigrams = 1 gram = 10^{-1} dekagram = 10^{-2} hectogram = 10^{-3} kilogram = 10^{-4} myriagram = 10^{-6} megagram

Avoirdupois Weight

(Used Commercially)

27.343 grains = 1 drachm
16 drachms = 1 ounce (oz) = 437.5 grains
16 ounces = 1 pound (lb) = 7000 grains
28 pounds = 1 quarter (qr)
4 quarters = 1 hundredweight (cwt) = 112 pounds
20 hundredweight = 1 gross or long ton *
2000 pounds = 1 net or short ton

(* NOTE.—The long ton is used by the U. S. custom-houses in collecting duties upon foreign goods. It is also used in freighting coal and selling it wholesale.)

14 pounds = 1 stone; 100 pounds = 1 quintal

Troy Weight

(Used in weighing gold or silver)

24 grains = 1 pennyweight (dwt)
20 pennyweights = 1 ounce (oz) = 480 grains
12 ounces = 1 pound (lb) = 5760 grains

The grain is the same in Avoirdupois, Troy and Apothecaries' weights. A carat, for weighing diamonds = 3.086 grains = 0.200 gram. (International Standard, 1913.)

1 pound troy = .8229 pound avoirdupois
1 pound avoirdupois = 1.2153 pounds troy

Apothecaries' Weight

(Used in compounding medicines)

20 grains = 1 scruple (℈)
3 scruples = 1 drachm (ʒ) = 60 grains
8 drachms = 1 ounce (℥) = 480 grains
12 ounces = 1 pound (lb) = 5760 grains

The grain is the same in Avoirdupois, Troy and Apothecaries' weights.

1 pound apothecaries = 0.82286 pound avoirdupois
1 pound avoirdupois = 1.2153 pounds apothecaries

* Definition: One atmosphere (standard) = 76 cm of mercury at 0 deg cent.
† Sometimes called a bar.
‡ To convert height h of a column of mercury at t degrees Centigrade to the equivalent height h_0 at 0 deg cent use $h_0 = h\left\{1 - \frac{(m-l)t}{1+mt}\right\}$ where $m = 0.0001818$ and $l = 18.4 \times 10^{-6}$ if the scale is engraved on brass; $l = 8.5 \times 10^{-6}$ if on glass. This assumes the scale is correct at 0 deg cent; for other cases (any liquid) see *International Critical Tables*, Vol. 1, 68.
§ 1 gram per sq cm = 10 kilograms per sq m.

* See note at the bottom of Table 17.

† Mean calorie and Btu used throughout. One gram-calorie = 0.001 kilogram-calorie; one Ostwald calorie = 0.01 kilogram-calorie.

The IT cal, 1000 international steam-table calories, has been defined as the 1/860th part of the international kilowatthour (see *Mechanical Engineering*, Nov., 1935, p. 710). Its value is very nearly equal to the mean kilogram-calorie, 1 IT cal = 1.00037 kilogram-calories (mean). 1 Btu = 251.996 IT cal.

‡ Absolute joule, defined as 10^7 ergs. The international joule, based on the international ohm and ampere, equals 1.0003 absolute joules.

Watts	17.58	10^{-7}	2.260×10^{-2}	1.356	745.7	69.77	1000	735.5	1

1 Cheval-vapeur = 75 kilogram-meters per second
1 Poncelet = 100 kilogram-meters per second

* The "horsepower" used in these tables is equal to 550 foot-pounds per second by definition. Other definitions are one horsepower equals 746 watts (U. S. and Great Britain) and one horsepower equals 736 watts (continental Europe). Neither of these latter definitions is equivalent to the first; the "horsepowers" defined in these latter definitions are widely used in the rating of electrical machinery.

Table 18. Quantity of Electricity and Electric Flux $[Q]$

Multiply Number of → by to Obtain ↓	Abcoulombs	Ampere-hours	Coulombs	Faradays	Stat-coulombs
Abcoulombs *	1	360	0.1	9649	3.335×10^{-11}
Ampere-hours	2.778×10^{-3}	1	2.778×10^{-4}	26.80	9.259×10^{-14}
Coulombs	10	3600	1	9.649×10^{4}	3.335×10^{-10}
Faradays	1.036×10^{-4}	3.731×10^{-2}	1.036×10^{-5}	1	3.457×10^{-15}
Statcoulombs *	2.998×10^{10}	1.080×10^{13}	2.998×10^{9}	2.893×10^{14}	1

* Conventionally, in the electrostatic and electromagnetic systems of units, the number of lines of electric flux emanating from a point charge is 4π times that charge (or quantity of electricity). The statcoulomb and the abcoulomb are units of charge, not flux.

Table 33. Specific Heat $[L^2T^{-2}t^{-1}]$

(t = temperature)

To convert specific heat in any unit given to any other unit multiply the number of original units by a factor obtained by dividing the factor in the last column for the final unit by the factor for the original unit.

Unit of Heat or Energy	Unit of Mass	Temperature Scale*	Factor
Gram-calories	Gram	Centigrade	1
Kilogram-calories	Kilogram	Centigrade	1
British thermal units	Pound	Centigrade	1.800
British thermal units	Pound	Fahrenheit	1.000
Joules	Gram	Centigrade	4.186
Joules	Pound	Fahrenheit	1055.
Kilowatt-hours	Kilogram	Centigrade	1.163×10^{-3}
Kilowatt-hours	Pound	Fahrenheit	2.930×10^{-4}

* Temperature conversion formulas:

t_c = temperature in Centigrade degrees
t_f = temperature in Fahrenheit degrees
1 deg fahr = (5/9) deg cent.
$t_c = \frac{5}{9}(t_f - 32)$
$t_f = \frac{9}{5}t_c + 32$

Table 34. Thermal Conductivity $[MLT^{-3}t^{-1}]$ and Thermal Resistivity $[M^{-1}L^{-1}T^{3}t]$

(t = temperature)

To convert thermal conductivity, in gram-calories transmitted per second from one face of a cube 1 cm on edge to the opposite face per degree centigrade temperature difference between these faces, to the units given in any line of the following table, multiply by the factor in the last column.

To convert thermal conductivity in any unit given to any other unit multiply the number of original units by a factor obtained by dividing the factor in the last column for the final unit by the factor for the original unit.

To convert thermal resistivity, in degrees centigrade between one face of a cube 1 cm on edge and the opposite face per gram-calories transmitted per second between these faces, to the units given in any line of the following table, divide by the factor in the last column.

To convert thermal resistivity in any given unit to any other unit multiply the number of the original units by a factor obtained by dividing the factor in the last column for the original unit by the factor for the final unit.

Surface emission resistance in thermal ohms per square centimeter is derived from degrees fahrenheit per Btu per hour per square foot by multiplying the number of the latter units by 1761.

Units of				Temperature Scale	Factor
Heat	Area	Thickness	Time		
Gram-calories	cm^2	cm	second	Centigrade	1
Kilogram-calories	m^2	cm	hour	Centigrade	3.6×10^4
British thermal units	ft^2	inch	hour	Fahrenheit	2903.
Joules *	cm^2	cm	second	Centigrade	4.186
Joules	ft^2	inch	second	Fahrenheit	850.6
Kilowatt-hours	m^2	cm	hour	Centigrade	41.86
Kilowatt-hours	ft^2	inch	hour	Fahrenheit	0.8506

* Thermal resistances in these units are known as *thermal ohms.*

18. GAGES

SHEET METAL GAGES. The important sheet metal gages in use in the United States are: the United States Standard Gage for sheet and plate iron and steel, the American Wire Gage (also called the Brown and Sharpe W.G.) for copper, aluminum, and brass and other non-ferrous alloys, the Tin Plate Gage, the Galvanized Sheet Gage, the American Zinc Gage, and the Birmingham Wire (or Stubs' Iron Wire) Gage. In Canada and England the Birmingham Gage (different from the Birmingham Wire Gage) and the Imperial Standard Wire Gage (S.W.G.) are used. Still other gages are used elsewhere. In Japan standard thickness of sheet metal is denoted by the thickness in millimeters. A standard Decimal Gage, in which the standard thicknesses are denoted by decimal parts of an inch and not by gage numbers, has been used in the United States. Copper sheets may be obtained with thicknesses any integral multiple of $^1/_{16}$ of an inch up to 2 in. Heavy copper sheets may be obtained in definite weights per square foot. Each ounce of weight is equivalent to approximately 0.001352 in. thickness. Lead is usually ordered in this manner, each pound being equivalent to approximately 0.017 in. thickness.

The United States Standard Gage for sheet iron and steel (Act of Congress, March 3, 1893; formerly the legal standard for duties) is a *weight* gage based on a density for wrought iron of 480 pounds per cubic foot. Since 1893, steel (density of 489.6 lb per cu ft) has come into general use. A given gage number of this gage represents a fixed weight per unit area; hence a steel sheet will have a smaller thickness than a wrought iron sheet of the same gage number. Monel metal sheets are rolled to the thickness given for wrought iron without regard to its weight, which is about 552.2 lb per cu ft. Practice among steel manufacturers is irregular, some keeping the *thickness* constant for a given gage number irrespective of weight. If this practice is followed, the weight per square foot and per square meter given in the second and third columns of Table 36 will vary, whereas thickness will remain near that given for wrought iron.

The American Wire Gage specifies thicknesses without regard to weight. For the basis of this gage see Wire Gages, p. 1-70, where are also given the Birmingham W.G and the S.W.G.

Tables of Thickness and Weight corresponding to United States Standard gage and American Wire gage numbers are shown in Tables 36 and 37. These tables are taken from *Circular* 391 of the Bureau of Standards, in which are given all the gages mentioned above and the tolerances customary in commerce.

WIRE GAGES. The sizes of wires having a diameter less than $^1/_2$ in. are usually stated in terms of certain arbitrary scales called "gages." The size or gage number of a solid wire refers to the cross-section of the wire perpendicular to its length; the size or gage number of a stranded wire refers to the total cross-section of the constituent wires, irrespective of the pitch of the spiraling. Larger wires are usually described in terms of their area expressed in circular mils. A circular mil is the area of a circle 1 mil in diameter, and the area of any circle in circular mils is equal to the square of its diameter in mils.

There are a number of wire gages in use, the principal ones being the following:

American or Brown and Sharpe Wire Gage. This gage is the one commonly used in the United States for copper, aluminum, and resistance wires. The gage is designated by either of the abbreviations A.W.G. or B. & S.

Basis of the A.W.G. or B. & S. Gage. The diameters of wires having successive numbers on this gage are in the ratio of $\sqrt[39]{92}$(= 1.1229 approx.) to 1, and the No. 36 wire has a diameter of 5 mils. No. 35 A.W.G., therefore, has a diameter of $5 \times 1.1229 = 5.61$ mils, and so on until No. 0000 is reached, having a diameter of 460 mils.

The ratio $\sqrt[39]{92}$ is approximately equal to $\sqrt[6]{2}$, which is 1.1225. This circumstance makes it possible to have a group of wires of regular gage size with an aggregate area approximately equal to that of another regular gage size. For example, a reduction of three gage numbers (as from gage No. 36 to No. 33) results in a new gage number representing a diameter approximately $\sqrt{2}$ times that represented by the original gage number—or an area approximately two times as great.

The following approximate relations are also useful:

An increase of 1 in the number increases the resistance 25 per cent.
An increase of 2 in the number increases the resistance 60 per cent.
An increase of 3 in the number increases the resistance 100 per cent.
An increase of 10 in the number increases the resistance 10 times.

Table 36. United States Standard Gage * for Sheet and Plate Iron and Steel, and Its Extension †

* For the Galvanized Sheet Gage, add 2.5 ounces to the weight per square foot as given in the table. Gage numbers below 8 and above 34 are not used in the Galvanized Sheet Gage.

† Gage numbers greater than 38 were not in the standard as set up by law, but are in general use.

Table 37. American Wire Gage—Weights of Copper, Aluminum, and Brass Sheets and Plates

Gage No.	Thickness		Approximate weight * per sq ft in lb		
	Inch	mm	Copper	Aluminum	Commercial (high) brass

* Assumed specific gravities or densities in grams per cubic centimeter; copper, 8.89; aluminum, 2.71; brass, 8.47.

A No. 10 A.W.G. copper wire has the following approximate characteristics:

Ohms per 1000 ft.	1
Circular mils area.	10,000
Weight, pounds per 1000 ft.	32

A No. 10 A.W.G. aluminum wire has the following approximate characteristics:

Ohms per 1000 ft.	1.6
Circular mils area.	10,000
Weight, pounds per 1000 ft.	9.5

Remembering these rules it is easy to find the approximate size, resistance, area, or weight of any size wire. For example, a No. 12 A.W.G. copper wire has a resistance of 1 plus 60 per cent = 1.6 ohms per 1000 ft approximately. Its area, being inversely as its resistance, is 10,000/1.6 = 6250 circular mils; its diameter is therefore $\sqrt{6250} = 79$ mils, and its weight 32/1.6 = 20 lb per 1000 ft.

U. S. Steel Wire Gage. This gage, known also as the "Washburn and Moen," "Roebling," "American Steel and Wire Co.'s gage," is the one usually employed in the United States for steel and iron wire. It is frequently abbreviated "S.W.G.," but to avoid confusion with the British Standard Wire Gage (*see below*) it should be abbreviated "Stl. W.G." or "A. (steel) W.G."

Birmingham (or Stubs' Iron) Wire Gage. This gage is still used in the United States for some purposes, e.g., to designate the size of brass wire, and is also employed to a limited extent in Great Britain. It is usually abbreviated "B.W.G." It is sometimes referred to as the "Stubs' Iron Wire Gage," but it should not be confused with the Stubs' Steel Wire Gage.

British Standard Wire Gage. This gage, usually called simply the "Standard Wire Gage" and abbreviated "S.W.G.," is also known as the "New British Standard" (abbreviated "N.B.S."), the English Legal Standard, or the Imperial Wire Gage, and is the legal standard of Great Britain for all wires, as fixed by order in Council, August 23, 1883. It was constructed by modifying the Birmingham Wire Gage, so that the differences between successive diameters were the same for short ranges, i.e., so that a graph representing the diameters consists of a series of a few straight lines.

Edison Wire Gage. The size of a wire on this gage is equal to its cross-sectional area in circular mils divided by 1000. For example, a solid wire 0.2 in. in diameter has the number $(200)^2/1000 = 40$. This gage is now rarely used.

Metric Wire Gage. The gage number is ten times the diameter in millimeters.

Other Gages. In addition wire sizes are sometimes specified in terms of the "Old English Wire Gage," known also as the "London Gage," and the "Stubs' Steel Wire Gage." The Old English Wire Gage is the same as B.W.G. for all gage numbers under 20.

Comparison of Wire Gages. A comparison of the different gages, in terms of the diameters (in mils or thousandths of an inch) of solid wires corresponding to the various numbers, is given in Table 38. The cross-section in **circular mils** is the square of the diameter in mils.

Table 38. Comparison of Wire Gage Diameters in Mils
(Bureau of Standards, *Circulars* 31 and 67)

Gage No.	American wire gage (B. & S.)	Steel wire gage	Birmingham wire gage (Stubs')	Old English wire gage (London)	Stubs' steel wire gage	(British) Standard wire gage	Metric gage *	Gage No.

* For diameters corresponding to metric gage numbers, 1.2, 1.4, 1.6, 1.8, 2.5, 3.5, and 4.5, divide those of 12, 14, etc., by ten.

SYMBOLS AND ABBREVIATIONS

19. ABBREVIATIONS FOR ENGINEERING TERMS

NOTE: This list is a selection of American Tentative Standard abbreviations, for scientific and engineering terms, recommended by the American Standards Association. (See ASA, Z10.1—1941.)

Absolute.............................. abs
Acre..............................spell out
Alternating-current (as adjective).......... ac
Ampere.............................. amp
Ampere-hour......................... amp-hr
Angstrom unit.......................... A
Atmosphere........................... atm
Atomic weight...................... at. wt.
Average.............................. avg
Avoirdupois.......................... avdp

Barometer............................ bar.
Barrel................................ bbl
Baumé................................ Bé
Boiler pressure..................... spell out
Boiling point.......................... bp
Brake horsepower...................... bhp
Brake horsepower-hour................ bhp-hr
Brinell hardness number................. Bhn
British thermal unit.......... .... Btu or B

Calorie............... .... cal
Candle.................................. c
Candle-hour.......................... c-hr
Candlepower........................... cp
Centigram............................. cg
Centiliter.............................. cl
Centimeter............................ cm
Centimeter-gram-second (system).......... cgs
Chemically pure.......................... cp
Circular............................... cir
Circular mils....................... cir mils
Coefficient........................... coef
Cologarithm.......................... colog
Concentrate.......................... conc
Conductivity.......................... cond
Constant............................. const
Cord................................... cd
Cosecant.............................. csc
Cosine................................ cos
Cotangent............................. cot
Coulomb.......................... spell out
Counter electromotive force............. cemf
Cubic.................................. cu
Cubic centimeter............. cu cm, cm^3, cc
Cubic feet per minute................... cfm
Cubic foot............................cu ft
Cubic inch.......................... cu in.
Cubic meter.................. cu m or m^3
Cubic yard.......................... cu yd
Cycles per second............... spell out or c

Decibel................................ db
Degree.......................... deg or °
Degree Centigrade....................... C
Degree Fahrenheit....................... F
Degree Kelvin........................... K
Degree Réaumur......................... R
Diameter............................. diam
Direct-current (as adjective)............. d-c
Dozen................................ doz
Dram.................................. dr

Efficiency............................. eff
Electric.............................. elec
Electromotive force..................... emf
Equation................................ eq
External............................... ext

Farad........................ spell out or f
Foot..................................... ft
Foot-candle............................ ft-c
Foot-Lambert.......................... ft-L
Foot-pound........................... ft-lb
Foot-pound-second (system)............... fps
Freezing point........................... fp
Fusion point........................... fnp

Gallon................................ gal
Grain............................ spell out
Gram.................................... g
Gram-calorie .... g-cal

Henry.................................... h
Horsepower............................. hp
Horsepower-hour...................... hp-hr
Hour.................................... hr
Hundred................................. C
Hyperbolic sine........................ sinh
Hyperbolic cosine...................... cosh
Hyperbolic tangent..................... tanh

Inch.................................... in.
Inch-pound........................... in-lb
Internal................................ int

Joule..................................... j

Kilocycles per second.................... kc
Kilogram................................ kg
Kilogram-calorie...................... kg-cal
Kilogram-meter........................ kg-m
Kiloliter................................. kl
Kilometer............................... km
Kilovolt.................................. kv
Kilovolt-ampere......................... kva
Kilowatt................................. kw
Kilowatthour.......................... kwhr

Lambert.................................. L
Latitude........................... lat or ϕ
Linear foot............................ lin ft
Liter...................................... l
Liquid.................................... liq
Logarithm (common)...................... log
Logarithm (natural) .... $\log_e$ or ln
Longitude......................... long. or λ
Lumen..................................... l
Lumen-hour............................. l-hr

Magnetomotive force...................... mmf
Maximum .... max
Melting point............................ mp
Meter..................................... m
Meter-kilogram......................... m-kg
Mho.............................. spell out
Microampere...................... μa or mu a
Microfarad.............................. μf
Micromicron................... $\mu\mu$ or mu mu
Micron............................. μ or mu
Microwatt....................... μw or mu w
Mile.............................. spell out
Milliampere.............................. ma
Milligram................................ mg
Millihenry............................... mh

Abbreviations for Engineering Terms—*Continued*

Milliliter	ml
Millimeter	mm
Millimicron	mμ or m mu
Million	spell out
Millivolt	mv
Mean horizontal candlepower	mhcp
Miles per hour	mph
Minimum	min
Minute	min
Minute (angular measure)	′
Ohm	spell out or Ω
Ounce	oz
Ounce-foot	oz-ft
Ounce-inch	oz-in.
Pint	pt
Potential	spell out
Pound	lb
Pound-foot	lb-ft
Pound-inch	lb-in.
Pounds per square foot	psf
Pounds per square inch	psi
Power factor	spell out or pf
Quart	qt
Radian	spell out
Reactive kilovolt-ampere	kvar
Reactive volt-ampere	var
Revolutions per minute	rpm
Revolutions per second	rps
Root mean square	rms
Secant	sec
Second	sec
Second (angular measure)	″
Sine	sin

Versed sine	vers
Volt	v
Volt-ampere	va
Watt	w
Watthour	whr
Weight	wt
Yard	yd
Year	yr

20. LETTER SYMBOLS FOR THE MAGNITUDES OF ELECTRICAL QUANTITIES

(Tentative American Standard Z10.5–1947) †

In the alphabetical order of the names of the quantities

Each quantity appears at only one place in this table (with a few exceptions), listed alphabetically under its preferred name. The non-preferred names appear in parentheses under the preferred names. Deprecated names are also in parentheses and in addition are asterisked thus: (electric force)*.

Names beginning with the qualifying adjectives, *electric*, *electrostatic*, *dielectric*, *magnetic*, *mutual*, *self*, and *relative*, are listed under the term that is so qualified.

Symbols for scalar quantities, whose values are expressed by real numbers, are printed in ordinary-face *italic letters.*

Symbols for vector quantities are printed in **bold-face Roman letters.**

Symbols for phasor quantities, whose values are expressed by complex numbers, are printed in ***bold-face italic letters.***

Item	Quantity	Symbol
1	admittance	Y
2	attenuation constant	α
3	capacitance	C
	(capacity) *	
	(permittance) *	
4	capacitivity	ϵ
	dielectric constant	
	(permittivity) *	
	of evacuated space	ϵ_v
5	capacitivity, relative	ϵ_r
	relative dielectric constant	
	(specific inductive capacity) *	
6	charge, electric or quantity of electricity	Q
	charge density	
7	line d. of charge	λ
8	surface d. of charge	σ
9	volume d. of charge	ρ
10	conductance	G
11	conductivity	γ
12	conductivity, equivalent	Λ

* Deprecated name.

Note 1. Designation of maximum, instantaneous, rms, and average values.

Where distinctions between maximum, instantaneous, root-mean-square (effective), and average values are necessary, E_m, I_m, Q_m, and P_m are recommended for maximum values; e, i, q, and p for instantaneous values, E, I, and Q for root-mean-square values and E_a, I_a, Q_a, and P for average values.

Note 2. Quantities per unit volume, area, or length.

It is recommended that quantities per unit volume, area, length, etc., be represented as far as practicable by lower-case letters corresponding to the cap letters which represent the total quantities, or by the cap letters with the subscript 1, except for those quantities for which this table has symbols for the quantity per unit volume, area, etc.

Note 3. Distinction between the symbols V and E for potential and electromotive force.

The distinction between the use of V for potential and E for electromotive force is:

V is to be used for potentials or potential differences that are attributed solely to that distribution of electric field intensities which is computed (by the inverse square law of force) from the segregated charges of the field.

E is to be used for the emf along a path from a terminal A to a terminal B when in the region A to B one or more non-electrostatic types of electric intensities exist. or turbulent actions occur—as in voltaic cells, electrostatic generators, and electromagnetic sources of emf.

Note 4. The sequence of the double subscripts to multiplying operators.

The sequence of the double subscripts to the *multiplying* operators (mutual impedances, resistances, or elastances or transconductances, etc.) that occur in the fundamental equations of networks is to be determined by the following consideration:

Consideration. The set of fundamental equations (e.g., Kirchhoff's emf equations) should yield a determinant in which the subscript sequence conforms to the mathematician's convention for writing determinants; namely,

Convention. In the double subscripts of the elements of a determinant, the subnumber designating the "row" is to precede the subnumber designating the "column" to which the element belongs, or the order is e_{rc}. Thus

$$D(e) = \begin{vmatrix} e_{11} & e_{12} \\ e_{21} & e_{22} \end{vmatrix}$$

This consideration leads to the following rule:

Rule for writing double subscripts.

The first subnumber in the symbol for a *multiplying* operator designates the number of the circuit in which the *product* of the *multiplication* is measurable, while the second subnumber designates the number of the circuit in which the operand or *multiplicand* is measurable.

As an illustration, Kirchhoff's emf law for the emfs of the rth circuit due to the currents in all the circuits of a network is written:

$$E_{r,d} = Z_{r1}I_1 + Z_{r2}I_2 + \cdots Z_{rr}I_r + \cdots$$

or

$$E_{r,d} = \Sigma c\ Z_{rc}I_c$$

($E_{r,d}$ being the driving emf impressed in the rth circuit).

Note 5. Notation for symmetrical components.

The standard notation for designating the symmetrical components of the currents and potential differences in unbalanced polyphase systems is that subscript notation in which:

(a) double subscripts are added to the symbols for current and potential difference;

(b) the first and second subscripts designate, respectively, the phase and the sequence to which the component belongs;

(c) the first, or phase, subscript may be the phase number, or the phase letter, or a two-letter combination that designates (on a diagram) both the phase and the direction in the phase;

(d) the second, or sequence, subscript is *always* to be the number that designates the sequence to which the component belongs; the positive, negative, and zero sequence components in three-phase systems being designated by the numbers 1, 2, and 0, respectively.

Illustration of notation:

$$I_a = I_{a1} + I_{a2} + I_{a0}$$
$$I_b = I_{b1} + I_{b2} + I_{b0}$$
$$I_c = I_{c1} + I_{c2} + I_{c0}$$

21. STANDARD GRAPHICAL SYMBOLS

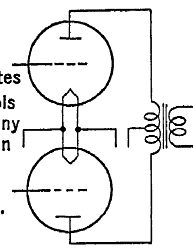
39. This figure illustrates how tube symbols may be placed in any convenient position as shown in a communication transformer circuit.



40. General Notes

(*a*) The diagram for a tube having more than one heater shall show only one heater symbol (inverted V) unless the heaters have entirely separate connections. If a tap is made, one heater symbol shall still be shown, and the tap shall be shown at the vertex of the heater symbol, regardless of the actual division of voltage across the heater

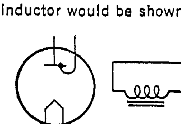
(*b*) Item (*a*) shall apply also to filaments. In case of a tap, either brought out to a pin connection or internally connected as to a suppressor grid, the tap shall be shown at the vertex of the filament symbol, regardless of the actual division of voltage across the filament.

(*c*) A type having more than one cathode shall be shown as having a single cathode unless separate cathode connections are made.

(*d*) A type having two or more grids tied internally shall be shown with symbols for each grid, except when the grids are adjacent in the tube structure. Thus the diagram for a twin pentode having a common screen-grid connection for each section and for a converter tube having the No. 3 and the No. 5 grids connected internally will show separate symbols for each grid. However, a triode where the control grid is physically in the form of two grid windings would show only one grid.

(*e*) A type having a grid adjacent to a plate but internally connected to the plate to form a portion of it shall be shown as having a plate only,

(*f*) Associated parts of a circuit such as deflecting coils, field coils, etc., are not a part of the tube symbol but may be added to the circuit in the form of standard symbols as shown in ASA Z32.3 or ASA Z32.5. For example, resonant-type magnetron plus symbol for ferromagnetic inductor would be shown



22. USE OF GREEK ALPHABET FOR SYMBOLS

Capital	Lower Case	Name	Commonly Used to Designate
Α	α	Alpha	Angles. Area. Coefficients. Attenuation constant.
Β	β	Beta	Angles. Flux density. Coefficients.
Γ	γ	Gamma	Conductivity. Specific gravity. Propagation constant.
Δ	δ	Delta	Variation. Density. Damping coefficient.
Ε	ϵ	Epsilon	Base of natural logarithms. Capacitivity.
Ζ	ζ	Zeta	Impedance. Coefficients. Coordinates.
Η	η	Eta	Hysteresis coefficient. Efficiency.
Θ	θ	Theta	Temperature. Phase angle.
Ι	ι	Iota	
Κ	κ	Kappa	Dielectric constant. Susceptibility.
Λ	λ	Lambda	Wavelength.
Μ	μ	Mu	Micro. Amplification factor. Permeability.
Ν	ν	Nu	Reluctivity.
Ξ	ξ	Xi	
Ο	o	Omicron	
Π	π	Pi	Ratio of circumference to diameter = 3.1416.
Ρ	ρ	Rho	Resistivity.
Σ	σ	Sigma	Capital: sign of summation.
Τ	τ	Tau	Time constant. Time phase displacement.
Υ	υ	Upsilon	
Φ	ϕ or φ	Phi	Magnetic flux. Angles.
Χ	χ	Chi	
Ψ	ψ	Psi	Dielectric flux. Phase difference.
Ω	ω	Omega	Capital: ohms. Lower case: angular velocity, or $2\pi \times$ frequency.

CONSTANTS

By Carl C. Chambers

23. PRINCIPAL PHYSICAL CONSTANTS AND RATIOS *

Velocity of light	$(2.99776 \pm 0.00004) \times 10^{10}$ cm sec^{-1}
Ratio of electrostatic to electromagnetic units	$(2.9971 \pm 0.0001) \times 10^{10}$ cm$^{1/2}$ sec$^{-1/2}$ (int ohms)$^{1/2}$ $(2.9978 \pm 0.0001) \times 10^{10}$ cm sec^{-1} (in absolute units)
Volume of a perfect gas (0 deg cent and normal atmospheric pressure)	$(22.4146 \pm 0.0006) \times 10^3$ cm^3 mole^{-1}
Normal atmospheric pressure	$(1.013246 \pm 0.000004) \times 10^6$ dynes cm^{-2}
45 deg cent atmospheric pressure	$(1.013195 \pm 0.000004) \times 10^6$ dynes cm^{-2}
Ice point (absolute scale)	$273.18 \pm 0.01°$ K
Mechanical equivalent of heat (15 deg cent)	4.1855 ± 0.0004 abs joule cal^{-1}
Electrical equivalent of heat (15 deg cent)	4.1847 ± 0.0003 int joule cal^{-1}
Faraday constant	96494 ± 5 int coulombs g-equiv^{-1}
Electronic charge	$(4.8025 \pm 0.0010) \times 10^{-10}$ abs-es unit $(1.60203 \pm 0.00034) \times 10^{-20}$ abs-em unit
Planck constant	$(6.624 \pm 0.002) \times 10^{-27}$ erg sec
Acceleration of gravity	980.665 cm sec^{-2}
Electrochemical equivalent of silver	1.11800×10^{-3} g. int coulombs^{-1}
Wave length of red cadmium line (15 deg cent, normal atmospheric pressure)	6438.4696 I.A. †
Effective grating space of calcite (18 deg cent)	3.02904×10^{-8} cm
Avogadro's number	$(6.0228 \pm 0.0011) \times 10^{23}$ mole^{-1}
Boltzmann constant	$(1.3708 \pm 0.0014) \times 10^{-16}$ erg deg^{-1}
Stefan-Boltzmann constant	$(5.672 \pm 0.003) \times 10^{-5}$ erg cm^{-2} deg^{-4} sec^{-1}
Mass of the electron	$(9.1066 \pm 0.0032) \times 10^{-28}$ g
Ratio of mass of H to mass of electron (measured by deflection)	1837.5 ± 0.5

* Values taken from Birge, *Rev. of Mod. Phys.*, Vol. 13, No. 4 (October, 1941).

† This defines the international angstrom unit (I.A.). The unit is of the order of 1 part in several million different from 10^{-8} cm.

24. STANDARD RADIO-FREQUENCY RANGES

The International Telecommunication Union in 1947 adopted officially the Nomenclature of Frequencies shown in Table 39. The designation of each metric subdivision of wavelength range is the name of the metric unit of length which is equal to the shortest wavelength in the range. The range number is the power of 10 which represents the approximate mean frequency of that range. The frequency subdivision designations are those first adopted by the Armed Forces of the United States and subsequently by other branches of the government.

The table is based on the approximation that the wave velocity is 300,000,000 meters per second. In any case, where the required precision makes this assumption inadequate, the exact boundaries of the ranges should be based on the frequency range, not the wavelength range.

It is suggested that the term radio be added where there is any possibility of confusion. A power engineer might be considerably startled to hear 100 kc referred to as a "low frequency."

The term microwave has been variously used: (1) as referring to waves less than 1 meter in length; (2) as certainly including ranges 10 and 11, and part of 9; (3) as referring to waves using cavities instead of *LC* tuned circuits; and (4) as referring to waves transmitted by wave guides. Where any confusion is possible, the term should be eschewed or clarifying text added.

Table 39. Nomenclature of Frequencies

Range Number N	Frequency Range		Wavelength Range		Metric Subdivision	Frequency Subdivision
	Lower Limit (Incl.)	Upper Limit (Excl.)	Lower Limit (Excl.)	Upper Limit (Incl.)		
0	0.3 c	3 c				
1	3 c	30 c				
2	30 c	300 c				
3	300 c	3 kc				
4	3 kc	30 kc	10 km	100 km	Myriametric waves	VLF (very low frequency)
5	30 kc	300 kc	1 km	10 km	Kilometric waves	LF (low frequency)
6	300 kc	3,000 kc	1 hm	10 hm	Hectometric waves	MF (medium frequency)
7	3,000 kc	30,000 kc	1 dkm	10 dkm	Decametric waves	HF (high frequency)
8	30,000 kc	300 Mc	1 m	10 m	Metric waves	VHF (very high frequency)
9	300 Mc	3,000 Mc	1 dm	10 dm	Decimetric waves	UHF (ultra high frequency)
10	3,000 Mc	30,000 Mc	1 cm	10 cm	Centimetric waves	SHF (super high frequency)
11	30,000 Mc	300 kMc	1 mm	10 mm	Millimetric waves	EHF (extremely high frequency)
12	300 kMc	3,000 kMc				
13	3,000 kMc	30,000 kMc				
14	30,000 kMc	300 MMc				

Note 1. Ranges 0–3 and 12–14 not standardized by I.T.U.

Note 2. Frequencies shall be expressed in kilocycles per second (kc/s) at and below 30,000 kilocycles per second and in megacycles per second (Mc/s) above this frequency.

Note 3. Used as an adjective the word "Range" shall precede the number; thus: "Range 3."

PROPERTIES OF MATERIALS

CONDUCTING MATERIALS

By Knox McIlwain

Since all materials possess, to some extent, the ability to conduct electricity, whether a particular material is called conducting or insulating is a matter only of relative degree. In general, if a moderate potential difference, say from a voltaic cell, is placed across a section of a material and a measurable current flows the substance is said to be conducting, but if no conveniently detectable current flows it is considered insulating.

Among conducting materials are included pure metals, some metallic salts and oxides, alloys, and the metalloids, carbon, silicon, and boron. Such substances as glass, dry paper and silk, porcelain, and rubber possess such a very low conductivity that they are considered insulating materials.

1. DEFINITIONS

Conductivity. The conductivity of a material is the direct current conductance between the opposite, parallel faces of a portion of the material having unit length and unit cross-section.

Effective Conductivity. The effective conductivity of a material to a periodic current is the effective conductance between the opposite, parallel faces of a portion of the material having unit length and unit cross-section.

Resistivity. The resistivity of a material is the reciprocal of its conductivity.

Units of Resistivity. The resistivity may be expressed as the resistance of a 1-cm cube of material; this unit is called the *ohm per centimeter cube* or preferably simply the *ohm-centimeter*. In the English system the *ohm-inch* is used. When the material is to be drawn into wires the *ohm per mil-foot* is used; this is the resistance of a wire 1 mil (0.001 in.) in diameter and 1 ft long.

Units of Conductivity. The conductivity of a material γ is numerically equal to the reciprocal of its resistivity ρ and is expressed in mhos and megmhos per centimeter, etc., instead of ohm-centimeters and microhm-centimeters, etc., as used to express resistivity. Thus γ equals $1/\rho$.

Annealed Copper Standard. The standard, or 100 per cent, conductivity is defined as follows:

1. At a temperature of 20 deg cent, the resistance of a wire of standard annealed copper 1 meter in length and of a uniform section of 1 sq mm is $^1/_{58}$ ohm = 0.01724 ohm.

2. At a temperature of 20 deg cent, the density of standard annealed copper is 8.89 grams per cubic centimeter. This corresponds to 8.90 grams per cubic centimeter at 0 deg cent.

3. Thus, at 20 deg cent, the resistance of a wire of standard annealed copper of uniform section, 1 meter in length and weighing 1 gram, is $(^1/_{58}) \times 8.89 = 0.15328$ ohm.

Temperature Coefficient of Electric Resistance. The resistance temperature coefficient β_t of a substance at any temperature t is defined as the rate of change of resistance at this temperature divided by the resistance R_t at this temperature:

$$\beta_t = \frac{1}{R_t}\left(\frac{dR}{dt}\right)_t$$

The "mean" temperature coefficient α_t between any two temperatures t and t_1 "referred to" the temperature t is defined as the "average" change in the resistance in this interval per degree change of temperature, divided by the resistance at the lower temperature:

$$\alpha_t = \frac{R_{t1} - R_t}{R_t(t_1 - t)}$$

The temperature coefficients of 100 per cent conductivity copper are given in Table 1.

Table 1. Temperature Coefficients of Copper

Ohms per Meter-gram at 20° C	Per Cent Conductivity	α_0	α_{15}	α_{20}	α_{25}	α_{30}
0.16134	95	0.00403	0.00380	0.00373	0.00367	0.00360
.15966	96	.00408	.00385	.00377	.00370	.00364
.15802	97	.00413	.00389	.00381	.00374	.00367
.15753	97.3	.00414	.00390	.00382	.00375	.00368
.15640	98	.00417	.00393	.00385	.00378	.00371
.15482	99	.00422	.00397	.00389	.00382	.00374
<u>.15328</u>	<u>100</u>	.00427	.00401	<u>.00393</u>	.00385	.00378
.15176	101	.00431	.00405	.00397	.00389	.00382

The underlined values in the table have been adopted as standard by the American Institute of Electrical Engineers.

2. PROPERTIES OF SPECIFIC CONDUCTORS

Conducting materials can be roughly divided into two groups: the good conductors, and the resistive conductors. The good conductors are all *metals*, a group of some 50 chemical elements recognized as such by their hardness, ductility, malleability, luster, and good conductivity of heat and electricity. Since these and other characteristics are possessed by these elements in varying degrees there are some which are metallic in some properties and non-metallic in others. Of these an electrically important group is carbon, silicon, and boron, often called the metalloids, which are rather good conductors of heat and electricity but have non-metallic mechanical properties. Almost all the resistive conductors on the market today are solid solution alloys or those composed largely of solid solutions. In electric circuits they are generally used either in devices for purposes of operation, protection, or control, or as heating elements. It is usually desirable for them to have properties of high resistivity and low temperature coefficient of resistance, but in some cases a high temperature coefficient is useful—witness the use of nickel as a filament control.

In general, the standard alloys for electrical resistance are made of nickel and chromium, compositions of 80 per cent nickel and 20 per cent chromium having high resistance to oxidation with maximum working temperatures up to about 1100 deg cent. By varying the proportions of these and by the addition of different amounts of iron, copper, manganese, zinc, and cobalt we are able to obtain alloys which have different resistivities, temperature coefficients, melting points, magnetic properties, and heat- and corrosion-resisting properties.

Tables 2 and 3 give the properties of materials available for the manufacture of conductors and resistors; Table 4 gives the physical properties of some beryllium-copper alloys.

Table 3. Properties of Conducting Materials at High Temperatures—*Continued*

Description of Material	Resistivity in Microhm-centimeters		
	500° C	1000° C	1500° C
Silfrax* B	0.92×10^6	0.84×10^6	0.7×10^6
Silicon	0.094×10^6 to 0.023×10^6		
Silicon powder	120×10^6	3.5×10^6	
Silver (fused)		17.01	23
Silver (solid)	5		
Silver chloride (fused)	0.547×10^6		
Sodium chloride (fused)		0.90×10^6	
Tantalum (solid)	36	57	
Tantalum (a) solid			78
Tantalum (b) solid			74
Tin (fused)	54.62	68	80.5
Tungsten (solid)			43
Tungsten (a) solid	18	30.5	
Tungsten (b) solid	18	33.4	50
Zinc (fused)	36.60		
Zinc oxide (powder)		26.7×10^6	

* Trademark names.

Table 4. Approximate Values for the Physical Properties of Beryllium-copper Alloys of the 21 Per Cent Beryllium Class

Condition	Solution-treated "Annealed"	Solution-treated and Cold-worked	Solution-treated and Precipitation-hardened	Solution-treated, Cold-worked, and Precipitation-hardened
Electrical conductivity % I.A.-C.S. at 20° C	17	17	(*a*) 20–25 (*b*) 32–38	(*a*) 20–25 (*b*) 32–38
Tensile strength, psi	70,000	90,000	(*a*) 160,000 (*b*) 130,000	(*a*) 180,000 (*b*) 140,000
Yield strength, psi, at 0.5% elongation under load			(*a*) 150,000	(*a*) 175,000
Elongation in 2 in., %	35		(*a*) 3.0	(*a*) 2.0
Modulus of elasticity, psi	16×10^6		$18.4\text{–}19.4 \times 10^6$	
Endurance limit, psi, at 10^8 reversals of stress		23,000	28,000	28,000

(*a*) Heat-treated for maximum hardness. (*b*) Heat-treated for maximum conductivity.

COPPER-CLAD STEEL WIRE. This wire consists of a steel core and a concentric coat of copper permanently welded thereto. It is used chiefly for long-span transmission and telephone wire. It is made in several grades, which differ in the relative amounts of steel and copper. The grades are designated by the corresponding conductivity expressed as percentages of the Annealed Copper Standard: e. g., 40 per cent grade has a conductivity of 40 per cent.

* Tensile strength in pounds per square inch ranging from 49,000 for No. 0000 to 66,200 for No. 14; see below.

† For wires having a tensile strength of S pounds per square inch, multiply by $S/100{,}000$. The tensile strength of steel varies from 60,000 to 225,000 lb per sq in.

INSULATING MATERIALS

By W. R. Dohan

4. DIELECTRIC PROPERTIES

Dielectric Constant. The dielectric constant, K, of an insulating material is the ratio of the capacitance of an electrode system using the material as a dielectric to its capacitance with a vacuum dielectric. When the material has appreciable losses so that the parallel capacitance, C_p (determined by comparison with a standard capacitor and a parallel conductance, G), differs significantly from the effective series capacitance C_s (determined by comparison with a standard capacitor and a series resistance, R), it is standard to use the value of C_p in computing the dielectric constant. These capacitances are related by the following formula:

$$C_p = \frac{C_s}{1 + \tan^2 \delta} = \frac{C_s}{1 + D^2} = C_s \cos^2 \delta$$

where δ = the loss angle or phase difference.
D = the dissipation factor.

Since the dielectric constant may vary considerably with frequency or temperature the conditions of measurement should always be stated.

Phase Difference or Loss Angle. The difference between the theoretical 90 electrical degrees phase advance of the current through a perfect capacitor and the actual angle of phase advance, θ, of the current through the dielectric material is known as the phase difference, or loss angle, δ.

Dissipation Factor. For convenience in reference and calculation the tangent of the loss angle, δ, has been assigned the standard designation "dissipation factor" and given the symbol D.

Power Factor. The power factor of a dielectric material is the ratio of the power loss in the material to the product of the applied voltage and current. The power factor therefore is equal to the cosine of the angle of phase advance, θ, and to the sine of the complementary angle, δ. The sine and tangent of a small loss angle are very nearly the same, so that the power factor is substantially equal to the dissipation factor for values less than 0.1.

Loss Factor. The product of the dielectric constant and the dissipation factor (or power factor if the value is less than 0.1) is known as the loss factor.

Power Loss. The power loss in a dielectric may be considered to take place in a fictitious shunt or series resistance, depending on the material, the applied frequency, and the temperature. For a series resistance, R, the dissipation factor is

$$D = \tan \delta = R2\pi fC_s \doteq \text{Power factor}$$

For a parallel conductance, G, or shunt resistance, r, the dissipation factor is

$$D = \tan \delta = \frac{G}{2\pi fC_p} = \frac{1}{r2\pi fC_p} \doteq \text{Power factor}$$

In the above formulas C_s and C_p are substantially equal for dissipation factors less than 0.1.

The power loss, P, in a parallel resistance is

$$P = \frac{E^2}{r} = E^2 2\pi fC_pD \text{ watts}$$

The power loss in a small series resistance is

$$P = E^2\,[2\pi fC_s]^2\,R = E^2 2\pi fC_sD \text{ watts}$$

Writing $C_s = C_p = C$ in terms of K, area in square centimeters A, thickness in centimeters t, and the dielectric coefficient for free space 8.854×10^{-12},

$$C = 8.854 \times 10^{-14} \cdot K \cdot \frac{A}{t}$$

and

$$P = 0.555 \times 10^{-12} \cdot E^2 \cdot \frac{AK}{t} \cdot f \cdot D \text{ watts}$$

which may be rewritten in terms of volume in cubic centimeters, V,

$$P = 0.555 \times 10^{-12} \left(\frac{E}{t}\right)^2 \cdot V \cdot f \cdot (K \cdot D) \text{ watts per cm}^3 \text{ per cycle per (volt per cm)}^2$$

Thus the power loss is seen to (1) increase as the square of the voltage gradient (E/t); (2) increase with the volume of material in the field; (3) increase with frequency if $(K \cdot D)$ is constant; (4) increase with the product $(K \cdot D)$, the loss factor. Shunt resistance or conductance is often the most important cause of losses at frequencies below 10 kc, since the impedance of the capacitor is relatively high compared to the shunt resistance. At a frequency of 100 kc the impedance will be much lower compared to the shunt resistance, and at 1000 kc the shunt resistance of good dielectric materials is extremely high compared to the impedance. In the frequency range from 1000 kc to 1000 Mc the dielectric constant and dissipation factor of good non-polar dielectric materials vary but slightly, thus indicating a constant loss per cycle.

Polar and Non-polar Materials. A polar substance is characterized by a permanent unbalance in the electric charges within a molecule. This unbalanced charge system is known as a "dipole" and tends to turn in an electric field. In liquids and soft solids which are polar, there is a free rotation of the dipoles at certain temperatures and applied frequencies, causing a very high loss.

Non-polar materials have no permanent charge unbalance: though the molecule may be distorted by an applied electric field, no tendency to rotate exists. Non-polar substances therefore are free of sharp loss peaks as the temperature or frequency is varied, any changes in dielectric constant and power factor occurring gradually. Whether a substance is polar or non-polar can usually be predicted from its chemical structure. Most hydrocarbons are non-polar and hence are numbered among the best dielectrics, e.g., polyethylene, polystyrene, mineral wax, and oil.

Dielectric Absorption in Solids. A pure capacitance may be completely charged or discharged almost instantaneously if the resistance in the external circuit is small. When the capacitor contains an imperfect dielectric, current continues to flow and the charge increases for a considerable period. The current slowly approaches a final value fixed by the insulation resistance of the dielectric. For this reason, insulation resistance readings are taken after the voltage has been applied for a standard time of 1 minute.

When the capacitance is discharged through a small resistance, a portion of the total charge will be instantaneously dissipated; this has been called the "free charge." If the circuit is opened, the capacitor will be found to have another and smaller charge known as the "residual" or "bound" charge. Sometimes this process may be repeated two or three times.

When an absorbing dielectric is subjected to an alternating electric field, the maximum charge is greater than the free charge but less than the total charge in a d-c field. The measured value of the dielectric constant decreases with increasing frequency, approaching a value corresponding to the "free charge." The instantaneous charge is not in phase with the applied a-c voltage, and a loss of energy results, heating the dielectric. The maximum loss occurs at a frequency which is equal to the reciprocal of the time constant of the charge or discharge current-time curve. When the frequency is increased until the time constant for one cycle is very short compared to the charging time constant with direct current, practically no loss remains.

The exact mechanism of absorption loss is not known, although many theories have been suggested, such as surface charges in non-homogeneous dielectrics (Maxwell and Wagner), space charges (Whitehead and Joffé), and dipoles (Debye).

Insulation Resistance. Insulation resistance is the ratio of the applied d-c voltage to the resultant current flowing, after 1 minute of voltage application, between two electrodes embedded in, or making contact with, the dielectric. The nature of the specimen determines whether the value represents principally surface resistance or volume resistance: when thin specimens with studs or bolts as electrodes are measured at high humidities, the value is more nearly representative of surface resistance; when electrodes of large area are applied to the faces of a slab and measured at low humidities the result is more nearly representative of volume resistance.

Surface Resistivity. Surface resistivity is the resistance between opposite edges of a square. Since the resistance of the body of a material is always in parallel with the surface resistance, the latter is measurable only when the volume resistance is much greater than the surface resistance, e.g., under conditions of high humidity and large ratio of surface to volume in the electric field.

The degree of surface contamination is an important factor since perspiration or other surface contaminant dissolves in the condensed moisture layer and increases its conductivity. While a layer of pure water 0.1 micron thick would result in a surface resistivity of about 3×10^{10} ohms at room temperature (a value commensurate with most wetted insulating materials at humidities above 90 per cent), a mere trace of salt on the surface would reduce the resistance by a factor of 10^{-3}.

The temperature coefficient of surface resistivity is negative.

Volume Resistivity. Volume resistivity is the resistance between opposite faces of a centimeter cube after the surface leakage is eliminated; it is expressed in ohm-centimeters. Volume resistivity is calculated from the resistance between two electrodes, one of which is completely surrounded by a guard electrode maintained at the same potential. The current due to the surface resistance flows through the guard circuit and does not influence the value of current in the guarded electrode circuit.

Volume resistivity has a negative temperature coefficient and often is found to have a negative voltage coefficient. Some materials, especially those of a fibrous nature, exhibit changes in resistance with polarity and the resistivity may change with time, owing to polarization or to water migration. This is known as the "Evershed effect."

Dielectric Strength of Solids. The dielectric strength of a material is the maximum potential that unit thickness can withstand without breakdown. The value obtained will depend upon sample thickness, temperature, applied frequency, wave form, electrode form, area and heat conductivity, the surrounding medium, and the rate and total time of voltage application.

In order that test values may be comparable, the American Society for Testing Materials has standardized these variables for specific classes of materials. The dielectric strength values for a given class of material, e.g., molded thermosetting plastics, are therefore comparable but do not bear a direct relation to the values for a different class of material, e.g., mica or oil.

The general effect of increase in thickness is to raise the total breakdown voltage: the increase for solid dielectrics is nearly linear for small thicknesses at room temperature but very much less than linear for large thicknesses or higher temperatures. Elevation of temperature invariably reduces the dielectric strength.

The peak value of the 60-cycle a-c breakdown voltage usually is less than that of the d-c breakdown voltage. The breakdown voltage decreases with increasing frequency, the rate depending on the loss factor of the material. Dielectric strength at 1 megacycle may be as low as 25 per cent of the 60-cycle value.

When an electrode is sharply curved, the potential gradient at the surface is raised according to the laws of electrostatics, and a reduction in breakdown voltage results. If the electrode area is increased, the probability of a weak dielectric spot within the electrode area is likewise increased, and the average dielectric strength is reduced.

The effect of time on breakdown voltage is best stated by Peek's equation:

$$g = g_0(1 - at^{-\frac{1}{4}})$$

where g = dielectric strength at time t seconds.
g_0 = dielectric strength at infinite time.
a = a constant.

Both g_0 and a vary with temperature and thickness. The formula is unsatisfactory for times less than 0.01 sec or for very long periods.

The general effect of placing dielectrics in series is to decrease the a-c breakdown voltage, since the voltage divides in inverse proportion to the dielectric constants if the resistivities are high. Laminated structures, unless bonded with a medium of the same dielectric constant or impregnated throughout with some medium, tend to have a lower dielectric strength than that of an equivalent thickness of homogeneous material. The presence of air or gas between laminae causes a pronounced reduction in dielectric strength.

Flashover. Flashover is an insulation failure by discharge between the electrodes over the surface of an insulator. Sometimes the insulator is permanently damaged by the flashover. In a uniform electric field the flashover voltage at low relative humidities approaches the dielectric strength of air as a limit. Increase in humidity causes a surface moisture film to form on the insulator, reducing the flashover voltage. Substances which are wetted by water form a more or less continuous film, and the flashover values are somewhat erratic, falling rapidly up to about 50 per cent relative humidity and then more slowly. Non-wetted substances such as waxes, on which the moisture condenses in droplets, show an almost linear, and quite consistent, decrease in flashover with increase in humidity. Higher temperatures and lower pressures both reduce the density of the air: therefore both factors decrease the flashover value. The flashover voltage at high humidities may be from three-quarters to one-half of the sparkover voltage in the absence of the insulator.

Arc Resistance. The power arc following a flashover or the breaking of contacts over the insulator surface subjects the surface to extreme heat, to chemical action, and to deposition of electrode material. Where exposure of the insulator to arcs cannot be avoided, it is important to know the degree of resistance to be expected. Glass, mica, and ceramic materials are quite resistant and become permanently conductive only by deposit of electrode material. Organic materials fail by carbonizing and become permanently conductive even with intermittent arcing. Unfortunately, the phenolic materials are very poor in this respect, failing in a few seconds when tested according to ASTM method D495. Plastics, such as polystyrene, which liberate volatile monomers, tend to blow the arc from the surface and fail in about 60 sec. Shellac, hard rubber, and vulcanized fiber are moderately arc resistant. Vinyl plastics and methacrylates likewise are somewhat resistant. The melamine resins are outstanding as a class: glass cloth melamine laminates last over 180 sec. Cellulose acetates and ethyl cellulose may be formulated to exceed 180 sec resistance. Non-refractory cold-molded compounds and glass-bound mica may last from 180 to 400 sec. Refractory cold-molded compounds last even longer, approaching the ceramics. Arc-resistant varnishes are available which considerably improve the rating of phenolic materials.

Test Methods. Methods of testing electrical insulating materials have been standardized by the American Society for Testing Materials (1916 Race St., Philadelphia 3, Pa.). A few of the more important standards are listed below:

Dielectric Constant and Power Factor	ASTM D150
Dielectric Strength	ASTM D149
Insulation Resistance	ASTM D257
Arc Resistance	ASTM D495

Reference should be made to the current *Index to ASTM Standards* for further information.

5. SOLID DIELECTRIC MATERIALS

Table 1 lists the important physical and electrical properties of solid materials useful for electrical insulation; it is followed by a list of trade names and additional information. The properties given are not intended to be design values but to illustrate the range of properties to be expected in a given class of material or a value typical of the class.

Note A. Thermal conductivity is expressed in $10^{-4} \times$ gram-calories per square centimeter per second for a temperature gradient of 1 deg cent per centimeter. The values are typical for the temperature range 0 to 100 deg cent. The temperature gradient is perpendicular to the laminations of laminar materials.

Note B. Maximum operating temperatures given are based on satisfactory operation under average conditions without excessive cold flow, distortion, or shortening of the operating life of the material. In many cases it will be necessary to reduce the operating temperature in order to obtain electrical properties or to reduce cold flow at higher unit stresses. In some cases higher operating temperatures may be used, particularly where the material can be obtained in special grades for this purpose. If thermal shock is involved the limit for many materials, especially the ceramics, will be much reduced.

Note C. Most of the materials listed are intended to be representative of a class rather than of a single sample, and the ranges of values should be interpreted accordingly. Since complete mechanical and electrical data seldom are available for a single sample or batch, and since data have been assembled from many sources, it is necessary to exercise good judgment in comparing the various materials. Values for laminated phenolic materials are those for sheets; properties of tubes are somewhat poorer.

Note D. Where possible, the ranges of dielectric constant and power factor include the variations to be expected over the indicated frequency ranges, although most of the values up to 2 kc are for 60

cycles or 1 kc, and most of the values in the higher frequency ranges are for 1 Mc. For good insulating materials, the dielectric constant does not change greatly at higher frequencies, but the power factor may rise or fall considerably. An auxiliary table of power factors, following the main table, gives data for some substances.

Note E. Volume resistivity has a large negative temperature coefficient. The values shown for temperature coefficient are the ratio of the resistivity at 20 deg cent to the resistivity at 30 deg cent. It should be remembered that at higher operating temperatures the order of merit of any two materials may be reversed. Furthermore, the volume resistivity may be seriously reduced by prolonged exposure to high humidities.

Note F. Dielectric strength given is for the short-time test at 60 cycles except in the case of the ceramics, where it is given for the step-by-step method. Only those values for the same thickness are directly comparable. Where two thicknesses are given, the higher dielectric strength applies to the lower thickness. The dielectric strength will be much less at higher temperatures or for long times (see discussion of dielectric strength). In the case of laminated materials, the electric field is perpendicular to the laminations; dielectric strength with the field parallel to the laminations may be very low.

Note G. For all wood the tensile strength and flexural strength are given for forces perpendicular to the grain, the compressive strength for forces parallel to the grain. Under Thermal Conductivity, the first figure is perpendicular, the second parallel, to the grain.

ADDITIONAL INFORMATION ON SOLID DIELECTRIC MATERIALS.

Acrylic Resins and Acrylates. Designations used for thermoplastic polymers derived from acrylic acid ($CH_2 : CHCOOH$), methacrylic acid [$CH_2 : C(CH_3)COOH$], or allied materials. The most important are the methyl **methacrylates,** q.v. Acrylics may be vulcanized to reduce thermoplasticity.

Alkyd Resins. Resins derived from reaction of polybasic acids with polybasic alcohols, glycerol and phthalic anhydride being the principal materials in use. They are used chiefly for varnishes and other coatings. Trade name: *Glyptal.*

Allyl Resins. A group of plastics derived from allyl alcohol ($CH_2 : CHCH_2OH$). The resins are marketed in the form of cast transparent sheets and rods, and in the form of liquid monomers which are polymerized with the aid of a peroxide catalyst and heat, but no gases or vapors are emitted. The resin is thermosetting in nature with good electrical properties which are maintained at elevated temperatures. Index of refraction, n_D, is 1.49 to 1.51. Light transmission is over 91 per cent. Specifications: ASTM D819. Trade names: *Allymer, MR Resins, Kriston.*

Allymer * CR-39 et al. Pittsburgh Plate Glass Co. **Allyl resins.**

Alsimag.* American Lava Corp. **Steatite, cordierite,** and other ceramic bodies.

Alvar.* Shawinigan Products Corp. **Polyvinyl acetal resin.**

Amber. Yellow or orange fossil resin found on the shore of the Baltic Sea. High insulation resistance makes it an excellent insulator for electrometers.

Amphenol * 912. American Phenolic Corp. **Polystyrene** sheet, rod, and tubes.

Amphenol * 912B. American Phenolic Corp. **Methacrylate** sheet, rod, and tubes.

Aniline-formaldehyde Resins. Derived from aniline and formaldehyde and fabricated by casting and very limited molding under heat and pressure. The resin is but slightly thermoplastic, and parts are usually made by machining sheet or rod stock. Color is reddish brown. Insulation resistance is high and dielectric losses are low over a wide frequency band. Trade names: *Dilectene, Cibanite.*

Armite.* Spaulding Fibre Co. Thin vulcanized fiber (**fish** paper).

Aroclors.* Monsanto Chemical Co. **Chlorinated diphenyl resins** and oils.

Asbestos. A hydrated magnesium silicate mineral in fibrous form. Two distinct groups of minerals are described as asbestos: amphibole, or hornblende asbestos, in various subgroups, most of which contain iron and have harsh and springy fibers, relatively weak and non-flexible; and serpentine asbestos, the principal subgroup consisting of chrysotile, so-called Canadian asbestos, which has soft, fine, strong fibers, suitable for manufacture of asbestos textiles. Chrysotile asbestos is stable up to temperatures of 400 to 500 deg cent and may be useful at still higher temperatures. It is not a particularly good electrical insulator and has very high losses when moist but is valued chiefly for its fire resistance and its heat resistance. Asbestos products should not be allowed to come into contact with fine wires since corrosion may result.

* Trademark names.

Asbestos Paper. Made by felting asbestos fibers, often with some rag fibers for additional strength. It is employed normally only as a flame barrier or for heat insulation and should not be depended upon for electrical insulation.

Asbestos Textiles. May contain up to 6 per cent total iron content and as much as 2 per cent iron in a magnetic form. A higher grade known as "non-ferrous," containing less than 1.75 per cent total iron and less than 0.75 per cent magnetic iron, is available. Non-impregnated asbestos products are extremely hygroscopic. In order to avoid absorption of moisture, the products often are treated with varnishes or oils, but impregnation reduces the maximum operating temperature sharply.

Asbestos Wood. Asbestos combined with Portland cement to form dense sheets (*Transite*). Also combined with magnesia and cement in an insulating board impregnated with a black insulating compound (ebony asbestos wood).

Asbestos Ebony.* Johns-Manville Co. Asbestos fiber and binding cement impregnated with compound.

Asphalts, Natural. Native asphalts are roughly divided into relatively pure deposits containing less than 10 per cent mineral matter and those containing a large amount of mineral matter. Both types of deposit contain water, but in the latter group the water is often in emulsified form. The water content may be as high as 40 per cent. It is very difficult to separate any but the largest particles of mineral matter by heating. Asphalt is used for potting and impregnating compounds, in the manufacture of varnishes and japans, and for the insulating covering of cables. It is closely related to petroleum asphalt and asphaltites, which are used for the same purposes. Refined Trinidad asphalt melts at 87 deg cent and contains about 38 per cent mineral matter. Bermudez asphalt melts from 57 to 87 deg cent and contains about 4 per cent mineral matter.

Asphalts, Petroleum. A "rubberlike" asphalt of almost any desired melting point up to 150 deg cent. The residue from the distillation of asphaltic or mixed-base petroleums. Sometimes called residual pitches or asphalts. Have greater purity and uniformity than natural asphalts. Used for potting, impregnating, etc. Some residual asphalts weather very badly when exposed to sunlight. Petroleum asphalt may be "blown" with air and steam to oxidize the asphalt partially and to increase the melting point. They also may be modified by adding rosin derivatives to increase the fluidity at high temperatures without drop in melting point.

Asphalts, Sulfurized. Sulfur has a hardening action on asphalt, similar to vulcanization of rubber in some respects. Used in corona-resisting wire insulation.

Asphaltites. Asphaltlike substances but much harder; have melting points above 120 deg cent. Not as soluble in petroleum hydrocarbons. The most important varieties are: **gilsonite,** m.p. 130 deg cent; glance **pitch** or manjak, m.p. 160 deg. cent; and grahamite, m.p. 175 deg cent Another group of asphaltites containing so-called pyrobitumens are practically infusible. Elaterite, wurtzilite, albertite, and impsonite are members of this group and are almost insoluble in the usual solvents. The first group is used in the manufacture of varnishes and japans.

Bakelite.* Bakelite Corp. **Phenolic, cellulose acetate, polystyrene, urea,** and other resins, plastics, and molding powders.

Balata. A rubberlike natural material similar to gutta-percha and used for similar purposes. M.p. 150 dec cent. Dielectric constant 2.6 to 3.5, depending on purity. May be deresinified to improve properties for use in submarine cables. See Kemp, *J. Franklin Inst.*, Vol. 211, No. 1, p. 37.

Beeswax. A white to yellow insect wax. Plastic at 30 deg cent. Melts from 62 to 64 deg cent. A good electrical insulator. Has a large negative coefficient of volume resistivity; is bleached by sunlight and turns brown with age.

Beetle.* American Cyanamid Co. **Urea formaldehyde molding powders.**

Buna N. Synthetic rubber made from butadiene and acrylonitrile by emulsion polymerization. Heat-, oil-, and solvent-resistant, but electrical properties are not good. Trade names: *Hycar OR*, *Perbunan*, *Chemigum*.

Buna S. Common type of synthetic rubber made from butadiene and styrene by emulsion polymerization. Rubber made in government plants is known as GR-S. Insulation fully equal to that of natural rubber in electrical properties can be made from Buna S although the mechanical properties are not quite so good. Its general behavior is quite similar to that of natural rubber.

Butacite.* E. I. du Pont de Nemours & Co. **Polyvinyl butyral plastics.**

Butvar.* Shawinigan Products Corp. **Polyvinyl butyral plastics.**

Butyl. A synthetic rubber made from isobutylene and butadiene by polymerization at low temperatures with a catalyst. It has excellent electrical properties, good resistance to heat, ozone, and corona, and low permeability to gases but is inferior to natural rubber in strength. When made in government plants it was known as GR-I.

Casein. Prepared from skim milk by rennet treatment and hardened by soaking in formaldehyde. Before hardening it can be extruded and pressed; after hardening it is readily machined. It softens in hot water at 100 deg cent and can be blanked or molded to a limited extent. It is not a particularly good electrical insulator but is occasionally useful for small parts. It is readily colored either before or after fabrication.

Catalin.* Catalin Corp. **Cast phenolic resins.**

Cellophane.* E. I. du Pont de Nemours & Co. Regenerated **cellulose film,** lacquered to reduce moisture transmission.

Celluloid.* Celanese Plastics Corp. **Cellulose nitrate.**

Cellulose Acetate. A thermoplastic prepared by treatment of cotton linters or other cellulose with acetic anhydride and acid and the addition of suitable plasticizers. Variation of processing and plasticizer gives a wide range of molding flows and of the heat resistance, flow mobility, and other properties of the product. Available in all colors and in the forms of film, sheet, rod, and molding powders for

---

* Trademark names.

compression and injection molding or for extrusion. Films and sheet of electrical grade are non-corrosive to fine copper wires even under conditions favorable to electrolysis and are superior for coil construction. Some molded materials contain volatile plasticizers and shrink in time or with heating. The heat distortion point of many grades is also quite low. Cellulose acetate is not attacked by oils but is dissolved by ketones, esters, and other solvents. Specifications for sheets: ASTM D786; for molding powders, ASTM D706. Trade names: *Fibestos, Lumarith, Plastacele, Tenite I.*

Cellulose Acetate-butyrate. Similar to cellulose acetate except that it is a mixed ester of cellulose. Less plasticizer is required to obtain molding flow, and heat resistance is improved slightly. It is widely used in tape form for wire insulation and as a molding powder. Specifications for molding powders: ASTM D707. Trade name: *Tenite II.*

Cellulose Nitrate. Also known as pyroxylin and *Celluloid.* It is made by nitrating cotton linters or wood pulp and adding suitable plasticizers such as camphor. Basically highly inflammable, but appropriate plasticizers reduce the inflammability. Very tough and is water- and chemical-resistant. Marketed as sheets, rods, tubes, and molding compositions. Specifications for sheet, rod, and tube: ASTM D701. Trade names: *Celluloid, Pyralin, Nitron, Nixonoid.*

Cellulose Propionate. A new plastic similar to cellulose acetate but with improved impact strength and excellent dimensional stability. Good electrical properties and low water absorption. Trade name: *Forticel.*

Celeron.* Continental-Diamond Fibre Co. Macerated-fabric-base **phenolic moldings.**

Ceramics. Electrical ceramics include materials sintered, fused, or fired at high temperatures, such as **porcelain, steatite, cordierite, glass, glass-bonded mica,** titanium and zircon ceramics, q.v. Ceramics are characterized by heat resistance, permanency of dimension, low water absorption, low thermal expansion, and excellent electrical properties. Care is required in mounting ceramic parts since the modulus of elasticity is high and a slight bending develops high stresses. With the exception of glass-bonded mica, ceramics are not machinable by normal methods and are normally cast, molded, pressed, or extruded and machined in the unfired state and then fired at a high temperature. Since firing shrinkage is around 12 per cent, tolerances are not close, usually of the order of 1 per cent of the dimension. A limited amount of grinding can be done after firing.

Ceresin. A white or yellow wax, with exceptional dielectric properties. Used extensively alone and mixed with other waxes. M.p. 65 to 67 deg cent. Soluble in oils and petroleum distillates. Very water-resistant and has high surface resistivity.

Cerex.* Monsanto Chemicals Co. **Polystyrene copolymer.**

Chatterton's Compound. Fusible composition of gutta-percha, rosin, and tar used in submarine cable construction for sealing cable ends, etc.

Copaline.* American Phenolic Corp. Solid-dielectric r-f cables.

Cordierite Ceramics. Consist principally of the crystal cordierite, a magnesium aluminum silicate, and are characterized by a very low coefficient of thermal expansion and a power factor much higher than that of steatites. Trade name: *Alsimag 72* and *202.*

Co-ro-lite.* Colombian Rope Co. Sisal-fiber-reinforced **phenolic materials.**

Corprene.* Armstrong Cork Products Co. Cork-loaded **neoprene** sheet in various grades.

Dilectene.* Continental-Diamond Fibre Co. **Aniline formaldehyde** sheets and rods.

Dilecto.* Continental-Diamond Fibre Co. **Laminated phenolic** sheet, rod, and tubes.

Dri-film.* General Electric Co. Silicone treatment for **ceramics.**

Durez.* Durez Plastics and Chemicals, Inc. **Phenolic resins** and **molding powders.**

Durite.* Durite Plastics, Inc. **Phenolic** and **furfural resins.**

Ebonite. Another name for **hard rubber.**

Empire.* Mica Insulator Co. **Varnished cloth,** sheet, and tape. Silk, rayon, *Fiberglas,* 2 to 40 mils thick.

Enamel. General term for a substance producing a colored glossy coating. Organic enamels are made by pigmenting or coloring lacquers or varnishes, and inorganic enamels by pigmenting low-melting glasses. (See discussions below.)

Enamel, Varnish. Pigmented varnishes or varnishes colored by asphalts or colored resins. Varnish enamels may either dry in air in 4 to 16 hr, depending on the type, or be compounded to dry by baking from 2 to 8 hr at 100 to 150 deg cent. The baking types usually have better adhesion and hardness and higher dielectric properties. The japans are varnish enamels made with asphalts for baking.

Enamel, Vitreous. A silicate or borosilicate glass with the melting point lowered by the addition of various fluxes, such as metallic oxides and salts. Some metallic oxides are used for coloring the enamel and others to increase the opacity. The enamel is usually applied in two or more coats when freedom from pinholes is desired. The same composition may be used for all coats in some cases, although specially formulated ground coats are usually superior. The enamel coats are applied by dipping or spraying, using a suspension of the finely ground enamel, known as frits, in a clay-and-water medium. For flat work the powdered frits are sometimes sieved onto the work in the so-called dry process. The coats are "fired" at temperatures up to 850 deg cent for periods of 3 to 30 min. The temperature and time are critical for a given composition of enamel and for the size of the enameled object. Some enamels have very satisfactory dielectric properties and may even be used for the dielectric of small adjustable capacitors, but the major electrical use is the manufacture of vitreous enamel resistors. For this use the formula is carefully adjusted to obtain a coefficient of thermal expansion suitable for the wire and coil forms, to prevent fracture of the wire with cycles of heating and cooling.

Enamel Wire. Enamel for insulating wire is usually a varnish enamel. A hard, tough, and flexible covering is produced with a high dielectric strength. The enamel thickness varies from 0.0001 to 0.0015 in., depending on the wire size. Enamel is suitable for continuous operation at 105 deg cent. Wire enamels vary slightly in resistances to oils and solvents. The better grades are suitable for con-

* Trademark names.

tinuous use in mineral oil up to 80 deg cent; 48 hr at 105 deg cent should have no visible effect. Most varnish and lacquer solvents will attack wire enamel to some degree if the contact is prolonged. It is important, therefore, to expel the solvents from varnish impregnation or cementing processes with reasonable promptness. It is necessary in most cementing processes for the solvents to attack the enamel slightly in order to secure a good bond. Wax impregnation has practically no effect on the enamel, but impregnation with asphaltic compositions may cause a severe attack on the enamel. The enamel is moderately resistant to abrasion and pressure, and wire may be random wound for some uses where a few shorted turns are allowable. It is also used successfully on core plates where it is subjected to considerable pressure and is occasionally filled with mica dust to improve the resistance to pressure.

Ethocel.* Dow Chemical Co. Ethyl cellulose molding powder.

Ethofoil.* Dow Chemical Co. Ethyl cellulose film.

Ethyl Cellulose. Prepared by replacing the hydrogen of cellulose hydroxyl groups with the ethyl group by means of ethyl chloride or ethyl sulfate. It is thermoplastic and is tough and flexible through wide ranges of temperature. It is very stable to heat and light and has excellent electrical properties. It is available in "hot-melt" compounds, in casting compositions (*Thermocast**), in films, as non-rigid sheets and extrusions, and as molding compositions. The electrical properties are well retained under moist conditions and actually may improve with increasing temperatures, contrary to the general rule. Specifications for non-rigid: ASTM D743; for molding: ASTM D787. Trade names: *Ethocel, Lumarith EC, Chemaco, Hercules EC.*

Fiber, Vulcanized. Manufactured by treating rag paper with zinc chloride, pressing into sheets, and thorough washing. Fiber will absorb water up to about 60 per cent if immersed for a sufficient length of time and will increase to nearly double the thickness. Solvents and oils have practically no effect on fiber. Fiber has a natural moisture content of 5 to 6 per cent at 40 to 60 per cent relative humidity, which will decrease at low humidities and increase at high humidities. Heating at 80 to 100 deg cent for long periods will dry out and warp the fiber and impair the flexibility and toughness. From 100 to 170 deg cent the drying is very rapid, and the fiber will become brittle in a few hours. Above 170 deg cent the material will char on long heating. It chars in a short time at 200 deg cent. The maximum safe operating limit is about 150 deg cent. Fiber is made in gray, black, red, and white, but there is little difference in the properties due to the colors of the same grade of stock. Grade differences are due to selection of rags, increased pressure in order to increase density and hardness, and more careful processing. The highest grade is the electrical grade made in thin sheets for use in slot insulation, etc., and commonly known as "fish paper." This grade has exceptionally high dielectric and mechanical strength and a density of about 1.3. Hard fiber (bone fiber, horn fiber) has a density of about 1.3, and is considerably harder than the commercial grade. The commercial grade has slightly lower mechanical strength but about the same dielectric strength and shows considerably higher water absorption on 1-hr immersion. A grade especially made for forming and swaging contains glycerin to soften the material by retaining moisture. It can be swaged, spun, and formed readily for bushings, grommets, etc. All grades are readily machinable and can be punched and also formed dry to a limited extent. For more severe operations, the sheets can be soaked in water and formed in heated dies. The fiber bends best parallel to the grain.

Fiberglas.* Owens-Corning Fiberglas Corp. Glass yarn and textiles.

Fibestos.* Monsanto Chemical Co. Cellulose acetate.

Fibron.* Irvington Varnish and Insulator Co. Flexible plastic products. Polyethylene tape and tubing.

Fish Paper. Common name for superior grade of thin vulcanized fiber, also known as tarpon paper, leather paper, leatheroid, and fiberoid. It is usually supplied in a dark gray color.

Flamenol.* General Electric Co. Polyvinyl chloride wire insulation.

Formex.* General Electric Co. Polyvinyl formal magnet wire insulation.

Formica.* Formica Insulation Co. Phenolic laminates.

Formvar.* Shawinigan Products Corp. Polyvinyl formal.

Forticel.* Celanese Plastics Corp. Cellulose propionate plastic.

Fortisan.* Celanese Corp. of America. High-strength regenerated cellulose yarns.

Fullerboard. Another name for pressboard.

Furfural Resins. Phenol and furfural react to form resins similar to phenol-formaldehyde resins but generally dark in color. They are used for transfer molding and cold molding. They withstand high temperatures and have comparatively good arc resistance. Trade name: *Durite.*

Gelva.* Shawinigan Products Corp. Polyvinyl acetate.

Geon.* B. F. Goodrich Chemical Co. Polyvinyl chloride and vinyl vinylidene chloride.

Gilsonite. Variety of natural asphalt. M.p. 122 to 188 deg cent.

Glass. Physically, glass is an amorphous, undercooled liquid composed of silica and metallic silicates and hence has no crystal structure or sharp melting point. The plastic nature of glass at elevated temperatures permits fabrication by drawing, blowing, and pressing, as well as by casting. Only simple shapes can be molded. All glass must be carefully annealed to prevent residual stresses which reduce the strength, or surface-chilled in a controlled manner, as in so-called tempered glass, so that the residual stresses will increase the strength. Since glass has a high elastic modulus and no internal structure to interrupt stress patterns, it is extremely sensitive to stress concentrations. Glass parts must be carefully designed, and surface damage must be avoided. Exclusive of glasses designed for sealing purposes, lime glass, lead glass, borosilicate glass (*Pyrex* types), and high-silica glass (Vycor) are the principal electrical glasses. The borosilicate and high-silica types have lower coefficients of thermal expansion, giving improved resistance to thermal shock. Electrical glasses have high dielectric strength and volume resistivity and low power factor. These properties depreciate with rising temperature, and at temperatures from 150 to 200 deg cent a rapid rise in power factor and decrease in dielectric strength

* Trademark names.

begin. The high-silica glasses are superior in this respect. The surface of glass is readily wetted by water so that the surface resistivity is seriously reduced by relative humidities above 70 per cent. This is perhaps the most serious defect of glass as an electrical insulator, but recent work has indicated that leakage may be considerably reduced by treatment with silicones, q.v. The *Multiform* process, in which glass is powdered, pressed to shape, and fired like porcelain, makes possible the production of complicated parts to tolerances of 1 to 2 per cent and permits the use of high-silica glasses with very low losses and low thermal expansion. Recently developed techniques permit the firing of metallic coatings on glass, which may be used as circuit conductors, for soldered connections, or hermetic sealing by soldering. By alteration of the composition of glass, the thermal expansion may be matched to certain metals so that dependable seals resistant to thermal shock can be produced. Lead-through seals are available in single or multiple form, which may be soldered in a metal container to give a hermetic seal.

Glass Textiles. Glass drawn into thin filaments (2 to 3 $\times$ 10^{-4} in. diameter) has an enormous tensile strength (4 to 5 $\times$ 10^5 lb per sq in.), owing to an absence of shearing stresses. Glass textiles (*Fiberglas* *) are made from glass yarn of two basic types: continuous-filament yarns made by hot drawing of filaments from glass "marbles" in a special machine, and staple yarns made from staple fiber produced by steam drawing of molten glass into fibers varying from 4 to 18 in. in length. The individual fibers are lubricated and combined into yarns of various constructions. Glass textiles are available as tapes, cloth, sleeving, cords, and yarns for serving or braiding. Outstanding uses for glass textiles have been: (1) high-strength plastic laminates; (2) fireproof braiding for insulated wire; (3) varnished glass cloth; (4) serving for magnet wire. Advantages of glass textiles in these and other services are greater resistance to heat, longer life, non-inflammability, increased moisture resistance, and high mechanical strength.

Glass-bonded Mica. Ground mica bonded with a low-melting glass, chiefly lead borate, and sometimes with the addition of cryolite (sodium aluminum fluoride). The material is hot-pressed at 600 to 700 deg cent to the required form. Certain types can be injection-molded. Metal inserts can be molded in place, in some cases for hermetic sealing purposes. It is also possible to cast aluminum around the material or to use it as an insert in plastic molded parts. It can be readily machined with carbide tools, or with ordinary tools for small quantities, to close tolerances. Glass-bonded mica has excellent electrical properties, good mechanical properties, low coefficient of expansion, and stability in dimensions up to 300 deg cent. Electrical properties do not deteriorate rapidly with rising temperature or under moist conditions, except that the surface resistivity of grades containing fluorides may be very low at high humidities. Under condensation conditions, the fluoride constituents are dissolved and may corrode metal parts. Polishing and waxing the surfaces will eliminate this condition but will reduce the arc resistance. Special varieties of glass-bonded mica (*Mycalex K* *) are available with controlled dielectric constants between 8 and 20. Specifications: Army-Navy Specification JAN-I-10, Grade L-3 or L-4. Trade names: *Mycalex*, *G. E. Mycalex*, *Mycroy*, *Turx*.

Glyptal.* General Electric Co. Alkyd resins and products such as varnishes, cements, varnished cloth, etc., made therefrom.

Gummon.* Garfield Mfg. Co. Asbestos coal-tar moldings.

Gutta-percha. A grayish-white to brown plastic substance but not elastic like rubber. Can be molded under pressure at 60 to 100 deg cent and melts from 120 to 140 deg cent. It vaporizes above 190 deg cent. Partly soluble in ether, carbon tetrachloride, benzol, chloroform, and carbon bisulfide; insoluble in water. Can be vulcanized with sulfur or sulfur chloride like rubber, forming a hard substance, but it is nearly always used unvulcanized. It is rather easily oxidized in the air and becomes brittle and yellowish gray. It is principally used for the insulation of submarine cables and is generally applied uncompounded by a tubing machine or in strips like rubber. The power factor of gutta-percha is maximum at room temperatures, so that the dielectric loss in actual service at sea-bottom temperatures is quite low. If the insulation is prepared with about 1.5 per cent moisture content, which is close to the saturation value in sea water, the constants do not change much in service. The life is very satisfactory under water but is not very satisfactory in air.

Halowax.* Bakelite Corp. Chlorinated naphthalene liquids and waxes for impregnating.

Hard Rubber. See **Rubber, hard.**

Hemit.* Garfield Mfg. Co. Cold-molded refractory materials.

Herculite.* Pittsburgh Plate Glass Co. Tempered glass products.

Hycar.* Hycar Chemical Co. Synthetic rubber in various grades, distinguished by suffix letters and numbers.

Insurok.* Richardson Co. Phenolic and urea laminates.

Isolantite.* Isolantite, Inc. Steatite ceramics.

Jute. A long bast fiber employed in cordage and rough textiles. Considerably used as a filler and core in cords and cables. Commercial jute often is softened and rendered less brittle by impregnation with mineral oil. Jute loses its strength when damp.

Kaolin. Also called china clay. An aluminum silicate clay free from iron, used in the manufacture of white porcelain. Valuable as a packing material around heating coils, etc.

Kriston.* B. F. Goodrich Chemical Co. Allyl monomer.

Lamicoid.* Mica Insulator Co. Phenolic laminates.

Laminates. Layers of paper, cloth, or glass cloth impregnated with resin and pressed under heat and high pressures. Resins are usually thermosetting, but thermoplastic resins have been used. Low-pressure laminates use resins which give off little or no gas or vapor during curing, and pressure just sufficient to hold the mass in contact is required. Very large, shaped parts can be produced by employing inflated or evacuated rubber bags to supply the low pressures needed. Knitted cloths are often used to allow stretching where required. Contact laminates can be made with still lower pressures (as

* Trademark names.

low as 1 lb per sq in.). Trade names of materials employed for contact laminating are: *Laminac,** American Cyanamid Co.; *Thalids,** Monsanto Chemical Co.; *Bakelite Copolymer Resins,** Bakelite Corp.; *Selectron,** Pittsburgh Plate Glass Co.; *Vibrins,** Naugatuck Chemical Co. The electrical properties of many of these low-pressure laminates are excellent. They were employed for such applications as radomes during the war. Properties of sample laminates: dielectric constant 3.54 to 4.59 at 1 Mc; power factor 0.0075 to 0.0105 at 1 Mc.

Latex. An emulsion of rubber, synthetic rubber, or synthetic resin in water, depositing a solid film on evaporation.

Lava.* American Lava Corp. Mineral talc machined to shape and fired at high temperatures.

Lavite.* D. M. Stewart Mfg. Co. **Steatite ceramic.**

Lenoxite.* Lenoxite Div., Lenox, Inc. **Steatite ceramic.**

Lignin. Lignin is the binding material in wood. Two types of plastic are made from lignin. In one type the whole wood is used; steamed chips are exploded by sudden pressure release and are pressed into boards under high pressure (*Masonite,** *Benalite,** Masonite Corp.). In the other type the separated lignin, usually a byproduct of paper manufacture, is combined with other materials, such as amines, furfural, or phenol, to form a thermosetting resin which may be combined with various fillers, or is used to impregnate paper which is hot-pressed into laminated boards (*Lignolite**). Lignin also is used as an extender for phenol-formaldehyde molding compounds.

Lignolite.* Marathon Chemical Co. **Lignin** plastic sheets.

Loalin.* Catalin Corp. **Polystyrene.**

Lucite.* E. I. du Pont de Nemours & Co. **Methyl methacrylate** sheet and molding powders, also in heat-resistant grades.

Lumarith.* Celanese Celluloid Corp. **Cellulose acetate** and **ethyl cellulose** products.

Lustron.* Monsanto Chemical Co. **Polystyrene** molding powders.

Magnesium Oxide. Compressed magnesium oxide is used in the insulation of heating units and, in Europe, for heat-resistant coaxial conductors (*Pyrotenax**). Single or multiple conductor cables are made by packing magnesium oxide preforms and the conductors inside a copper tube and drawing the assembly to a smaller size. As a r-f coaxial line the losses are higher than those of polyethylene insulation, and the ends must be well sealed against moisture. It is electrically smooth compared to an insulator-spaced air line.

Makalot.* Plastics Div., Interlake Chemical Co. **Phenolic resins** and compounds.

Masonite* Die Stock. Masonite Corp. Exploded wood fiber, densified under high pressure.

Melamine-formaldehyde. Thermosetting resins prepared by reaction of formaldehyde, melamine, and sometimes dicyandiamide; the latter two are derived from calcium cyanamid. These resins are heat- and arc-resistant and have excellent electrical properties and low water absorption. Alpha cellulose, chopped rag, and mineral fillers are used in various compounds. Specifications: ASTM D704. Resin trade names: *Melmac, Resimene, Plaskon Melamine.*

Melamine Glass Laminates. These laminates are characterized by high arc resistance and great mechanical strength. They are also heat-resistant and burn with some difficulty. The fumes from the burning laminate are said to be less toxic than those from phenolics; hence these laminates were used for combat-vessel equipment. The high-frequency properties are not outstanding and are not controlled in production. Specifications: Joint Army-Navy Spec. JAN-P-13 Type GMG.

Melmac. American Cyanamid Co. **Melamine-formaldehyde resins** and molding powders.

Methacrylates. These resins are members of the acrylic or acrylate resin group. The most important member is methyl methacrylate. This plastic is produced by the reaction of acetone and hydrogen cyanide to form acetone cyanhydrin, which is allowed to react further with methyl alcohol to produce methyl methacrylate monomer [$CH_2 : C(CH_3)COOCH_3$]. This monomer is polymerized by the aid of peroxide catalysts and heat. The polymers are characterized by great optical clarity, light transmission of 92 per cent, high refractive index of 1.48 to 1.51, stability to light and weather, and good mechanical and electrical properties. Arc resistance is high; vapor from the plastic actually tends to quench arcs. Power factor and dielectric constant decrease with increasing temperature and frequency instead of exhibiting the normal increase. Methyl methacrylate in common with other thermoplastics has a low heat distortion point. Heat-resistant grades are available that will withstand boiling in water. Specifications for sheet, rods, and tubes: ASTM D702; for molding compounds: ASTM D788. Trade names: *Plexiglas, Lucite.*

Mica. A group of natural complex aluminum silicates with highly developed basal cleavage into thin, tough, flexible laminae. It is probable that if sufficient care were taken it could be split into thickness approaching molecular dimensions. Owing to the fact that blocks are very expensive, mica is usually split and punched into parts for capacitors and spacers. For other uses the flakes are cemented together with adhesives to make "built-up" or "pasted" mica, which forms flexible or rigid sheets, depending on the binder. Flake or dust mica is combined with resins or glasses to form simple molded shapes as well as rods and sheets. There are several varieties of mica, including:

Biotite—iron mica, black mica	Muscovite—potassium mica, common mica
Paragonite—sodium mica	Phlogopite—magnesium mica, rhombic mica
Lepidolite—lithium mica	
Lepidomelane—iron mica	

but only the last two are used for electrical work. Muscovite comes in three colors: white and ruby, both of which are superior grades, and green, which is inferior electrically and mechanically to clear grades of white and ruby. Muscovite mica is in general superior electrically and mechanically to phlogopite, but phlogopite has superior heat resistance. Phlogopite ranges from a deep amber color to dark amber and milky white. It is not so readily split as muscovite; it is softer, and is lower in mechani-

* Trademark names.

cal strength. Phlogopite mica does not lose water up to temperatures of 800 to 900 deg cent, and some grades will resist 1200 deg cent without complete disintegration. For this reason it is valuable for spacing the elements in vacuum tubes and in heating devices. The maximum operating temperature is best limited to 1000 deg cent, and that of muscovite to 500 deg cent. The power factor and resistivity of phlogopite are much worse than those of muscovite, although the dielectric strength is nearly the same. Stained muscovite and all phlogopite are unsuitable for use in capacitors where low power factor is required. Mica, in general, does not decrease in dielectric strength with frequency as fast as most dielectrics. This fact, together with its low power loss, enables carefully designed and built mica capacitors to operate at extremely high frequencies. The defects occurring in mica are air bubbles, stains, and spots. Mica is graded according to freedom from defects as follows: highest-grade mica is clear and free from all defects; second highest grade has air bubbles between laminae; stained mica sometimes has some iron stains present; spotted mica is badly stained and usually has inclusions of other minerals. Mica splittings are graded for size according to the largest usable rectangular area. For grading methods, see ASTM D351. The dielectric strength of mica is considerably reduced by air or moisture between the laminae, but the flexibility is somewhat increased. Specifications for block mica and films: ASTM D748; for electrical tests: ASTM D351.

Mica, Reconstructed or Pasted. Flake mica is bound and pressed together with shellac, gum, asphalt, or synthetic resin varnishes and milled to thickness to form sheets which may be punched and sheared. Some grades are flexible and may be formed to a limited extent cold. Others use a thermoplastic binder and can be formed to quite intricate shapes at 100 deg cent. Hard grades contain as little as 3 per cent binder and do not compress appreciably. See also **Mica cloth** and **Mica paper.** Specifications for materials: NEMA Standards 39-55; for testing methods: ASTM D352.

Mica Cloth. A composite insulation of high dielectric strength used for insulating transformers and field windings.

Mica Paper. Flake mica cemented between sheets of glassine, rice, kraft, or express paper. Mica also is combined with asbestos paper or fibers to form composite insulations.

Mica Plate. Another name for **reconstructed mica** sheets.

Micabond.* Continental-Diamond Fibre Co. **Reconstructed mica** tape, tubes, and sheets.

Micanite.* Mica Insulator Co. **Reconstructed mica** products.

Micarta.* Westinghouse Electric Corp. **Phenolic laminates.**

Minerallac.* Minerallac Electric Co. Fusible **asphalt** compounds.

Molded Compounds. *Hot-molded* products are formed in molds or platens heated to a temperature sufficient to cause the binder to flow, cementing the particles and producing a pure smooth binder surface which lowers water absorption and increases surface resistivity. Compounds in which binder hardens under heat are called thermosetting; those in which binder becomes plastic are called thermoplastic, and molds must be cooled before the article is removed. Some thermosetting binders are synthetic resins of the phenol **formaldehyde, urea formaldehyde,** or **melamine** type. Some thermoplastic binders are **shellac, cellulose nitrate** and acetate, **vinyl resins,** mixtures of **asphalts** and hardened **rosin,** copals, **casein resins,** sulfur chloride phenol resins, cumarin resins, **polystyrene,** and **methacrylate.** Fillers may be either fibrous or powdered, wood flour being the commonest. Cotton, silk flock, or threads are used to improve resistance to impact, and macerated cloth to give high impact resistance, with thermosetting compounds. Asbestos is used for heat-resistant products, mica to obtain low power factor, and ground flint, china clay, silex, stone, etc., to cheapen the article. Compounds can be hot-molded in great varieties of shapes with thin sections, metallic inserts, threads, etc. Tolerances can be held to within plus or minus 0.003 in. per in. when not depending on mold closure. *Cold-molded* products are formed under pressure and subsequently baked for periods of from a few hours to a week at temperatures of 150 to 300 deg cent. There is little flow of the binder, and the surface is not very smooth and depends on the fineness of the filler. Pieces distort slightly in baking, and the accuracy of dimensions is much lower than in the hot-molded process: it amounts to plus or minus 0.009 to 0.015. Binders are thick **varnishes, asphalts,** tung and linseed oils, anthracene oils, and various gums or varnish resins in suitable solvents. Cold-molded compounds are subdivided into refractory and non-refractory, according to the degree of heat resistance. In general, close tolerance, loose mold pieces, and threaded parts increase molding cost. For low cost the parts should be designed with adequate radii, and with no projections, indentations, or holes which require loose pieces in the molds.

Multiform Glass.* Corning Glass Works. Powdered **glass,** pressed and fired.

Muscovite. Variety of mica suitable for electrical insulation. See **Mica.**

Mycalex.* Mycalex Corp. **Glass-bonded mica,** sheet, rod, and molded.

Mycalex,* G. E. General Electric Co. **Glass-bonded mica,** sheet, rod, and molded.

Mycroy.* Electronic Mechanics, Inc. **Glass-bonded mica.**

Neoprene. Produced by emulsion polymerization of chloroprene, which is derived from acetylene. Polychloroprene is the chemical name for neoprene but neoprene generally is used even though it is the trade name for the E. I. du Pont de Nemours & Co. product. Neoprene can be vulcanized like rubber but sulfur is not always required. There are many types of neoprene distinguished by suffix letters; some of the types are copolymers with nitriles. Neoprene made in government plants was called GR-M; freeze-resistant neoprene, FR; general purpose, GN; low oil swelling and low gas diffusion, ILS, etc. All types are outstanding in oil, ozone, and sunlight resistance and will not support combustion. Neoprene may be compounded to give power factors of 1 per cent and resistivities of 10^{12} ohm-cm, but many compounds are poor electrically. Neoprene may also be formulated for high heat resistance or for good abrasion resistance. One application of great value is the jacket of portable cords and cables. Neoprene also may be made with low specific resistivity for use as electrostatic shields or for potential control. It also is an excellent gasket material.

Nitrocellulose. See **Cellulose nitrate.**

---

* Trademark names.

Nitron.* Monsanto Chemical Co. **Cellulose nitrate.**

Nixonite.* Nixon Nitration Works. **Cellulose acetate.**

Nixonoid.* Nixon Nitration Works. **Cellulose nitrate.**

Nylon.* E. I. du Pont de Nemours & Co. **Polyamide** products of all kinds.

Ozokerite. A natural mineral wax, amorphous and black to dark brown. When bleached, it is white to yellow or brown. Melting point is 70 to 80 deg cent. The purified wax is known as **ceresin.**

Panelyte.* St. Regis Paper Co. **Phenolic laminates.**

Paper. Paper for insulating purposes should be as free as possible from all chemicals and from conducting particles and should be strong mechanically. Paper changes its moisture content very rapidly with changes of atmospheric humidity. Single sheets of thin paper will come to equilibrium in as little as 15 minutes, so that all testing, both mechanical and electrical, is done best under conditions of controlled humidity and temperature. The principal types of paper of interest are those following. Rag papers made with a minimum of chemicals and short "cooks" give strong paper with heat resistance somewhat improved over that of chemical wood papers. Manila papers, made from manila fiber or from old rope, etc., sometimes with cotton or linen rags, have been the standard cable papers for some years because of high mechanical and electrical properties. Kraft papers can now be made, however, with equal or superior properties; kraft papers properly made are very strong, have excellent dielectric properties, and are cheaper than rag or manila paper. Glassine or onion-skin paper is a highly beaten sulfite stock with fair mechanical and electrical properties. It does not take impregnation well, however. High-density, well-beaten, heavily calendered stocks in the thicker sizes are much used as insulating strips. See **Pressboard.** Material intermediate between paper and boards in density or thickness is known by various names—express paper (chemical wood fiber), rope paper (from old ropes), etc.

Paragutta. Submarine cable insulation compounded of purified gutta hydrocarbon and deresinified rubber.

Perbunan.* Standard Oil Co. of N. J. Synthetic rubber: a copolymer of butadiene and acrylonitrile.

Petrolatum. Comes in liquid, soft, and hard grades. The soft form is similar to vaseline and is used extensively as a paper-cable-impregnating material. M.p. 50–55 deg cent. The electrical properties vary with purity.

Phenol Fiber. General term for paper-base **phenolic laminates.**

Phenolic Insulating Materials. Obtainable in two principal forms: molded parts; and laminated sheets, rods, or tubes with paper or fabric base. For molding compounds, the resins are combined with the desired fillers, either by working on rolls or by coating the filler particles with a varnish and drying (see discussion of **molded compounds**). For laminated products, sheets of paper or fabric are coated or impregnated with varnish and pressed hydraulically between heated platens. Rods are wound on small mandrels which are removed and the roll is cured in a mold. This leaves a weak center section, and for some purposes rod turned from sheet stock is preferred, although it does not machine as well and splits more readily. For molded tubes the impregnated paper is wound on mandrels and the assembly cured in heated molds. Since the pressure, of course, is not radial unless an expanding mandrel is used, the seams in molded tubes are weak and tend to split apart. To overcome this, a rolled tubing is manufactured which is cured by heated rolls during the winding. Since the pressure is limited in this process, the electrical properties generally are not equal to molded tubing but the mechanical properties are superior. Laminated phenolic insulation is hard, tough, and rigid, but more elastic than equivalent molded compounds. It is infusible and resists temperatures up to 125 deg cent, but becomes slightly more brittle upon cooling after continuous operations above 90 deg cent, and usually shrinks somewhat more than it had expanded. A slight softening is noted while the compound is hot, of which advantage is taken to reduce breakage in punching operations. Stress applied while hot causes a slight permanent set, and a limited forming is thus possible. The dielectric properties are not so good as those of hard rubber, but, mechanically, phenolic insulating compounds are superior and do not corrode metals or deteriorate with age. Specifications for laminates: NEMA Standards, and ASTM D709; for molding compounds ASTM D700.

Phenolic Resins. Phenol and various other phenolic substances, such as cresol, will condense and polymerize with aldehydes under the influence of heat and a suitable catalyst. Formaldehyde and hexamethylene tetramine are the commonest substances employed to react with phenols or cresols. The reaction is catalyzed by ammonia, alkalies, acids, and other agents. The reaction proceeds in two or more stages. In the first stage the resin is fusible and soluble in acetone and other solvents. Upon further heating the resin becomes infusible and practically insoluble. This second stage is the base of thermosetting molding compounds and of some phenolic laminating or baking varnishes.

Phenolite.* National Vulcanized Fibre Co. **Phenolic laminates.**

Phlogopite. Variety of **mica,** q.v.

Piccolastic.* Pennsylvania Industrial Chemical Corp. Substituted **styrene** polymers.

Plaskon.* Plaskon Div., Libby-Owens-Ford Glass Co. **Urea** or **melamine** molding compounds.

Plastacele.* E. I. du Pont de Nemours & Co. **Cellulose acetate** products.

Plax.* Plax Corp. **Polystyrene.**

Plexiglas.* Rohm and Haas Co. Methyl **methacrylate** products.

Pliolite.* Goodyear Tire and Rubber Co. **Cyclicized rubber** thermoplastic **resin.**

Polectron.* General Aniline & Film Corp. **Polyvinyl carbazole** resin.

Polyamides. Thermoplastic resins formed from dibasic acids and diamines. *Nylon,* the most important, is formed from adipic acid and hexamethylene diamine. It is characterized by extraordinary strength and toughness, and by a high degree of resistance to solvents and chemicals. The electrical characteristics of nylon are good but not so outstanding as its mechanical properties. It has been used

* Trademark names.

successfully for thin-wall coil forms and for thin-wall jacketing of assault wire. Its strength and fungus-resisting properties have led to its use for many military applications in connection with parachutes, aircraft, guy, mooring, and tow ropes, cords, etc. It is available as yarn, monofilament, and molding compound. Yarn and monofilament are cold-drawn or orientated to effect a very considerable increase in tensile strength. Specifications: ASTM D789.

Polydichlorostyrene. Thermoplastic prepared by polymerization of dichlorostyrene. It is similar in most respects to polystyrene except that a considerable increase in heat distortion temperature has been made with only a slight sacrifice in electrical properties. Trade name: *Styramic H.T.*

Polyethylene. Prepared by the polymerization of ethylene, polyethylene is outstanding for low electrical losses at high frequencies and has found extensive application as a dielectric in r-f coaxial cables. In thin sections it is flexible, but thick sections are rigid and can be machined. It is thermoplastic and is fabricated by injection or extrusion. It is available in the forms of molding compound, tape, tubing, monofilament, and rods or slabs. English practice includes plasticizing with polyisobutylene, which lowers the cold-brittleness point. Polyethylene is insoluble in common solvents when cold but dissolves in hot hydrocarbons. Coatings of polyethylene may be applied by flame-spraying or by the use of emulsions. Coatings have a low moisture permeability. Trade name: *Polythene.*

Polyflex.* Plax Corp. Flexible polystyrene sheet.

Polystyrene. Thermoplastic resin produced by polymerization of monomeric styrene with heat and sometimes a catalyst such as a peroxide. Polystyrene is outstanding for low dielectric loss at high frequencies. It has high dielectric strength and good arc resistance. It has zero water absorption and good mechanical strength, and it does not become more brittle at low temperatures. It has exceptional optical clarity and high refractive index. Unfortunately, it cannot be used at temperatures much above 65 deg cent without cold flow occurring, and some tendency for surface crazing exists. Crazing may be minimized by suitable heat treatment to remove surface strains. Attempts to increase the operating temperature by the use of fillers have not been too successful, for they increase the tendency to crack. The usual method of fabrication is injection molding, although many parts are machined from sheet, rod, or tube stock. Polystyrene may be drawn or oriented to form a flexible sheet (*Polyflex* *) or plasticized to make films for use in capacitors, etc. Specifications: ASTM D703. Trade names: *Loalin, Lustron, Plax, Polyflex, Styron.*

Polystyrene, Modified. Polystyrene has been combined with chlorinated diphenyl to form a noninflammable plastic with a heat distortion point somewhat higher than that of polystyrene. It is also easier to machine, but the electrical losses are slightly higher. Trade name: *Styramic.* Other modifications are possible, such as copolymerizing styrene with other materials such as butadiene. With about 25 per cent styrene **Buna** S rubber is formed, but if the styrene is considerably in excess a semi-flexible thermoplastic (*Styraloy* *) is produced. This material has good dielectric properties and is very tough. It is suitable for wire and cable insulating. *Cerex* * is another recently introduced styrene copolymer with improved heat resistance, high strength and hardness, and unusual chemical resistance, but somewhat higher losses than polystyrene.

Polytetrafluoroethylene. Manufactured by polymerizing gaseous tetrafluoroethylene; a plastic with remarkable heat, chemical, and solvent resistance. Polytetrafluoroethylene is very tough over a wide temperature range and has a loss factor less than that of polystyrene; its dielectric constant of 2.0 is the lowest of any solid insulating material. It is very expensive as of 1949, and extrusion or molding is slow. Some machining is necessary on most parts since molding is very difficult. Trade name: *Teflon.*

Polythene.* E. I. du Pont de Nemours & Co. **Polyethylene.**

Polyvinyl. See **Vinyl.**

Porcelain. A ceramic body usually composed of clay, feldspar, and flint, finely ground, mixed with water, formed to desired shape, dried, and fired at temperatures usually ranging from 1300 to 1800 deg cent. When desired, glaze is applied on all surfaces, except the base on which the part rests in the kiln during firing, by painting on a composition which fuses to a translucent or transparent glass. Mixtures of china clay or **kaolin,** which are slightly plastic, and ball clay, which is very plastic, are used to give the necessary working properties to the wet dough. Feldspar is a naturally occurring potassium aluminum silicate. Flint is added in the form of ground sand or quartz. Normal porcelains contain from 20 to 60 per cent of clay, from 15 to 50 per cent of feldspar, and from 0 to 65 per cent of flint. Magnesia sometimes is added up to 50 per cent to improve the strength at high temperatures. Special porcelains vary widely in composition. Some are made from natural aluminum silicates such as andalusite with enough clay to give a bond. Magnesium silicate ceramics made with bases of talc, **steatite,** etc., give modified porcelains with superior electrical and mechanical properties. The raw "body" or dough is formed into shape by two distinct processes. In the dry process the mass is compressed in steel dies. Parts must have "draft" and taper similar to die castings, and a tolerance of plus or minus 1/64 in. per in. is necessary to allow for shrinkage variation in firing and wear of molds by abrasion. Minimum commercial tolerance on thickness is plus or minus 0.010 in. Dry-process porcelain is used for insulation under 5000 volts only, since it is porous and weaker mechanically and electrically than wet-process porcelain. The porosity is from 3 to 5 times as high as that of wet-process parts. Wet-process porcelain is made by forming the dough to the approximate shape, drying, and machining on vertical or horizontal lathes to final shape. It also is sometimes cast in a fluid state in absorbent molds which remove enough water to enable the part to be removed after some time and dried. Cast porcelain compares favorably with formed wet-process porcelain. Wet-process porcelain has a very low porosity and high dielectric strength. A tolerance of about 1/32 in. per in., plus or minus, is necessary for commercial manufacture. All porcelain is relatively weak in tensile, flexural, and impact strength. It has poor resistance to thermal shock except in special grades. The mechanical strength depends upon the flint content, the heat resistance upon the clay, and the dielectric strength

* Trademark names.

upon the feldspar, which unfortunately tends to make the parts brittle. Porcelain is comparatively inexpensive and chemically inert. Dry-process parts are considerably cheaper than wet-process parts. Glazing improves the resistance to weathering, but it must have a coefficient of expansion similar to that of the body, for a cracked or "crazed" glaze reduces the strength. The insulation resistance of normal porcelains drops rapidly above 300 deg cent; to minimize this effect, alkali metals are reduced in amount as much as possible. For high-temperature work free quartz in the fired body is undesirable since it has irregularities in its thermal expansion curve which tend to cause cracking, and so it is eliminated as far as possible. The desirable structure is usually crystals of aluminum silicates (known as mullite and sillimanite) evenly embedded throughout a glassy matrix. Pores are, of course, highly undesirable. Fired porcelain parts can be ground to meet close tolerances, and two or more subparts can be fastened together with neat Portland cement, litharge-glycerin cement, or asphalt and resin base compounds. Low-melting metals, such as babbitt, may be cast around porcelain with some attendant danger of cracking.

Pressboard. A material similar to paper except that it is thicker, less flexible, and usually denser. Grades containing above 50 per cent cotton fiber may be formed by heat and pressure into simple shapes. The better grades are also known as fullerboard. Pressboard is much used for low-frequency coil construction with subsequent impregnation. The material, of course, is hygroscopic and must be treated with oil, wax, varnish, or other compounds to increase dielectric strength and repel moisture. The impregnated material is a cheap and satisfactory insulator where the highest dielectric properties are not required.

Prestite.* Westinghouse Electric Corp. Special dry-process **porcelain.**

Pyralin.* E. I. du Pont de Nemours & Co. **Cellulose nitrate.**

Pyrex.* Corning Glass Works. Electrical, heat, and chemical resistant **glasses.**

Pyroxylin. See **Cellulose nitrate.**

"Q" Max.* Communication Products Co. Low-loss r-f coil lacquer.

Quartz, Fused. Silicon dioxide fused at 1750 deg cent to a clear, translucent, glassy mass. Very stable, will not absorb water, and is an exceptional insulator. Strong mechanically and extremely resistant to thermal shock on account of the low coefficient of expansion. It is not attacked by solvents or solutions except by hydrofluoric acid and slowly by concentrated alkalies. For high temperatures it must be kept clean, as traces of metallic salts or oxides will flux the quartz to form a low-melting glass and cause failure of the tube or other device. It is available in rods, blocks, tubes, and extruded shapes. Special shapes can be cast in graphite molds. It can be ground and disk-sawed readily since it does not crack easily. It is very expensive.

Rayon. The three common types of rayon are acetate, viscose, and cuprammonium. Viscose rayon is the strongest and most suitable for protective braids on hook-up wire but is not so resistant to abrasion as cotton. Viscose rayon contains traces of residual sulfur which may cause corrosion if it is used for magnet wire insulation; acetate and cuprammonium rayon are suitable for such applications. Acetate rayon is especially suitable for use with very fine wires for it is non-corrosive even under conditions where electrolysis would take place.

Resimene.* Monsanto Chemical Co. **Melamine** molding compounds.

Resinox.* Monsanto Chemical Co. **Phenolic** molding compounds.

Resistoflex.* Resistoflex Corp. Polyvinyl alcohol products.

Rosin. Rosin is a natural resin obtained by steam distillation of turpentine and rosin oils from the exudations of certain varieties of pine trees. Rosin comes in letter grades. WW (water white) is the best, descending in reverse alphabetical order to A and B, which are very impure grades, containing much dirt, and almost black. It is universally graded by the color. Although the properties do not vary directly with the color, the color is important for use in varnishes. Rosin in grades from WW to H is extensively used in oil and wax impregnating compounds. It also is very cheap. Probably the most important use in the electrical industry is non-corrosive soldering flux. Solutions of rosin in No. 1 S.D. alcohol, or in alcohol and ethyl acetate, form a substantially non-corrosive soldering flux and yet the activity of rosin at the temperature of melted solder is sufficient to remove thin coats of metallic oxides and insure a good joint on tin, copper, brass, or nickel silver. It is unsatisfactory for steel. Any rosin left around the joint is non-conductive, which is a further advantage.

Rubber, Cyclicized. Thermoplastic resin derived from natural or special synthetic rubber by treatment with stannic chloride or chlorostannic acid. This resin is extremely resistant to moisture diffusion and may be added to wax mixtures to decrease cracking at low temperatures. Trade names: *Pliolite*, *Marbon B*.

Rubber, Hard. Hard rubber is usually vulcanized with 20 to 30 per cent sulfur, in the form of sheets, rods, tubes, or molded shapes. It is also called vulcanite and ebonite, and is known under various trade names. It is a hard, dense material, is easily machinable, takes a high polish, and is resistant to wear. At temperatures slightly below room temperature it becomes increasingly brittle, and at higher temperatures it softens and flows under pressure. Under heavy load, "cold flow" occurs at room temperature. In a small intermediate temperature range it is tough and almost "unbreakable." It is combustible but is not easily ignited. It has low water absorption and is immune from attack by most acid and alkali solutions and fumes. It is attacked and swelled by oils and rubber solvents. It is attacked by ozone, although less than soft rubber, but special grades are available with improved oil and ozone resistance. It is resistant to sparks but will not withstand heavy arcs. The sulfur is never fully combined, which leads to some serious difficulties. The sulfur has a tendency to appear in a surface film known as "bloom," causing discoloration. Ultraviolet light produces sulfuric acid from this layer, seriously lowering the surface resistivity and causing corrosion of nearby metals. "Blooming" can be greatly reduced by careful compounding. Metallic inserts should be protected by a coating of tin or other corrosion-resistant substance. The tendency to "cold flow" and the high co-

* Trademark names.

efficient of expansion can be reduced by incorporating suitable fillers such as talc; lower grades of hard rubber usually are filled for economic reasons, however. Rubber can be "preformed" before molding to nearly the final shape and hence may be used for fine tubes and thin-walled sections not easily obtainable with phenolic moldings, but the accuracy in molding is usually much lower, owing to shrinkage, distortion, and high coefficient of expansion. Hard rubber is easily machined by normal methods, but grinding is sometimes more economical. Special drills also give improved performance, and lubricants are valuable for drilling, tapping, and turning. Tungsten carbide and diamond tools give more nearly satisfactory production. The material may be sheared and punched if heated. Many moldings as well as machined parts require polishing with pumice on a moderately hard "buff" at low speed to avoid excessive heat. The material usually is black but can be obtained in a number of colors, mostly with high filler content. Hard rubber has very high dielectric strength and resistivity, and low dielectric constant and power factor, but all the dielectric properties are affected seriously by rising temperature. The mechanical temperature limit is about 45 deg cent for unloaded and 70 deg cent for loaded hard rubber with light pressures.

Rubber, Synthetic. The principal synthetic rubbers are **Buna S, Buna N, neoprene, butyl,** and *Thiokol,** although elastomeric vinyl compounds might also be classed as synthetic rubber. All the above are discussed elsewhere in this section.

Rubber, Vulcanized. Sulfur and rubber react at temperatures in the vicinity of 100 deg cent to form a tough, elastic, strong material. The crude rubber is washed, sheeted, and dried. The sheets are then mixed on hot rolls with sulfur, fillers, plasticizers, accelerators, and anti-oxidants as wished, and sheeted, molded, or extruded to the desired forms. The article then is vulcanized by heating to temperatures from 125 to 145 deg cent for soft rubber articles, and 160 to 170 deg cent for hard rubber parts. With plain rubber, from 2 to 10 per cent sulfur gives a soft rubber stock. Hard rubber contains from 20 to 32 per cent sulfur. With plain sulfur, vulcanization or "cure" may take 2 or 8 hours, but by means of accelerators the time may be reduced to as low as 20 minutes. Litharge, lime, and magnesia are inorganic accelerators as well as fillers. Complex organic compounds, such as tetramethylthiuram disulfide, phenylguanidines, and mercaptobenzothiazole, function to give fast cures which are not critical as to the time required to obtain maximum physical properties and are known as "flat" cures. Fillers in the form of fine powders, such as carbon black, zinc oxide, clay, and whiting, are employed in nearly all rubber goods. They cheapen the compound, of course, but they also increase the strength and toughness. Soft rubber compounds usually contain from 50 to 80 per cent of filler. Although the natural resins and proteins assist in the "milling" or breaking down of the rubber to some extent, very often improved working is obtained by adding plasticizers or softeners, including paraffin, waxes, para-cumaron resin, oils, fats, and asphaltic and bituminous materials in various percentages. Reclaimed rubber also improves the working properties. So-called mineral rubber, which is an asphaltic residue, is sometimes added up to 20 per cent and can be classed as a filler. The dielectric constant of rubber-sulfur compounds at 25 deg cent rises from 2 to 11 per cent of sulfur and falls again from 16 to 19 per cent sulfur, and then changes very slightly up to 32 per cent sulfur. The power factor goes through somewhat similar variation, starting at 8 per cent sulfur. The maxima of these curves are displaced to higher sulfur content by increasing temperature. The normal soft and hard rubber compositions thus have low dielectric constant and power factor, and the intermediate region, which is seldom used, has poor electrical properties. Resistivity rises in a fairly regular curve from 2 to 28 per cent sulfur. (See *Bureau of Standards Scientific Paper* 560, part II, by H. L. Curtis, A. T. McPherson, and A. H. Scott.) Softeners change the dielectric constant slightly but may seriously increase the power factor in quantities of only 10 per cent. The dielectric constant is increased nearly proportionally to the filler content. Carbon black causes a sharp increase of dielectric constant from 2.7 to 6.0. Zinc oxide, lead oxide, and selenium show much slower rates of increase. Powdered quartz gives only a slight increase. The effect on the power factor is much the same: 20 per cent carbon black elevates the power factor from 0.0025 to nearly 0.05. Increasing quartz content slightly improves the power factor. The introduction of carbon black greatly reduces the resistivity of rubber. Carbon black is, however, the best filler from a mechanical standpoint: a several-fold increase in the tensile strength is produced. Rubber compounds absorb water, which causes an increase of dielectric constant and power factor, and decrease of resistivity, but on long immersion the power factor may decrease again. Water absorption can be considerably lowered by extended washing of the crude rubber to remove water-soluble matter and by the use of water-insoluble fillers such as silica, zinc oxide, or hard rubber dust. Absorption of water is less in sea water than in distilled water. The usual grade of wire insulation contains 20 per cent minimum of rubber; better grades have 30 per cent, and high grades 40 per cent. Covering of portable cords, etc., subject to mechanical wear may contain up to 60 per cent. The mechanical and dielectric strength of rubber is lowered by the action of oxygen and more rapidly by ozone which is present in corona discharge: the rubber cracks when normally vulcanized and may melt if the temperature is high and the compound is undervulcanized. In order to improve the resistance to oxygen, organic compounds, such as diphenylamines or hydroquinone, known as antioxidants, are added in small percentage. Rubber stocks are tested for this defect under 300 lb per sq in. in oxygen gas at 70 deg cent and by contact with ozone at atmospheric pressure. Stretching the rubber under test seriously increases the rate of ozone attack. Ultraviolet light also sharply accelerates the combination with oxygen. Heat deteriorates rubber rapidly; 49 deg cent is the maximum operating temperature for Code rubber insulation. Performance grades are satisfactory at 60 deg cent, and heat-resistant grades at 75 deg cent. Rubber is swelled quickly and eventually dissolved by hydrocarbon solvents and oils. Special grades are available which minimize this defect. At low temperatures a low-sulfur rubber compound is no longer elastic, and a piece stretched and cooled to −20 deg cent or lower will not return to its original length until the temperature rises. The power factor also increases sharply to a maximum in this region, with a value over 10 times the value at 20 deg cent,

* Trademark names.

indicating a change of state in the compound. The power factor also rises with increasing temperature, but less rapidly.

Rutile (TiO_2). A particular crystalline form of titanium dioxide, with a dielectric constant of 80 to 110, which is used in the manufacture of high-dielectric-constant ceramics.

Saflex.* Monsanto Chemical Co. Polyvinyl butyral.

Saran.* Dow Chemical Co. Vinylidene chloride.

Saturated Sleeving. Cotton sleeving impregnated with thin varnish or compound which does not fill completely the interstices of the fabric. Dielectric strength is low, and resistance to humidity is poor. It is valuable mainly to space conductors apart.

Scotch Tape.* Minnesota Mining and Mfg. Co. Pressure-sensitive, non-corrosive electrical tape with various backing materials.

Shellac. Produced by the insect *Tachardia lacca*, which attaches itself to numerous species of trees native to India, Indo-China, and Siam, and excretes the resin at several parts of the 6-month life cycle. The kusmi tree is the most valuable host to the parasite lac insect since the lac therefrom is of higher quality. Crude lac consists of about 75 to 85 per cent resin, 2 to 4 per cent dye, 1 to 2 per cent ash, 2 to 3 per cent water, and 9 to 15 per cent residue and dirt. The natives wash the crude lac, dry it, and press it through a bag with the aid of heat. The mass is plastered into a sheet on a heated object and stretched while still hot. After it cools it is broken into flakes and shipped in bags. Native shellac is sometimes adulterated with rosin. Machine-made shellac is extracted by various processes employing solvents or heat. Refined shellac contains over 90 per cent resin, from 3 to 5 per cent of wax, 1 to 2 per cent moisture, and 1 to 5 per cent of matter insoluble in alcohol. Shellac is sold in many grades which are principally determined by the color. D.C. is a very high grade, free from dirt. Superfine is made from best kusmi lac. Fine and Standard No. 1, T.N., and garnet lac follow in descending order of quality. Rosin is limited by trade standards to 3 per cent maximum except in garnet shellacs which may sometimes contain 20 per cent. Machine-made shellac is graded somewhat differently. One manufacturer's grades are Fine, Superfine, and ABTN. All are hard, pure shellacs. BB is used for blending, and amber where a light color is required. Completing the list are: T.N.S. pure orange shellac, various grades of T.N. shellac, and garnet. Machine-made garnet is low in wax and rosin, and is valuable for insulating use. Shellac is naturally variable in quality, depending on the source and methods of collection. A small amount of orpiment (arsenic sulfide) is added to some orange shellac to lighten the color. Orpiment is insoluble in solvents, but otherwise usually has no beneficial or harmful effect. Shellac has been used for some time in hot molding compounds, in insulating varnishes, and as a binder for composite insulations of paper, mica, etc. Various mineral fillers, such as asbestos, powdered mica, clays, marble, and wood flours, are blended with shellac on rolls in a manner similar to rubber compounding. The material is sheeted off the rolls, and blanks are cut to size. The preheated blanks are usually molded in steam-heated molds at about 160 deg cent under hydraulic pressure for about 1 minute, the dies are then chilled with water, and the piece is removed. Little or no chemical action takes place. The finish is excellent if the mold surface is polished, but parts can be polished subsequently. Accuracy of molding is about the same as that of phenolic moldings, and the dies are much the same except for the cooling feature. The moldings have good weather resistance and are fairly impervious to moisture, but they are somewhat brittle at low temperatures and soften at 75 deg cent. It is not well known that shellac is somewhat thermosetting under certain circumstances. Long-continued heating above 100 deg cent will solidify the melted shellac to a tough, horny mass. This action is accelerated by increased heat and by hexamethylenetetramine, aluminum chloride, urea, and other agents, and is retarded by alkalies, alkaline salts, aniline, and other substances. (See *Bulletin* 14, Indian Lac Research Institute.) Shellac is soluble in alcohols and ketones, and the solutions are used for varnishes and cements. Shellac loses solubility on standing for long periods of time, and the plasticity is also decreased somewhat. The flexibility of shellac films may be increased by plasticizing with castor oil or tricresyl phosphate.

Silaneal.* Dow Corning Corp. Silicone treating fluid for ceramics.

Silastic.* Dow Corning Corp. Silicone rubbers.

Silica, Fused. Fused silica is similar to translucent fused quartz in its properties, but it is not made from as pure a sand and usually contains some iron. It is an excellent insulator.

Silicones. Silicones are a class of organo-silicon compounds with a chemical structure analogous to that of hydrocarbons, but with the carbon atoms of the chain replaced by silicon atoms with an oxygen atom inserted in each bond between the silicon atoms. By attaching various hydrocarbon chains to each silicon atom, and varying the chain length by different polymerization procedures, fluids, greases, plastics, and resins are produced. The general properties of silicones compared to those of hydrocarbons are: (1) improved heat resistance; (2) smaller change in viscosity with temperature; (3) resistance to oxidation; (4) resistance to arcing; (5) high flash and fire points. In common with some hydrocarbons, they have low power factors and are water-repellent to a high degree. Silicone fluids are available in viscosities from 0.65 to 1000 centistokes at 25 deg cent, and in volatilities from nearly zero to approximately that of water. They have dielectric constants of 2.4 to 2.75, and power factors of 0.0002 from 100 cycles to 10 Mc, rising to 0.0006 at 100 Mc. Power factor increases with temperature but is always less than that of a good grade of mineral oil. Silicone fluids may be used to treat glass or ceramics (*Silaneal;* Dri-film* *) to produce a water-repellent surface, giving a greatly increased surface resistivity under condensation conditions. Silicone greases (DC No. 4 Ignition Sealing Compound) may be used to fill connectors to prevent arc-over, corona, or leakage, or to render surfaces water-repellent. Silicone resins are used in conjunction with glass textiles to form heat-resistant boards, cloths, and wire insulation, and in the form of varnishes for coil impregnation. Silicone rubber (*Silastic* *) is heat-resistant to 250 deg cent, remains flexible down to -55 deg cent, and has good dielectric properties.

Silk. Silk is obtained from cocoons spun from double continuous filaments secreted by the "silkworm," which is the larva of the *Bombyx mori* and other moths. The fiber is unwound from the cocoon by hand, usually scoured (degummed) to remove the natural sticky gum or wax, called sericin, which cements the duplex filaments, and twisted into thread. Cultivated silkworms are fed on mulberry leaves; wild silkworms give a coarser quality known as tussah silk. Orgazine silk is from the best selected cocoons, and tram silk is from the poorer cocoons. Floss silk is spun from broken lengths of filaments. Silk for insulation should be free of loading materials and as well washed as possible, since thorough washing greatly improves the insulating qualities. Silk is used in the form of cloth and tapes, plain or varnished, and as wrapped or braided insulation on wires. Silk insulation for a given dielectric strength is thinner than cotton and has somewhat higher insulation resistance and lower dielectric constant but is not as resistant to heat. Silk flock is sometimes used to add strength to molding compounds.

Sisal Hemp. A bast cordage fiber obtained from the leaves of the century plant or agave. In strength and length of fiber it is inferior to manila hemp. It is used to some extent in making paper and pressboard, and for reinforcing large molded laminated parts.

Spauldite.* Spaulding Fibre Co. Phenolic laminates.

Steatite. Principal ceramic used for radio apparatus. Made chiefly from magnesium silicate which, after firing, forms clinoenstatite crystals. Low water absorption and excellent electrical properties are characteristic. Special grades (L-5) are available with even lower losses than standard or regular grades (L-4 or L-3). Specifications: Joint Army-Navy Spec. JAN-I-10, Grades L-3, L-4, or L-5.

Styraloy.* Dow Chemical Co. Elastomeric polystyrene copolymer.

Styramic.* Monsanto Chemical Co. Polystyrene and chlorinated diphenyl molding compound.

Styramic H. T.* Monsanto Chemical Co. Polydichlorostyrene molding compound.

Styrene. Volatile liquid monomer, also known as vinyl benzene, used for manufacture of polystyrene, Buna S rubber, and other plastics. Polymerizes spontaneously in time to polystyrene or more rapidly with the aid of heat or a catalyst. It also is used as a fully reactive constituent in polyester laminating liquids so that no solvent evaporation is necessary.

Styrofoam.* Dow Chemical Co. Expanded polystyrene.

Styron.* Dow Chemical Co. Polystyrene of various types.

Synthane.* Synthane Corp. Phenolic laminates.

Teflon.* E. I. du Pont de Nemours & Co. Polytetrafluoroethylene products.

Tegit.* Garfield Mfg. Co. Asbestos coal-tar moldings.

Tenite I.* Tennessee Eastman Corp. Cellulose acetate.

Tenite II.* Tennessee Eastman Corp. Cellulose acetate-butyrate.

Textolite.* General Electric Co. Phenolic and other molded or laminated products.

Thalid.* Monsanto Chemical Co. Low-pressure or contact laminating resins.

Thiokol.* Thiokol Corp. Polysulfide rubbers.

Transite.* Johns-Manville Corp. Portland cement and asbestos molded products.

Tuf-flex.* Libby-Owens-Ford Glass Co. Tempered glass.

Turx.* International Products Corp. Glass-bonded mica.

Urea Resins. Reaction of urea, $CO(NH_2)_2$, and formaldehyde produces methylol ureas which are water-soluble. Paper, alphacellulose, cloth, or wood is impregnated with solutions and cured with heat and catalysts to a thermosetting, water-insoluble plastic. Urea moldings are light weight, rigid, and hard. They have high dielectric strength, good arc resistance, and moderate electrical losses. Impact strength is lower than that of phenolic materials. Translucent moldings in any color may be obtained. Specifications: ASTM D705. Trade names: *Beetle, Plaskon.*

Varnishes, Insulating. Varnishes are generally classified according to composition, as oleoresinous or "oil varnishes" and "spirit varnishes," but some commercial types do not fall strictly into either class. Oil varnishes are made by combining a resin, commonly a copal, with a drying oil. It is usually necessary to melt or "run" the resin before adding the oil to get a clear solution. Varnishes with a high oil content are known as "long-oil" varnishes; they are slow drying but deposit very flexible films. "Short-oil" varnishes have high resin content and deposit a hard film. Oil varnishes harden as a result of oxidation and polymerization of the drying oils, such as linseed, tung (China wood), or soya bean, and often of the resin or asphalt as well. Drying is accelerated by adding small percentages of catalytic agents, called "driers," usually in the form of resinates or linoleates of cobalt, lead, or manganese, which increase the rate of oxidation. Short-oil varnishes will air-dry in 4 to 18 hr, depending on the type, to a reasonable degree of hardness. Long-oil varnishes will not air-dry in a reasonable time. By baking at 100 to 110 deg cent the drying time can be shortened to 2 to 8 hr because of the faster oxidation. Baking produces a harder film and gives better adhesion to the object. It also serves to drive out moisture from fibrous materials which are being treated, and to improve the dielectric properties. Many modern insulating varnishes contain synthetic resins of the phenol-aldehyde or alkyd type which give hard durable films as the result of the thermosetting of the resins during baking. Thermosetting resins are also used dissolved in "spirit"-type solvents instead of oils, yielding a moderately hard film, on air-drying, which is increased in hardness and durability by baking. The dielectric properties of the synthetic resin varnishes are usually excellent. Asphalts are used with resins in some black oil varnishes and without oil or resin in the so-called asphaltum varnishes which are merely solutions of asphalts in benzine or other hydrocarbons. These varnishes dry principally by evaporation, but the last traces of solvent leave the asphalt very slowly, and if the object is heated to drive off the solvent many of the asphalts will oxidize and polymerize to a certain extent, producing a fairly hard film.

* Trademark names.

Spirit varnishes dry by evaporation of the solvent, leaving a film of the dissolved resin, asphalt, or gum. Cellulose nitrate and acetate varnishes are in this class but are usually considered separately as "lacquers." Many of the resins leave a brittle film when used alone so that a soft gum or plasticizing agent like castor oil is usually added to give the necessary flexibility, except in shellac which ordinarily does not need plasticizing. The principal spirit varnish resins are shellac, manila copal, dammar, mastic, kauri, and sandarac. The solvents and thinners used are alcohols, esters, hydrocarbons, and turpentine. Spirit varnishes are commonly air-drying, although the evaporation of the solvent is often hastened by moderate heating. Spirit varnishes are generally not used for impregnation but are common for external coats and for sticking, and for bonding of mica and other materials. For external coating work, varnishes are applied by spraying, dipping, roller coating, or brushing, depending on the nature of the work. For impregnation, dried articles are dipped while still hot into a varnish of low viscosity and low surface tension to insure thorough penetration. Dipping time must be determined for each article by experiment. A much better impregnation is secured by drying coils in a vacuum and admitting the varnish to the work container, then "breaking" the vacuum and applying pressure. Impregnated coils should be drained and baked at 100 to 110 deg cent for a period sufficient to harden the varnish film. Higher temperature tends to disintegrate fibrous materials in prolonged baking, and lower temperatures do not remove moisture. For short drying schedules, temperatures up to 150 deg cent are sometimes employed satisfactorily. Objects should be exposed to fresh currents of air during drying in order to remove solvent vapors which retard hardening. For methods of testing dielectric strength, heat endurance, and oil proofness, see ASTM D115.

Varnished Cloth. A suitable fabric coated with yellow or black insulating varnish so that the fibers are thoroughly impregnated. Varnished silk usually is from 0.003 to 0.005 in. and cotton from 0.005 to 0.040 in. thick. Tensile strength of cotton-base cloth per inch width of warp runs from 45 to 100 lb, and Elmendorf tearing strength across the warp varies from 100 to 300 grams. Dielectric strength usually runs from 800 to 1500 volts per mil.

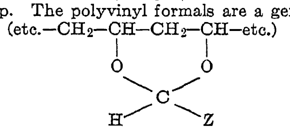
Varnished Tubing. Commonly called "spaghetti," magneto tubing, etc., according to manufacturer and grade; made by coating, or impregnating and coating, cotton sleeving with varnishes. ASTM Specification D372 distinguishes three grades (see specification for details). Grade A is generally known as flexible varnished tubing, or motor and transformer tubing, or impregnated magneto tubing; it has a minimum dielectric strength of 7000 volts average. Grade B, generally known as "radio spaghetti," has a minimum average dielectric strength of 4000 volts. Grade C is similar to saturated sleeving, and its dielectric strength is lower.

Vibrin.* Naugatuck Chemical Co., Div. U. S. Rubber Co. Liquid polyesters and cross-linking monomers.

Vinyl Plastics. An extremely important class of thermoplastic resins, composed of linear chains formed by the polymerization of monomers of the general type $\left(CH_2{:}C\begin{smallmatrix}X\\Y\end{smallmatrix}\right)$. The result is a continuous chain $\left(\text{etc.—}CH_2\text{—}\overset{X}{\underset{Y}{C}}\text{—}CH_2\text{—}\overset{X}{\underset{Y}{C}}\text{—etc.}\right)$.

If group X is	*and group Y is*	*the product is*
hydrogen	hydrogen	polyethylene (*Polythene* *)
hydrogen	chlorine	polyvinyl chloride (*Geon* *)
chlorine	chlorine	polyvinylidene chloride (*Saran* *)
hydrogen	hydroxy (—OH)	polyvinyl alcohol
hydrogen	phenyl (C_6H_5—)	polystyrene
hydrogen	carbazyl ($C_{12}H_8N$—)	polyvinyl carbazole (*Polectron* *)
hydrogen	acetoxy ($CH_3\cdot CO\cdot O$—)	polyvinyl acetate
methyl (CH_3)	methylcarboxy ($CH_3O\cdot OC$—)	methyl methacrylate (*Plexiglas*,* *Lucite* *)

If mixtures of two monomers are copolymerized, a copolymer such as polyvinyl chloride-acetate is produced in which all the Y's are hydrogen, most of the X's are chlorine, and the remainder of the X's are the acetoxy group. The polyvinyl formals are a general group of polymers with modified chains constructed like this:



If group Z is	*the product is*
hydrogen	polyvinyl formal (*Formex*,* *Formvar* *)
methyl (CH_3—)	polyvinyl acetal (*Alvar* *)
butyl (C_3H_7—)	polyvinyl butyral (*Butacite*,* *Butvar*,* *Saflex*,* *Vinylite** X)

Of course, different conditions of temperature, pressure, catalyst, and carrier solvent or emulsion are required for each case, and the length of the chain of molecules is varied to suit requirements by altering these conditions. Only those plastics with vinyl in the product name are usually classed as vinyl plastics, but by this illustration the relationship of many of the thermoplastics is immediately apparent.

Vinyl Chloride. Perhaps the most important vinyl plastic from a tonnage viewpoint, vinyl chloride is very extensively used for hook-up wire insulation, cable jackets, insulating tubing, and tape. It is

* Trademark names.

also employed for non-rigid or elastomeric molded parts since it has rubberlike characteristics when plasticized properly. The amount and kind of plasticizer may be varied over wide limits to form compounds ranging from hard, stiff, non-extensible plastics, to limp, flexible, and high-elongation products resembling rubber. The electrical properties and inflammability likewise vary with the kind and amount of plasticizer, but, in general, these resins have a rather high dielectric loss and a lower insulation resistance than those of rubber compounds, although they have a high dielectric strength. Wire insulation for operating temperatures of 80 deg cent is now available, although 60 deg cent has been the limiting temperature for most older compositions. These compounds are nearly non-inflammable and do not oxidize like rubber but are subject to some stiffening due to loss of plasticizer with time. Except for flexing at low temperature the life should be very long. Specifications for resin: ASTM D728. Trade names: *Flamenol*, *Geon* 100 series, *Vinylite* Q series, *Koroseal.*

Vinyl Chloride-acetate. This resin is similar to straight polyvinyl chloride resin except that about 5 per cent of the resin may be vinyl acetate, which improves the processing and extrusion characteristics and reduces the amount of plasticizer required. Uses and characteristics are similar to those of polyvinyl chloride, but in addition these resins are used for rigid, transparent, or colored sheets of high dimensional stability and good electrical properties. These resins also have proved to be very successful for high-quality phonograph records and for manufacture of textiles (*Vinyon*). Specifications for rigid sheet: ASTM D708; for non-rigid resin: ASTM D742. Trade names· *Vinylite* V series.

Vinylidene Chloride. Similar to vinyl chloride resins but contains more chlorine, is harder, and is capable of orientation by drawing or other cold work to increase the tensile strength. For molding purposes, it is commonly copolymerized with 10 per cent of vinyl chloride to serve as an internal plasticizer. Though the electrical properties are not outstanding, the strength, toughness, and non-inflammability of this plastic have made it valuable for fungus-resistant cable braids and ropes, as tubing for water cooling, etc. Specifications for molding compounds: ASTM D729. Trade name: *Saran.*

Vinylite.* Carbide and Carbon Chemical Co. Vinyl resins, of which various grades are distinguished by suffix letters.

Vinyon.* Carbide and Carbon Chemical Co. Polyvinyl chloride-acetate textiles.

Vistanex.* Standard Oil Co. of N. J. Polyisobutylene.

Vitreosil.* Thermal Syndicate, Inc. Fused silica.

Voltron.* Industrial Synthetics Corp. Vinyl tubing and tape.

Vulcabeston.* Johns-Manville Corp. Asbestos with rubber or gum binder.

Vulcoid.* Continental-Diamond Fibre Co. Resin-impregnated vulcanized fiber.

Vycor.* Corning Glass Works. High-silica glass.

Waxes. Waxes are of three origins: animal, vegetable, or mineral. The principal animal waxes are: beeswax, m.p. 63 deg cent; wool wax, m.p. 35 deg cent; spermaceti, m.p. 49 deg cent; insect or Chinese wax, m.p. 81 deg cent. The principal vegetable waxes are: carnauba, m.p. 85 deg cent, and candelilla, m.p. 68 deg cent. The principal mineral waxes are: montan, m.p. 72 deg cent; ozokerite refined to form ceresin, m.p. 65–73 deg cent; paraffin waxes obtained from petroleum. Waxes in general are not "wetted" by water and are very resistant to penetration by moisture. Ceresin and non-crystallizable high-melting-point paraffin waxes such as *Superla,** *Syncera,** and *Cerese wax* * have higher insulation and moisture resistance than the low-melting paraffins and the animal and vegetable waxes. Waxes which crystallize, such as montan, have a tendency to crack and admit moisture by capillary action; mixture with a soft wax or resin usually minimizes this tendency. Wax compounds are hardened and the flow point raised by incorporating rosin or other resins and higher-melting waxes such as ceresin, montan, or carnauba. Most naturally occurring waxes have low dielectric constants and low power factors as well as high resistivity. Synthetic waxes made by chlorinating naphthalene or paraffin have somewhat higher dielectric constants and losses. Long heating of liquid waxes at high temperatures in contact with air tends to cause decomposition and development of acidity, particularly in the presence of copper, which acts as a catalytic agent to increase oxidation markedly.

Zircon Porcelain. This material consists chiefly of zirconium silicate with addition of small amounts of clay and metallic oxides to aid in manufacture. It has higher mechanical strength than other electrical ceramics, and a lower coefficient of expansion than all but cordierite. It is extremely resistant to thermal shock. The electrical characteristics at radio frequencies are excellent, except that the dielectric constant is 50 per cent higher than that of steatite and changes more rapidly with temperature. The resistivity at high temperatures is about the same as that of steatite and is superior to that of cordierite and high-voltage porcelain.

6. LIQUID DIELECTRICS

Dielectric Constant. The dielectric constant of liquids ranges from about 1.5 to almost 100. Non-polar liquids at room temperature have constants of 1.84 to 2.3, which are nearly equal to the square of the index of refraction. The dielectric constants of non-polar liquids are independent of frequency and vary only slightly with temperature, owing to thermal expansion. On the other hand, polar liquids have higher dielectric constants which vary to a marked degree with temperature and frequency in certain regions. When a polar liquid freezes, part of the influence of the dipoles is lost and the dielectric constant drops very sharply. High rates of change in dielectric constant with frequency or temperature are normally associated with high power factors at the same frequency and temperature. The dielectric constants and dipole moments of some liquids are shown in Table 2.

Notes. A wavelength greater than 10,000 cm is denoted by ∞.
Zero indicates that substance has no polar moment.
Plus sign indicates that substance is polar but value for polar moment was not available.

D-c Conductivity and Resistivity. The d-c conductivity of liquids is ionic in nature and has a high positive temperature coefficient. Change in conductivity with temperature is expressed by

$$G = G_0 e^{a/T} \quad \text{or} \quad G = G_0 e^{bt}$$

where G_0, a, and b are constants, T is the absolute temperature, and t is the temperature in degrees centigrade for small temperature differences. Thus a plot of the logarithm of either conductance or resistivity against $1/T$ is a straight line, and against t is approximately straight for small temperature intervals. The increase in conductivity with temperature is the result of an increase in ionic mobility arising from the reduction in viscosity. Log resistance-temperature curves therefore change slope at regions where the viscosity varies sharply, as at freezing or transition points.

The conductivity of pure liquids may be increased enormously by small amounts of impurities or moisture which readily ionize in the particular liquid. Fortunately the degree of ionization is a function of the dielectric constant, so that the non-polar liquids having a low dielectric constant are less sensitive to impurities, especially in low concentration. The difficulty of preventing contamination of liquids of higher dielectric constant has effectively prevented their use for capacitors. The resistivities characteristic of commercially pure liquids are approximately in inverse relationship to the dielectric constants, as is shown by the following table taken from The Properties of Dielectrics, by F. M. Clark, in the *J. Franklin Inst.*, Vol. 208, 17 (July 1929).

Table 3. Relation between Dielectric Constant and Resistivity

Material	Dielectric Constant	Characteristic Resistivity, ohm-cm	Material	Dielectric Constant	Characteristic Resistivity, ohm-cm

Linseed oil.....	3.3	0.61×10^{12} "			

At very high voltage gradients, some evidence of a saturation range similar to that of gases has been obtained. With long applications of voltage, impure liquids undergo a so-called electric cleaning. This is due to a very low rate of ion production so that all ions are swept to the electrodes and the conductivity drops nearly to that of a pure liquid. Solid phases also are removed in some cases by cataphoresis, but the breakdown strength is usually affected to a greater extent than the conductivity.

Dielectric Absorption and Losses. Liquids exhibit some of the phenomena of dielectric absorption shown by solids, but the rate of decrease of the initial current with time is much faster and normally is detectable only with an oscillograph. The characteristic "bound charge" of solids also is absent: the discharge current shows practically no evidence of absorption, except in highly viscous liquids of a mixed nature.

The initial high current is reduced, owing to the accumulation of space charges in front of the electrodes. The resultant non-linear potential distribution can be measured with probes; or porous cells can be used to remove the space charges from the liquid for measurement. Although the absorption results in a higher a-c conductivity, the effect is of much smaller magnitude than that in solids, and the a-c losses are much lower. The non-existence of any discharge phenomena has been attributed to the absorption of space charges by part of the electrode charges.

The power factor of most commercial non-polar insulating liquids is low, ranging from 0.0001 to 0.01. The power factor at 60 cycles is influenced by the d-c conductivity and may be expected to double for each 10 to 20 deg cent rise in temperature. At high frequencies, little change in power factor with temperature is to be expected with true non-polar dielectrics. Many mineral oils have some polar impurities which produce characteristic peaks in the power-factor curves at frequencies or temperatures where rapid changes in dielectric constant are occurring.

For an excellent summary of the effects to be expected in polar substances, consult Dielectric Properties of Organic Compounds, by S. O. Morgan and W. A. Yager, *Industrial and Engineering Chemistry*, Vol. 32, 1519 (November 1940).

Dielectric Strength. Breakdown in liquids, like that in gases, is not permanent, nor is the subsequent breakdown voltage necessarily reduced. Discussion of breakdown must be considered for two cases: pure liquids containing no dissolved or suspended gas, solid, or foreign liquid; and impure liquids.

Breakdown in pure liquids probably occurs by an ionization process similar to that in gases and undoubtedly is aided by intense voltage gradients built up by space charges near the electrodes. Change in pressure has practically no effect, but increase in temperature decreases the breakdown strength, particularly when the boiling point is approached. The time involved in the breakdown process may be as short as 10^{-7} sec with sufficient overvoltage

Impure liquids usually break down at much lower voltages for a variety of reasons, the most important of which is the presence of moisture or gases. The electric field tends to liberate dissolved gases, and, since the gas dielectric strength is only about one-tenth that of the liquid, the gas ionizes and starts the discharge. The harmful effects of moisture and gases are greatly increased by fibers or other suspended solid particles which absorb the impurity. Fibers, particles, or foreign liquids may form "bridges" or "chains" if the dielectric constant is higher than that of the liquid. Sometimes these bridges lead only to preliminary or "pilot" sparks which exert no effect on the breakdown. A very small percentage of impurity usually produces a marked lowering of breakdown strength, but larger percentages have only a slightly greater effect. Particles of carbon formed by arcs or sparks give but a small decrease, which is proportional to the concentration.

Although the breakdown voltage of pure liquids is linear with distance in uniform fields, that of impure liquids is considerably influenced by gap geometry. A horizontal gap gives lower breakdowns with impure oils than a vertical gap because of the difference in the ease of gas elimination. Small gaps are quite liable to breakdown by fiber bridges; long needle gaps are scarcely affected by most impurities. Increased gap area obviously results in lower average breakdown with impure liquids.

The effect of temperature on breakdown of impure liquids depends on the kind of impurity. Materials of low dielectric constant are more readily expelled from the field as the viscosity is reduced by raising the temperature, but the conductivity of the liquid is increased. Moisture may be expelled, raising the breakdown. Pressure increases the dielectric strength by preventing gas elimination or vaporization of the liquid.

Since formation of fiber bridges and gas elimination take an appreciable time, the strength of liquids to transient voltages is little influenced by these impurities. With steady-state currents, the strength increases slightly as the frequency increases up to 1000 cycles, but may be as low as 30 per cent of the 60-cycle value at radio frequencies, probably on account of the heating effect.

Commercial Oils. For service in which the liquid will be in contact with air, the use of mineral oil has been practically universal because of its stable nature and low cost. Since the breakdown of all oils is approximately 30 to 40 kv rms in a standard 0.1-in. gap between 1-in.-diameter disks, little is to be gained by substituting other oils except a higher dielectric constant, which is obtained at the cost of lower resistivity. For hermetically sealed applications, such as capacitors, purified castor oil, with a constant of 4.7, is often used. Carefully purified, chlorinated hydrocarbons, such as "Pyranol," with a constant of 4.5, are also employed for this purpose and have an effective advantage in being explosion-proof.

Mineral oils must be carefully purified to remove unsaturated compounds which cause accelerated oxidation in service, resulting in low resistivity, low dielectric strength, high power factor, and the rapid development of sludge. Too drastic a purification, however, removes naturally occurring antioxidants in the oil, and stability is decreased. The oxidation of transformer oils may be avoided by the use of oxygen-free atmospheres above the oils as in the "Inertaire" system.

Filtration through diatomaceous earth is effective in increasing the resistivity of many liquids. Filtration through hard papers is commonly used for purifying and drying oils in transformer service. Oil should be filtered when the dielectric strength in the standard 0.1-in. gap drops below 22 kv rms. A good oil will show 30 to 50 kv rms. Low-viscosity oils seem to have the highest dielectric strength, although the flash and fire points usually are lower.

Testing methods for electrical insulating oils have been standardized by the American Society for Testing Materials; see ASTM D117. Typical properties for commercial oils are shown in Table 4.

Table 4. Properties of Commercial Oils

Property	Mineral Transformer Oil	Mineral Capacitor Oil	Castor Oil
Density, average	0.87	0.91	0.96
Viscosity at 37.8° C (100° F), in Saybolt seconds, average	57	100	1400
Flash point, in deg cent, minimum	133	149	....
Fire point, in deg cent, minimum	148	170	....
Pour point, in deg cent, maximum	−40	−40	−15
Neutralization number, in mg KOH per gram, maximum	0.03	0.03	2.0

Power factor, at 100° C and 1000 cycles	....	0.0025 max	0.01
Resistivity, ohm-cm, at 100° C	4×10^{11}	$>5 \times 10^{12}$	6.6×10^{10}
Dielectric strength, at 25° C, in kv, minimum	30	30	28
Coefficient of expansion per deg cent	6.3×10^{-4}	6.3×10^{-4}	....
Thermal conductivity, in cal per sec per cm per deg cent	3×10^{-4}	....	4.3×10^{-4}

Synthetic Liquids. Synthetic insulating liquids of the non-inflammable type are known as askarels, and a draft of proposed testing methods has been published in the *Proceedings of the American Society for Testing Materials*, Vol. 43, 353. These liquids consist of mixtures of various chlorinated diphenyls and tri- or dichlorobenzene so adjusted that the pour point is reduced below service temperatures. The dielectric constant is about 4.2. Viscosity at 100 deg fahr is about the same as that of mineral transformer oils. Dielectric strength is slightly higher, and the fact that the liquids are non-inflammable permits the use of large transformers without fireproof vaults. On account of the non-explosive nature of the liquid, the air space above it may be sealed from the atmosphere with a safety diaphragm designed to relieve pressure if a fault occurs. Improved stability to oxidation and sludging is another advantage of these liquids. Trade names: *Pyranol, Inerteen.*

Silicones. Silicone fluids are a recent development and are expensive (as of 1949), but they appear to be most promising as an insulating medium. Silicone liquids consist of chains of alternate silicon and oxygen atoms with various organic groups attached in pairs to the silicon atoms. Those with two methyl groups attached are dimethyl silicones (Dow-Corning DC 200 fluids). The viscosity increases with the chain length. These fluids are suitable for use from −40 deg fahr to 400 deg fahr. Another series (DC 500 fluids) is serviceable from −70 deg fahr to 200 deg fahr. The general advantages of silicone fluids are:

1. Low temperature-viscosity slopes.
2. High flash and fire points.
3. Low volatility and negligible vapor pressure.
4. High resistance to oxidation and heat.
5. Lack of color, odor, or toxicity.
6. Low power factor over a wide frequency range.
7. Non-corrosive to metals and non-solvent for rubber and plastics.

The characteristics of these fluids are shown in Table 5.

Table 5. Properties of Some Liquid Silicones (Dow Corning)

Volume resistivity, 1×10^{14} ohm-cm

7. GASES AS DIELECTRICS

Dielectric Constant. The dielectric constants of gases are close to unity and nearly independent of frequency. The change in dielectric constant of dry non-polar gases with temperature or pressure is slight and may be calculated approximately from the equation

$$K - 1 = A \times \frac{p}{273 + t}$$

where A is a constant (2.12×10^{-4} for air).
p is the pressure in millimeters of mercury.
t is the temperature in degrees centigrade.

Table 6. Dielectric Constant of Gases

Conductivity and Ionization. The conductivity of gases at low potential gradients is negligible in the absence of ionizing radiation, such as ultraviolet light or X-rays. If a sufficient voltage gradient exists, all the ions are drawn to the electrodes as fast as they are produced and the very small ion current is constant over a considerable range of gradient. Increasing the gradient beyond this saturation range accelerates the negative ions (or electrons) to a velocity which is sufficient to expel electrons from neutral gas molecules at each collision.

If the number of ions liberated by the collisions exceeds the number of negative ions which are lost by recombination to form neutral molecules and by diffusion out of the field, the collision process is cumulative and the current increases continuously to breakdown. If the electric field is uniform, sparkover will occur, but if the high voltage gradients are confined to a small region, such as the vicinity of a pointed electrode, a local discharge, known as corona, occurs. Local discharges produce visible and ultraviolet light which is effective in increasing ionization throughout the field. This internal photo-ionization causes extremely rapid breakdowns of air gaps at sufficiently large voltage gradients.

Corona. The production of a corona discharge requires a considerable current which is carried by ions of lower velocity in the dark regions of the field. A significant power loss may occur if the corona becomes appreciable. Corona is objectionable because it causes radio-frequency interference and produces ozone if oxygen is present. Ozone and the ultraviolet light from the discharge cause rapid deterioration of many solid dielectric materials, especially of rubber. Corona is normally prevented by operation at reduced voltages or by the use of suitable corona shields which are designed to produce a more nearly uniform voltage gradient throughout the air space.

Dielectric Strength and Sparkover. Dielectric strength is the maximum potential gradient at the instant of sparkover or at the onset of corona. The gradient is determined by the geometry and spacing of the electrodes. Dielectric strength is influenced by the nature and purity of the gas, by the density of the gas, and to a lesser degree by the electrode material. When the mean free ion path between collisions is lengthened by lowering the gas density, the critical terminal velocity necessary for ionization by collision is attained with a lower potential gradient. The reduction in dielectric strength with decreasing density continues until the number of atoms between the electrodes is so small that very few collisions occur. If the density is still further reduced and the electric field is non-uniform, the sparkover will occur over some path longer than the shortest distance between electrodes. If the field is uniform, the sparkover voltage will increase as the density decreases to very low values, until, in a high vacuum, gradients as high as 6000 kv per cm may be obtained. The minimum in the sparkover voltage is independent of electrode spacing for uniform fields and depends solely on the nature and purity of the gas and on the electrode material. A typical set of values for various gases is shown in Table 7.

Table 7. Minimum Sparking Potentials

Gas	Volts (d-c)	Gas	Volts (d-c)
Air	341	Hydrogen	278
Carbon dioxide	419	Nitrogen	251
Helium	261	Oxygen	455

Sparkover voltage in uniform fields is a nearly linear function of the product of gas density and electrode spacing (Paschen's law).

An empirical equation which reproduces the entire sparkover curve in air for uniform fields, including the region around the minimum sparking potential, is

$$V = \frac{404pS \dfrac{293}{273 + t}}{3.000 + \log_e \left(pS \dfrac{293}{273 + t} \right)} + 300 \text{ volts (crest)}$$

where p is the pressure in millimeters of mercury.
S is the electrode spacing in centimeters.
t is the temperature in degrees centigrade.

The calculation of the sparkover voltage for non-uniform fields is not simple; see F. W. Peek, *Dielectric Phenomena in High Voltage Engineering*, McGraw-Hill (1929) for extensive formulas and tables for this purpose. At spacings of the order of one-half the sphere radius, the sparkover voltage of a gap between equal spheres is slightly higher than for a uniform field, but as the ratio of spacing to radius increases the sparkover voltage becomes much less than for a uniform field. At ratios above 2, corona occurs before sparkover, but corona is not easily detected at 60 cycles until the ratio is about 8. Representative sparkover voltages for sphere gaps are shown in Table 8.

* NG = electrodes balanced to ground.
† G = one electrode grounded.

Table 9 shows the influence of altitude on sparkover voltage at constant temperature for uniform fields in gaps of various lengths. The table also is approximately correct for closely spaced sphere gaps. Correction for the lower air temperatures shown is seldom warranted unless the actual temperature of the air in the gap is known.

Table 9. Sparkover Voltages at High Altitudes

Ratio of sparkover voltage to sea-level sparkover in uniform fields

Altitude, Unit = 1000 ft	Standard Air Temp, 0° C	Pressure		Relative Pressure	Sparkover Voltage at Constant Temperature

The dielectric strength of gases is subject to large changes with impurities. At low pressures, 0.1 per cent of argon in neon gas reduces the dielectric strength by 75 per cent. Mercury vapor likewise lowers the sparkover voltage. At atmospheric pressure, the addition of small amounts of carbon tetrachloride or chloroform vapor increases the dielectric strength by 50 per cent. Table 10 shows the approximate relative dielectric strength of gases. Although Freon (dichlorodifluoromethane) has a higher relative dielectric strength, its vapor pressure varies from 9.3 psi at −40 deg cent to 139 at +40 deg cent, whereas the pressure with sealed-in nitrogen increases by only 35 per cent in this interval. Furthermore, if the Freon does break down, its decomposition products are corrosive and carbon is deposited. Dry, oil-pumped nitrogen is undoubtedly the best gas dielectric unless cooling is involved, which may necessitate the use of hydrogen.

Table 10. Approximate Relative Dielectric Strength of Gases

Gas	Pressure in Absolute Atmospheres				
	1/3	1	2	4	8
Nitrogen	1.0	1.0	1.0	1.0	1.0
Air	0.9	0.9	0.9	0.9	1.0
Oxygen	0.9	0.8	0.8	0.8	....
Carbon dioxide	0.9	0.9	0.9	0.9	0.8
Hydrogen	0.6	0.6	0.6	0.6	....
Freon	....	2.4	2.2	2.2	2.2
Nitrogen plus carbon tetrachloride vapor	....	1.6	1.5	1.3	1.2
Helium	0.3	....	....	....	....

At frequencies above 10 kc the dielectric strength of air decreases slightly. Owing to the low velocity of positive ions, they are not swept to the electrodes during one half cycle, so that they remain to distort the field on the next half cycle. At frequencies above 60 kc, a reduction of 7 to 13 per cent in breakdown voltage is to be expected, but no further decrease occurs up to at least several megacycles. If the gap is illuminated with ultraviolet light, a decrease of 17 to 20 per cent is obtained.

MAGNETIC MATERIALS

By R. M. Bozorth and R. A. Chegwidden

Of all the common elements only iron, cobalt, and nickel have magnetic properties greatly different from those of air or vacuum. The magnetic materials in common use consequently contain at least one of these elements and sometimes all three. These materials, called *ferromagnetic*, make possible the operation of motors, generators, transformers, and practically all electromagnetic devices.

Non-ferromagnetic materials are of little importance on account of their magnetic properties. They fall into two classes: *paramagnetic* materials which are but slightly more magnetic than a vacuum, and are therefore attracted weakly by the poles of an electromagnet, and *diamagnetic* materials which are repelled weakly by an electromagnet Because the magnetic materials used in communication are almost without exception ferromagnetic materials, this article will be devoted to a description of this class. They may be divided into "high permeability" (or magnetically "soft") and "permanent magnet" (or magnetically "hard") materials. Ferromagnetic materials are commonly referred to as simply "magnetic" materials.

The magnetic properties of materials depend primarily on the nature of the atoms which compose them. In magnetic materials the atoms are small permanent magnets that owe their magnetic moments to uncompensated spinning electrons lying in electron shells inside the atom. For a material to be ferromagnetic these shells must be incomplete (i.e., have spaces for more electrons than are present) and have an excess of electrons spinning in one direction, and the atoms must be arranged in regular fashion on a space lattice, with atom centers not too close together. The important elements whose atoms fulfil these conditions occur in one part of the periodic table—they are iron, cobalt, and nickel. Gadolinium has been found to be ferromagnetic, and manganese and chromium can also give rise to ferromagnetism when alloyed or chemically combined with the right non-ferromagnetic elements. The *Heusler alloys* are composed of manganese, aluminum, and copper; in comparison with many of the alloys of iron, cobalt, and nickel, they are quite inferior from a practical magnetic standpoint and have had no commercial use.

Magnetic properties depend also on crystal structure, state of strain, temperature, and other factors.

8. MAGNETIC CHARACTERISTICS

MAGNETIZATION AND PERMEABILITY CURVES. The properties of magnetic materials are usually described first of all by a *magnetization curve* such as that shown in Fig. 1. Here the *magnetic induction*, B, in a ring sample is plotted against the *magnetizing force*, H.

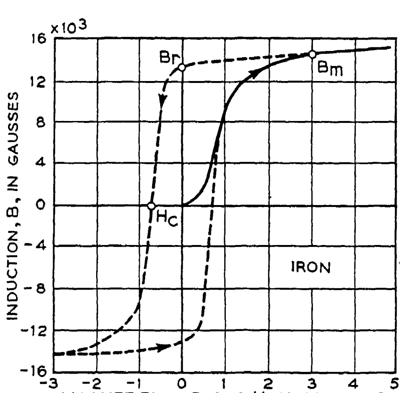

FIG. 1. Magnetization Curve and Hysteresis Loop for Annealed Iron Ring

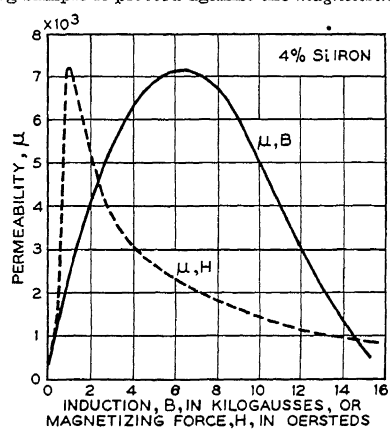

FIG. 2. Typical Permeability Curves for Hot-rolled 4 Per Cent Silicon Iron

B is a measure of the amount of the magnetization; it is defined specifically below under "Definitions." H represents the magnetizing force required to produce the magnetic induction, B; it is usually measured in oersteds or in ampere-turns per inch. The magnetic induction is sometimes described in terms of the intensity of magnetization, I, equal to $(B - H)/4\pi$. The increase in induction due to the material alone is $B - H$, sometimes called the *intrinsic induction;* this quantity becomes important when the magnetizing force is high, e.g., when determining B_s, the saturation induction, highest attainable value of $B - H$ in a material.

The ease with which a magnetic material can be magnetized is measured by the ratio B/H, called the *permeability*, μ. Typical permeability curves plotted against B and H are shown for a sample of 4 per cent silicon-iron in Fig. 2.

In communication work, the permeability in low fields is especially important. Figure 3 shows the characteristic μ, H curves for several common materials; in the lowest fields the curves usually become straight lines.

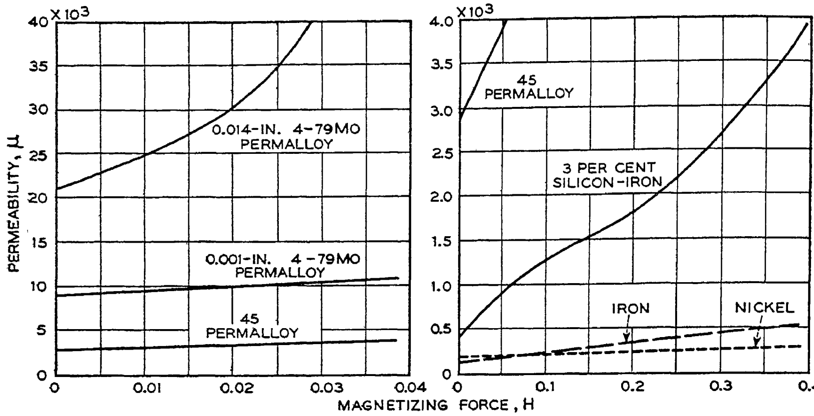

FIG. 3. Characteristic μ vs H Curves at Low Magnetizing Forces

Hysteresis Loops. Other important properties of magnetic materials are shown by the hysteresis loop produced when B is plotted against H, as H is increased to a maximum, decreased to zero, increased to a maximum in the negative direction, again reduced to zero, and finally increased to the first maximum as shown by the dotted line in Fig. 1. The values of B and of H at which this curve crosses the axes are called respectively the residual induction, B_r, and coercive force, H_c, as indicated in the figure. The area enclosed within the hysteresis loop is a measure of the magnetic energy transferred into heat during the cycle and is designated W_h. Quantitatively

$$W_h = \frac{1}{4\pi} \oint H\, dB$$

in ergs per cm³ when B and H are in gausses and oersteds, respectively.

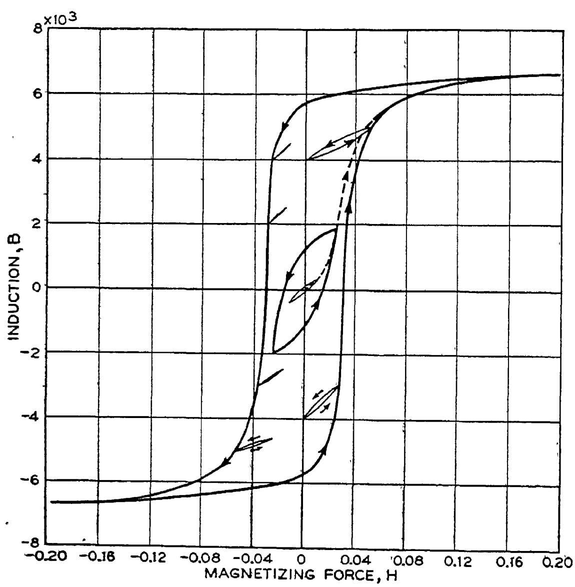

FIG. 4. Minor Hysteresis Loops Shown at Various Points on the Major Loop for a Specimen of 4–79 Molybdenum Permalloy

Demagnetization Curve. That part of the hysteresis loop that lies in the second quadrant, extending from B_r to H_c in Fig. 1, is called the demagnetization curve and is especially important for the description of permanent-magnet materials. This is described more fully in Article 10 and Fig. 10. Hysteresis loops which do not have equal excursions of H (and B) in opposite directions are unsymmetric or minor loops. Some of these are shown in Fig. 4. In a minor loop the ratio of the total change in B, ΔB, to the total change in H, ΔH, is called the incremental permeability $\mu_\Delta = \Delta B/\Delta H$. In the limit as ΔB and ΔH approach 0, the incremental permeability is the *reversible permeability*, μ_r. This is sometimes referred to as superposed permeability, and is discussed in more detail in Article 15 (Fig. 24).

Air Gaps. When an air gap is cut in a closed magnetic circuit, such as a ring sample, magnetic poles are produced on either side of the break, and the apparent permeability of the material is reduced because of the reluctance of the gap. The effect of even a small air gap in a high-permeability circuit may be very appreciable. See Fig. 5, and Fig. 19 of Article 15.

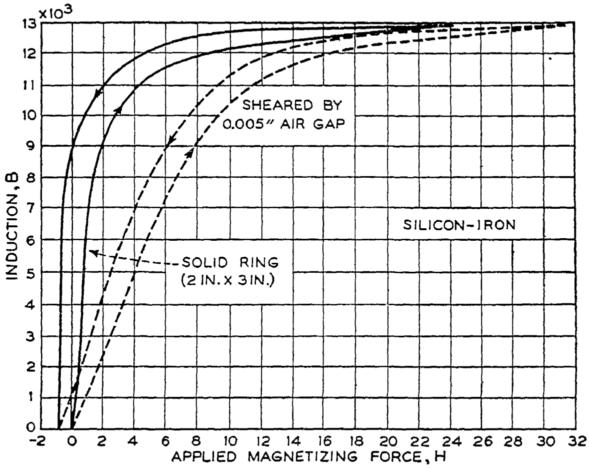

FIG. 5. Magnetization Curves and Parts of Hysteresis Loops Showing Effect of 0.005-in. Air Gap Cut in a Silicon Iron Ring 2-in. I.D. by 3-in. O.D.

Eddy-current Loss. When magnetic fields are varied with some rapidity, as they are in most machinery, the material is subject not only to the hysteresis loss already described but also to eddy-current loss. This results from the flow of electric currents within the material, induced by the changing flux in them. They increase with increase in the frequency, conductivity, and permeability of the material. Since time is required for these currents to build up and to decay, the application of a varying field is accompanied by a delay in the corresponding magnetic induction. The summation of the hysteresis and eddy-current losses is frequently called the core loss or iron loss of the material.

DEFINITIONS. The following definitions are taken from ASTM Specification A127 which may be referred to for definitions of other terms relating to magnetic materials. This list is in alphabetical order, for reference only.

Coercive Force. H_c. The magnetizing force required to bring the induction to zero in a magnetic material which is in a symmetrically cyclically magnetized condition. The *coercivity* is that property of a material measured by the maximum value of the coercive force.

Induction, Intrinsic. B_i. The excess of the induction in a magnetic material over the induction in vacuum, for a given value of the magnetizing force. The equation for intrinsic induction is

$$B_i = B - H$$

Induction, Magnetic (Magnetic Flux Density). B. Flux per unit area through an element of area at right angles to the direction of the flux. The cgs unit of induction is called the gauss (plural gausses) and is defined by the equation:

$$B = \frac{d\phi}{dA}$$

Under a-c conditions B_{max} may be calculated as follows:

$$B_{max} = \frac{E \times 10^8}{4\,ff\,NAf}$$

where E is in rms volts; ff is the form factor.

Induction, Normal. B. The limiting induction, either positive or negative, in a magnetic material which is in a symmetrically cyclically magnetized condition.

Induction, Residual. B_r. The magnetic induction corresponding to zero magnetizing force in a magnetic material which is in a symmetrically cyclically magnetized condition. The *retentivity* is the property of a magnetic material measured by the maximum value of the residual induction.

Induction, Saturation. B_s. The maximum intrinsic induction possible in a material.

Magnetic Flux. ϕ. A condition in a medium produced by a magnetomotive force, such that when altered in magnitude a voltage is induced in an electric circuit linked with the flux. The cgs unit of magnetic flux is called the maxwell and is defined by the equation:

$$e = -N\frac{d\phi}{dt} \times 10^{-8}$$

where e = induced emf in volts, and $d\phi/dt$ = time rate of change of flux in maxwells per second.

Magnetizing Force. H. Magnetomotive force per unit length. The cgs unit is called the oersted and is defined by the equation:

$$H = \frac{dF}{dl}$$

where F is in gilberts and l in centimeters. For a toroid, or at the center of a long solenoid, the magnetizing force in oersteds may be calculated as follows:

$$H = \frac{0.4\pi NI}{l}$$

where I is in amperes and l is in centimeters.

Magnetomotive Force. F. That which tends to produce a magnetic field. In magnetic testing it is most commonly produced by a current flowing through a coil of wire, and its magnitude is proportional to the current and to the number of turns. The cgs unit of magnetomotive force is called the gilbert and is defined by the equation:

$$F = 0.4\pi NI$$

where I is in amperes. Magnetomotive force may also result from a magnetized body.

Permeability, a-c. μ_{ac}. A-c permeability is variously defined, and the values obtained for a given material depend on the methods and conditions of measurement. As measured by the Standard Methods of Test for Magnetic Properties of Iron and Steel (ASTM Designation A34), it is the ratio of the maximum value of induction to the maximum value of the magnetizing force for a material in a symmetrically cyclically magnetized condition.

It is sometimes defined as the ratio of the rms flux density to the rms magnetizing force. Some of the factors which affect a-c permeability are thickness of laminations, frequency, and resistivity.

Permeability, Incremental. μ_Δ. The ratio of the cyclic change in magnetic induction to the corresponding cyclic change in magnetizing force when the mean induction differs from zero.

Permeability, Initial. μ_0. The slope of the normal induction curve at zero magnetizing force.

Permeability, Normal. μ. The ratio of the normal induction to the corresponding magnetizing force. In the cgs system the flux density in a vacuum is numerically equal to the magnetizing force, and, consequently, the magnetic permeability is numerically equal to the ratio of the flux density to the magnetizing force. Thus:

$$\mu = \frac{B}{H}$$

Note: In a non-isotropic medium the permeability is a function of the orientation of the medium, since, in general, the magnetizing force and the magnetic flux are not parallel.

Permeability, Reversible. μ_r. The incremental permeability when the cyclic change in induction is vanishingly small.

9. HIGH-PERMEABILITY MATERIALS

Preparation and Heat Treatment. In many applications such as motors, generators, transformers and relays, it is desirable to have materials of high permeability. The common materials used are iron, silicon-iron alloys, and iron-nickel alloys to which various other metals have been added. Commercial materials are usually melted in open-hearth or electric furnaces, poured to form ingots, then rolled to slabs and finally to sheets or rods of the required dimensions. After fabrication into the final form in which they are to be used, they must be subjected to a heat treatment which is appropriate to the particular alloy, in order to develop their best magnetic qualities. These heat treatments usually consist of heating to some temperature lying between 800 and 1200 deg cent and cooling at a definite rate to room temperature. Figure 6 shows magnetization curves for ingot iron, (1) as hot and cold rolled to final size, (2) as annealed at 900 deg cent for 1 hour, and (3) after heat treatment at the unusually high temperature of 1400 deg cent for 6 hours. The anneal at 900 deg cent may be referred to as a strain-relief anneal; that at the higher temperature as a purifying anneal because during the process some of the impurities have been removed from the iron.

In processes involving annealing, account must be taken of phase transformations and "order-disorder" phenomena (orderly arrangements of the atoms) like those found in iron and Permalloy, respectively. In some materials, such as the nickel-manganese alloys, a magnetic material may be made non-magnetic by cooling rapidly from a high temperature and thus preserving the disorderly distribution of nickel and manganese atoms stable at this temperature. In the iron-nickel alloys containing 50 to 80 per cent nickel, marked changes in properties are produced by annealing in the presence of a magnetic field.

Magnetic Elements. Of the magnetic elements, iron, cobalt, and nickel, iron is the only one used commercially to any considerable extent in unalloyed form. It is made in large tonnages for motors, generators, and relays. Its characteristic properties are described in Fig. 9 and Table 1. Nickel finds a limited use because of its magnetostrictive properties, for example in supersonic underwater apparatus.

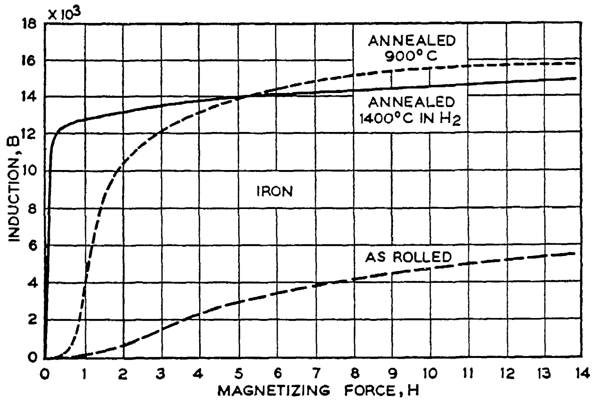

FIG. 6. Effect of Heat Treatment on the Magnetic Properties of Iron

Iron-silicon Alloys. Next to unalloyed iron, these alloys are used in the greatest quantities, in power transformers, motors, generators, relays, and receivers. The addition of silicon increases the resistivity and so cuts down the power loss due to eddy currents, and it also has some effect in increasing the permeability and decreasing the hysteresis loss. Various commercial grades are available containing up to about 5 per cent silicon. Great advances have been made in the last few years by fabricating the sheet by cold rolling instead of hot rolling. As with most magnetic materials, the iron-silicon crystals are most easily magnetized along one particular crystallographic direction, and the cold rolling and associated heat-treating processes are adjusted to orient the crystals so that as many as possible have their directions of easy magnetization aligned in the direction of rolling. Material made in this manner is called *grain oriented.* The grain-orienting process

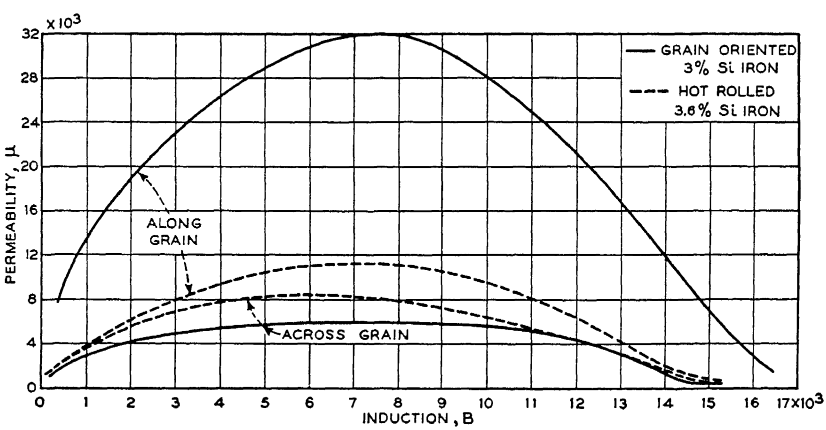

FIG. 7. Comparison of the μ *vs* B Curves for Samples of Hot-rolled and Grain-oriented Silicon Iron

increases the permeability and reduces hysteresis loss. The increase in permeability, however, is effective only when the sheet is magnetized in the direction in which it is rolled, and in most other directions the permeability is lowered. Grain-oriented silicon-iron is available in grades containing up to slightly over 3 per cent silicon. Properties of the grain-oriented material containing 3 per cent silicon are compared with the hot-rolled product in Fig. 7.

Iron-nickel Alloys. These alloys are used when particularly high quality is desired, usually in transformers of various kinds and in magnetic shields. Their permeabilities are much greater than those of other alloys, and they have high resistivity and low energy loss. The most important binary alloys contain 78 per cent nickel and 45 to 50 per cent nickel. The former, called *78 Permalloy* or Permalloy A, has a high initial permeability (about 10,000) and a low coercivity (0.05) and requires special heat treatment for the development of these properties. After the usual anneal at 1000 to 1100 deg cent it must be cooled rapidly in order to develop maximum quality. The iron-nickel alloys containing 45 to 50 per cent nickel are useful in certain relays, transformers, receivers, and other apparatus. They have reasonably high permeabilities and incremental permeabilities, and their saturation inductions and resistivities are higher than those of the 78 per cent alloy. The cooling rate from the annealing temperature is not critical for these alloys.

Another development in this field is the grain-oriented 50 per cent nickel-iron alloy, originated in Germany and called Permenorm 5000-Z. After special heat treatment, this material exhibits hysteresis loops which are practically rectangular. The grain orientation is accomplished by a 99 per cent cold reduction before the final heat treatment.

When higher resistivities are required, other elements are added to the iron-nickel alloys, and it is often found that the resulting alloy has also higher initial and maximum permeabilities. One of the most useful of these is *Molybdenum Permalloy* containing 4 per cent molybdenum and 79 per cent nickel. Similar properties are obtained in *Mumetal* containing 2 per cent chromium, 5 per cent copper, and 75 per cent nickel. Initial permeabilities of 20,000 to 30,000 and maximum permeabilities of about 100,000 are often found in these alloys. The molybdenum Permalloy must be heat-treated under non-oxidizing conditions and preferably cooled at a definite rate; the Mumetal must be heat-treated in a hydrogen atmosphere for best results. An alloy containing 5 per cent molybdenum and 79 per cent nickel is called *Supermalloy* and has an initial permeability of 50,000 to 150,000 and a maximum permeability of about 1,000,000. These properties are obtained by controlled melting of suitable raw materials, heat treating in hydrogen at 1300 deg cent, and cooling at a critical rate.

Some interesting properties have been obtained in alloys containing nickel, iron, and cobalt, called *Perminvars*. A typical alloy contains 45 per cent nickel, 25 per cent cobalt, and 30 per cent iron, and its permeability is characteristically independent of magnetizing force over a relatively large range. To retain this property, however, it must never be magnetized above this range. Above the range of constant permeability the hysteresis loops have peculiar constricted forms with very low residual induction at intermediate field strengths. At present these alloys are not being used commercially.

Iron-cobalt Alloys. Alloys of iron with approximately 35 per cent to 55 per cent cobalt are remarkable in that the saturation, B_s, is higher than that of either iron or cobalt. One of these alloys, containing equal parts of iron and cobalt, is called *Permendur;* it is useful where high flux densities are necessary as in the pole tips of electromagnets. The binary alloys of iron and cobalt can be hot rolled and machined, but they are very difficult to cold roll. *Vanadium Permendur* contains 2 per cent vanadium and equal parts of iron and cobalt; the addition of vanadium makes it possible to cold-roll the alloy to thin sheets. In this form it has found an important application in telephone diaphragms. Vanadium Permendur can be machined and even punched after cold rolling, but it becomes somewhat brittle when annealed. At high inductions the superposed permeability of the iron-cobalt alloys is higher than that of any other material (see Fig. 24).

Other Alloys. Among the other alloys that have high permeability may be mentioned aluminum-iron, molybdenum-iron, and *Sendust*, the last developed by the Japanese. *Aluminum-iron* containing up to about 6 per cent aluminum has been produced having magnetic properties somewhat better than the iron-silicon alloys, but because of manufacturing difficulties it has never been popular. In Japan high permeabilities have been obtained in the alloy containing 14 to 15 per cent aluminum, called *Alfer*. *Iron-molybdenum* alloys also have good magnetic permeabilities at low and moderate flux densities and are more ductile than the iron-silicon alloys. Although they are not in common use, at least one manufacturer is planning to market them. *Sendust* contains about 9 per cent silicon, 5 per cent aluminum, and the rest iron. Both initial and maximum permeability are high, the initial sometimes as high as 35,000. *Sendust* is an unusual high-permeability material in that it is quite brittle and must be cast and ground to finished size. Because of its brittleness, *Sendust* has been formed into powder and used, especially in Japan, in pressed powder cores for loading coils and other coils for high-frequency circuits.

Other materials are useful in powdered form for applications of this kind. Most important among them are *powdered Permalloy* and *Carbonyl iron*. The former has the nominal composition of 2 per cent molybdenum, 80 per cent nickel, and 18 per cent iron; it is melted without the addition of a deoxidizer or desulfurizer, and after hot rolling it can

be crushed to a fine powder. It is then mixed with a small amount of insulation and pressed into a solid core and heat-treated. The permeability varies, depending upon the amount of insulation, from about 10 to 125. Both hysteresis and eddy-current losses are extremely small, and the permeability is constant over a large range of magnetizing force.

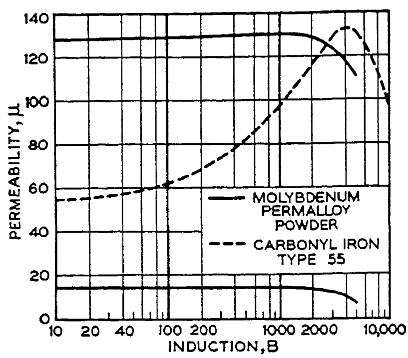

Fig. 8. Examples of Permeability Curves for Cores of Molybdenum Permalloy and Iron Carbonyl Powders

Carbonyl iron powder, prepared by decomposing iron carbonyl, $Fe(CO)_5$, in the vapor phase, consists of small spheroids which are later insulated and pressed. All these powdered materials are used in the cores of coils operating at high frequency; Fig. 8 shows some of their properties.

Often, when the frequency is greater than 1 megacycle, a powder is used composed of one of the iron oxides Fe_2O_3 or Fe_3O_4. Also, properly treated mixtures of complex ferrites, e.g., manganese and zinc ferrites, have been found to have very high electrical resistivities and initial permeabilities of the order of 1000. Materials of this type, developed in Holland under the name *Ferroxcube*, have been used advantageously for certain types of high-frequency coils. The ferrites in general have much higher initial permeabilities but less stability with temperature as compared with the insulated powder materials.

Many of the properties of the most important commercial magnetic materials of high permeability are collected in Table 1 and Fig. 9.

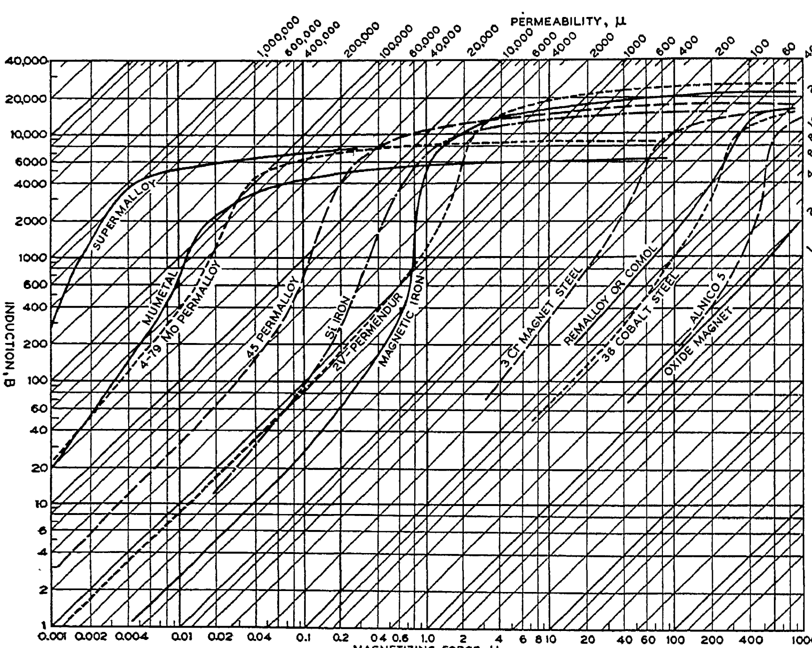

Fig. 9. Magnetization and Permeability Curves for Magnetic Materials in Common Use

Non-magnetic Materials. It is often desirable in dealing with magnetic circuits to have a steel for structural purposes which is non-magnetic. One commonly used material of this sort, called *Lomu*, contains about 10 per cent manganese, 8 per cent nickel, and the remainder iron; chromium and silicon are also sometimes added. Another material is of the stainless-steel type containing 20 to 25 per cent nickel and 25 per cent chromium.

10. PERMANENT-MAGNET MATERIALS

Permanent magnets are useful for their ability to maintain a magnetic field in space without the aid of an external source of power. Since there is no heating, and since modern alloys can produce very high fields, they are used extensively in loudspeakers, small generators, etc. The properties of these materials are best described by means of the demagnetization curve already mentioned. Typical curves for many of the common materials are shown in Fig. 10. In evaluating materials it is also desirable to use an *energy*

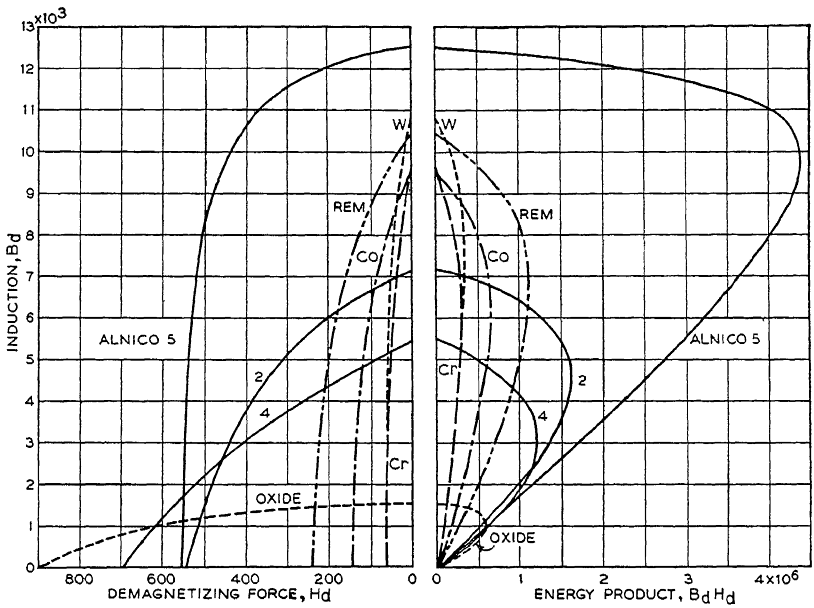

FIG. 10. Demagnetization and Energy Product Curves of Some Important Permanent-magnet Materials. The materials corresponding to the abbreviations may be recognized by reference to Table 2.

product curve formed by plotting the product of B and H, BH, against the magnetic induction B, for points on the demagnetization curve; this is plotted also in Fig. 10. Such a curve is a measure of the energy that can be stored in the magnet, and the best single criterion for the value of a permanent-magnet material is the maximum value of this product, designated $(BH)_m$. In the design of magnetic circuits involving permanent magnets an attempt is usually made to have the magnetic induction in the magnet equal to the B for which (BH) is equal to $(BH)_m$.

The magnetic behavior of a magnet may be described by reference to Fig. 11. The line OA depends on the dimensions of the magnet and is called the load line; it is fixed by the demagnetizing action of the air gap in the magnetic circuit. When the external field has been removed, B and H will be determined by some point on this line, preferably the point for which (BH) is a maximum. It is common practice to "stabilize" a magnet by applying a small negative magnetizing field (point C) and then removing it (point D). Extraneous disturbing fields will then cause changes in induction corresponding to minor loops such as $CDEC$. The minor loops in the third quadrant, under the demagnetizing curve, have slopes approximately the same as the slope of the demagnetizing curve just below the point B; they are important in predicting the changes in induction that occur, e.g., in generators.

Permanent-magnet materials may be classified under the following headings:

- Carbon steel with or without alloying elements.
- Dispersion-hardened alloys.
- Types heat-treated in a magnetic field.
- Ductile alloys.
- Powdered materials.
- Miscellaneous special materials

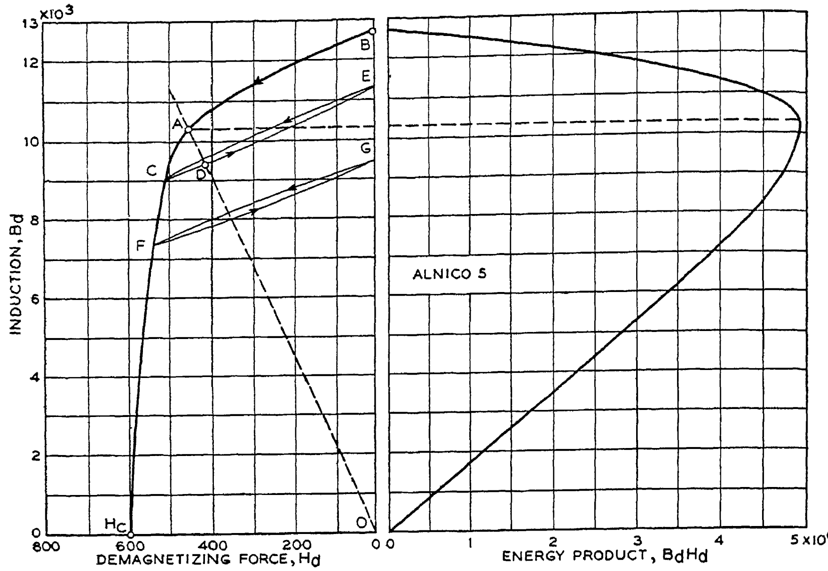

FIG. 11. Curves Useful in the Design of Permanent Magnets. See text.

Carbon Steels. The carbon steels are so called because they depend upon carbon compounds for their permanent-magnet qualities. These materials are usually prepared by hot rolling to finished size and quenching from about 800 to 950 deg cent in water or oil. Their permanent-magnet characteristics tend to deteriorate with time, and it is customary to pre-age such magnets before use by maintaining them for many hours at temperatures between 100 and 150 deg cent. Although their magnetic properties are not of very high quality, many of the carbon-steel magnet alloys are very useful because of their low cost.

The most common steels are carbon-manganese, chromium, tungsten, and cobalt steels. There is a great variety of materials of this kind containing various percentages of the alloying elements and about 0.8 per cent carbon. Representative alloys have been included in Table 2. The coercive force and energy product, as well as the cost, usually increase with the alloying element. The highest energy product obtained in this group is about 1.0×10^6.

Dispersion-hardening Alloys. These alloys contain no essential carbon but depend for their hardening upon the precipitation of one solid phase in another. They are ordinarily heated to 1300 deg cent and quenched in air or oil and are subsequently maintained at 600 to 700 deg cent for several hours; they are therefore often referred to as "age-hardening" alloys. Generally they are quite brittle and, with the exception of one type, must be cast and ground to final size. One of the first alloys of this type to be used commercially contains 71 per cent iron, 12 per cent cobalt, and 17 per cent molybdenum; it is called *Remalloy* or *Comol.* This alloy may be hot-rolled and machined to required size like the carbon steels. To give it permanent-magnet qualities, it is quenched from 1200 deg cent and aged at 700 deg cent for about an hour. Like most dispersion-hardening alloys, the properties of Remalloy do not change appreciably with time. It has found use in meters, receivers, and other devices.

Large quantities of dispersion-hardening alloys are made of the iron-nickel-aluminum type to which have been added cobalt, copper, or titanium. All these alloys, called in this country the *Alnicos*, are brittle and must be cast and ground to size. The addition of titanium up to 8 per cent is sometimes effective in causing high coercive force. Heat treatments and properties are given in Table 2.

Types Heat-treated in a Magnetic Field. The most important of the dispersion-hardening alloys was developed in Holland as *Ticonal* and, with slight variations, is known in the United States as *Alnico 5* and in England as *Alcomax.* The alloy of the proper composition as given in the table is heated to 1300 deg cent and then cooled in air in the presence of a strong magnetic field which must be applied to the magnet in the direction in which the best properties are desired. After aging at about 600 deg cent energy products as high as 5×10^6 are obtained.

* Trade names.

The interesting oxide magnets made by the Japanese also require a strong magnetic field for developing their best properties. The proper amounts of iron and cobalt oxides (Fe_2O_3, Fe_3O_4, and Co_2O_3) are pressed and heated to 1000 deg cent. They are then cooled and crushed and pressed to final form, then reheated to 1000 deg cent, and finally cooled in a strong magnetic field. Large variations are found in coercivity and retentivity, depending on how the oxides are mixed and treated; H_c ranges from 600 to 1000 and B_r from 4000 to 1500. This material is unusually light in weight and has exceptionally high resistivity. One product, marketed under the trade name *Vectolite*, has a coercivity of 900 and a retentivity of 1600.

Ductile Alloys. Within the last few years a number of ductile permanent-magnet alloys have appeared on the market. The largest application has been in wire and tape form for the magnetic recording of speech. The first alloys of this type were based on the German material containing 20 per cent iron, 20 per cent nickel, and 60 per cent copper, known in this country as *Cunife*. Another variation, called *Cunico*, contains cobalt. Most of these alloys can be cold-drawn to fine wires; in fact, such cold reduction is often necessary to develop their best properties. *Vicalloy*, made of iron, cobalt, and vanadium, is another alloy of this type. Its properties also depend upon the amount of cold reduction, and an energy product of 1.5×10^6 can be developed after cold rolling and annealing at about 700 deg cent. By drastic cold reductions energy products as high as 4×10^6 can be obtained.

Powdered Materials. Several of the brittle alloys mentioned above can be produced from powders which are pressed into the desired shape, sintered at a high temperature, and heat-treated to give the best magnetic properties. This is often advantageous in producing small magnets, when the methods of powder metallurgy can be used. Alnico 2 is important in this class, and Alnico 5 has been used on an experimental scale.

A recent development is material obtained by pressing powder of very fine size, such as that produced by the reduction of iron compounds at low temperature. One product, manufactured in France, is composed essentially of fine particles of iron, sometimes with admixture of cobalt, and has properties much like those of Alnico 2.

Special Alloys. A few other alloys are worthy of brief mention. These are the cobalt-platinum alloys, the manganese-silver-aluminum alloy (*Silmanal*), and certain alloys formed by electrodeposition on a mercury surface, e.g., iron with a small admixture of zinc or iron-cobalt-nickel-aluminum alloys. Experimentally this alloy has been made with coercivities of 400 to 500 and retentivities of 9000 to 11,000.

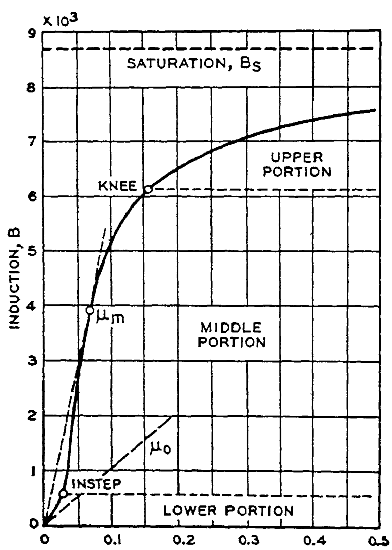

FIG. 12. Magnetization Curve Showing the Points of Special Interest, and Division into Three Main Parts

11. MAGNETIZATION CURVE

In this section will be considered briefly the nature of the changes in magnetization that correspond to different parts of the magnetization curve, and some relations valid in each part.

The magnetization curve may be divided into three parts separated by the "instep" and "knee" (see Fig. 12). At the instep the curve takes a sudden upward turn and the permeability increases rapidly. At the knee this trend is reversed and the curve becomes more and more horizontal and approaches asymptotically to saturation. In each of the three parts of the curve, magnetization proceeds by a different mechanism, as described below.

A magnetic material is composed of many small magnetized regions or *domains*, each of which is always magnetized to saturation in some one direction. When the material as a whole is unmagnetized, these domains are arranged in various directions so that the net magnetization of the material is zero. The effect of the field is to change either the direction in which the domains are magnetized or to change the volume of some of the domains at the expense of their neighbors. This may be made clear by reference to Fig. 13, where the domains are represented by arrows indicating the directions in which they are magnetized. The directions of stable magnetization are determined in an annealed material by the magnetic properties of the crystals of which it is composed, and in severely cold-worked material by the internal strains present.

In the first part of the magnetization curve, below the instep, magnetization proceeds by small displacements of the boundaries between domains, a process illustrated in part (*b*) of Fig. 13. In this portion the permeability usually increases linearly with magnetizing force:

$$\mu = a + bH$$

In the second part of the curve, between the instep and the knee, the domains change direction suddenly and the magnetization changes from one direction of stable magnetization to another. In this section Steinmetz' law of hysteresis is applicable:

$$W_h = \eta B^{1.6}$$

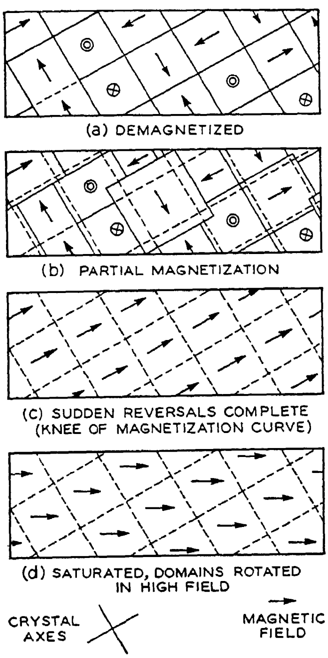

FIG. 13. Diagram Illustrating Changes in Domain Structure with Magnetization in a Single Crystal of Iron

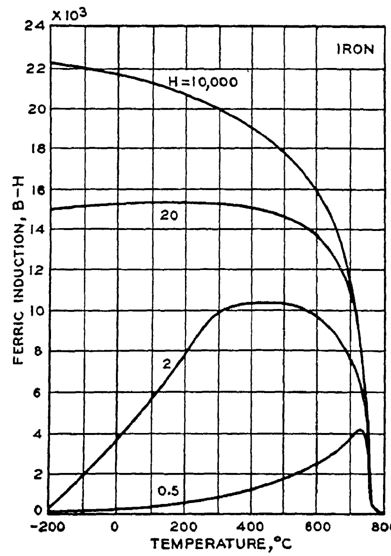

FIG. 14. The Magnetic Induction of Iron Measured at Various Temperatures, with Various Impressed Fields

In the third section the domains rotate smoothly from the stable directions indicated in (*c*) into parallelism with the magnetic field as indicated in (*d*); here the Fröhlich-Kennelly relation

$$\frac{1}{\mu} = c + dH$$

is approximately valid.

Evidence for the domain structure of materials is found in the Barkhausen effect, which proves that sudden changes in magnetization occur in the middle section of the magnetization curve, and in the existence of powder patterns which can be seen under a microscope and which show that the magnetic field at the surface of a demagnetized magnetic material varies from place to place over regions about 0.1 mm apart.

12. EFFECT OF TEMPERATURE

The magnetization of a material can be altered not only by changing the magnetic field but also by varying mechanical stress or temperature. Temperature affects the magnetic properties of all materials, in a way that depends on the induction and the character of the material. Figure 14 shows this effect for iron. Eventually, as the temperature is raised, the material becomes non-magnetic, the temperature at which this occurs being called the *Curie point* of the material. When a high constant magnetic field is present, the magnetization decreases continually as the temperature increases, and at a faster and faster rate as the Curie point is approached. When a low field is present, the permeability first increases with temperature and then decreases again and approaches 1 at the Curie point.

For some applications it is desirable to have a material with a permeability that decreases rapidly as the temperature increases. These materials are used in compensating permanent magnets for changing temperature and for stabilizing pressed powdered cores to make their inductance independent of temperature. The alloys used for this purpose have a Curie point near room temperature so that the material loses its magnetism rapidly as the temperature increases in this region. One such alloy contains about 30 per cent nickel and the rest iron; it has been used for compensating permanent magnets. Another type, containing 80 per cent nickel, 12.5 per cent molybdenum, and the rest iron, is commonly used for stabilizing pressed powdered Permalloy cores. Still another type contains about 35 per cent nickel, 5 per cent chromium, 0.3 per cent silicon, and the rest iron.

13. STRESS AND MAGNETOSTRICTION

Figure 15 shows the way in which the magnetization may be affected by the application of tensile stress. A tension well within the elastic limit of the material will *increase* the magnetization of *45 Permalloy and decrease* that of pure nickel. Under certain conditions the permeability of some materials is increased by a factor of 50 by a stress within the elastic limit. Materials whose permeabilities are increased by tension are said to have positive magnetostriction, because they expand a few parts per million when they are

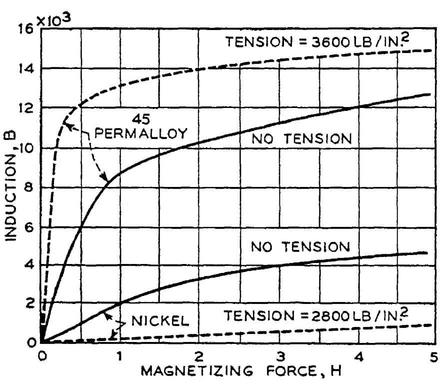

FIG. 15. Magnetization Curves for 45 Permalloy and Nickel as Affected by Tension

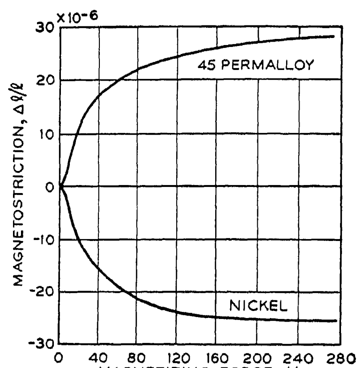

FIG. 16. Fractional Change in Length with Magnetizing Force for 45 Permalloy (Positive Magnetostriction) and for Nickel (Negative Magnetostriction)

magnetized; conversely, the permeability is decreased by tension if magnetization causes contraction of the material (negative magnetostriction, as in nickel). Some materials, like iron, have positive magnetostriction in low fields and negative magnetostriction in high fields.

Figure 16 shows how *45 Permalloy* and nickel change in length as the field strength increases. Such *magnetostriction* is capable of converting magnetic energy into mechanical energy, and nickel is often used in magnetostriction oscillators to produce supersonic vibrations in air or under water, where they are effective in sound ranging. The Japanese have used a new alloy, *Alfer*, containing 13 per cent aluminum and the rest iron, for magnetostriction oscillators; its magnetostriction is about the same in magnitude as that of nickel, but is opposite in sign.

14. EFFECT OF FREQUENCY

When the field acting on a magnetic material is alternated rapidly, eddy currents are induced in the material. They act so as to keep the a-c field from penetrating effectively more than a certain distance below the surface; this distance is measured in a rough way by the expression:

$$s = \frac{\sqrt{\rho/\mu f}}{2\pi}$$

wherein μ = true permeability (d-c).
ρ = 10^3 times resistivity in microhm-centimeters.
f = frequency in cycles per second.

The properties of the material are affected in three ways: (1) the effective permeability is reduced, (2) the energy loss in the material is increased, and (3) there is a time lag between the magnetizing force and the corresponding induction.

Only under certain restricted conditions can the effects of alternating current be predicted with any assurance of correctness. When the permeability is constant, as it usually is only when B *is very small*, the effective permeability, $\bar{\mu}$ (as determined with an inductance bridge) is given by the relation:

$$\frac{\bar{\mu}}{\mu} = \frac{1}{\theta} \cdot \frac{\sinh\theta + \sin\theta}{\cosh\theta + \cos\theta}$$

in which $\theta = 2\pi t\sqrt{\mu f/\rho} = t/s$.
t = thickness of sheet in centimeters.

Effective permeabilities, calculated by means of this equation, are compared with actual measurements in Fig. 17.

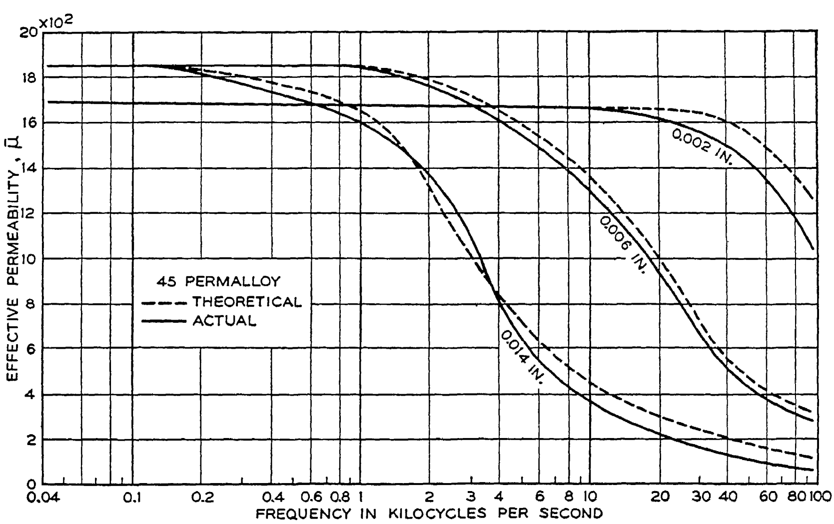

Fig. 17. Change in Effective Permeability with Frequency for 45 Permalloy of Different Thicknesses

When $\theta \gg 1$ (at high frequencies) this expression reduces to:

$$\bar{\mu} = \frac{\sqrt{\mu p}}{2\pi t} \cdot \frac{1}{\sqrt{f}} = \frac{\mu s}{t}.$$

Similar expressions are applicable to specimens in the form of wire or cylinders.

When μ is constant and $\theta < 1$ (frequency and induction low) the power loss may be expressed by the equation:

$$\frac{R}{L} = 2\pi f(h_0 + hB + ef)$$

in which R = excess of a-c resistance (by a-c bridge) over d-c resistance, in ohms.
L = inductance of coil in henrys.
B = maximum induction in gausses.

This relation is especially adapted to materials used in communication circuits in which there are feeble alternating currents. The constants h and e measure the hysteresis and eddy-current losses, respectively, and h_0 is of unknown origin, important only at the lowest B's.

At low frequencies ($\theta < 1$) and *high inductions* (B = 1000 to 14,000 in silicon-iron), the power loss in ergs per centimeter^3 per second is:

$$W = \eta B^{1.6} f + e B^2 f^2$$

The hysteresis constant, η, and the eddy-current constant, e, can be determined in an approximate way by plotting W/f vs. f for given values of B. At high frequencies eddy-current loss is usually more important than hysteresis loss, and is given in ergs per centimeter^3 per second by the relation:

$$W_e = \frac{\pi t \bar{B}^2 f^{3/2}}{\sqrt{\mu\rho}}$$

in which $\bar{B}$ is the value of B averaged over the cross-section of the sheet.

At frequencies higher than 10^8 cps the true permeability, μ, of magnetic materials begins to decrease substantially, approaching a value of the order of 1 at frequencies around 10^9 to 10^{11} cps.

Magnetization also affects the resistivity of magnetic materials. The change is almost invariably an increase in resistivity with magnetization, the amount of the increase varying from less than 1 per cent to about 5 or 10 per cent at room temperature, and even more at low temperatures. Similarly Young's modulus may be changed by about 10 per cent by magnetizing to saturation. Unusual variations are also observed in specific heat, thermal expansion, and other physical properties of magnetic materials.

15. MEASUREMENT OF MAGNETIC CHARACTERISTICS

Although it requires many different measurements to determine all the magnetic characteristics of a material, the most important properties can be obtained from a magnetization curve and hysteresis loop, an a-c measurement of the permeability and losses, and a measurement of the incremental permeability at various polarizing inductions.

Of the several methods that can be used for measuring magnetic properties, the *ballistic ring test*, due to Rowland, is perhaps the most reliable. In this test, a ring sample is wound with two uniformly distributed windings, consisting of a primary connected to a source of current, and a secondary connected to a *ballistic galvanometer* or *fluxmeter*. The induction produced by current in the primary winding is observed in terms of the fluxmeter deflection as the primary current is changed suddenly or reversed. The use of a ring sample eliminates the possibility of errors due to air gaps. To obtain uniformity of magnetizing force throughout the sample, the ratio of the outside diameter to the inside diameter of the ring should be not greater than 1.2. Figure 18 shows a typical electrical circuit for

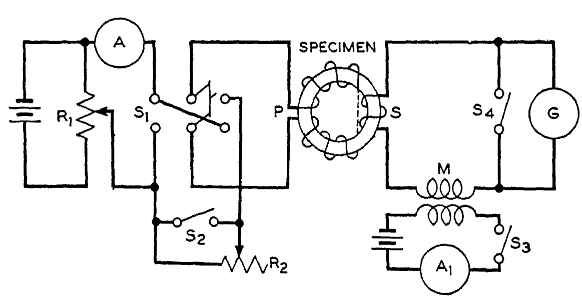

FIG. 18. Simplified Diagram of a "Ballistic Test" Circuit

this type of test, including a mutual inductance for calibrating the galvanometer or fluxmeter, G, and resistances R and switches S for regulating and changing the current in the primary winding, P. The field is calculated using the relation:

$$H = \frac{4N_pI}{10d}$$

and the induction using the expression:

$$B = K\delta = \frac{I_c M \times 10^8 \delta}{\delta_c N_s A_s}$$

in these equations N_p = number of turns in primary winding.
I = primary current in amperes.
d = mean diameter of ring in centimeters.
I_c = calibrating current in amperes.
M = calibrating mutual inductance in henrys.
δ_c = calibrating deflection resulting from a reversal of I_c.
N_s = number of turns in secondary winding.
A_s = sectional area of sample in square centimeters.
δ = fluxmeter deflection resulting from reversal of current in primary winding.

Straight bar or rod samples are sometimes tested with this circuit. A long solenoid is used for producing the magnetizing force, and the secondary winding or search coil is placed around a short central portion of the sample. However, under these circumstances the true magnetizing force is difficult to determine because the field from the magnetic poles produced at the ends of the sample reacts with the field of the solenoid. The field created by the sample itself is sometimes called the end effect or demagnetizing field. Its value is usually specified by the *demagnetizing factor*, N, which depends on the ratio length/diameter of the rod. The field, H, acting at the center of the rod is the resultant of the field in the solenoid, H_0, and the demagnetizing field:

$$H = H_0 - \frac{N}{4\pi}(B - H)$$

The apparent permeability, μ', is given by B/H_0, and its relation to the true permeability, μ is given by:

$$\frac{1}{\mu} = \frac{1}{\mu'} - \frac{N}{4\pi}$$

The relation between μ and μ' for cylindrical rods is shown graphically in Fig. 19.

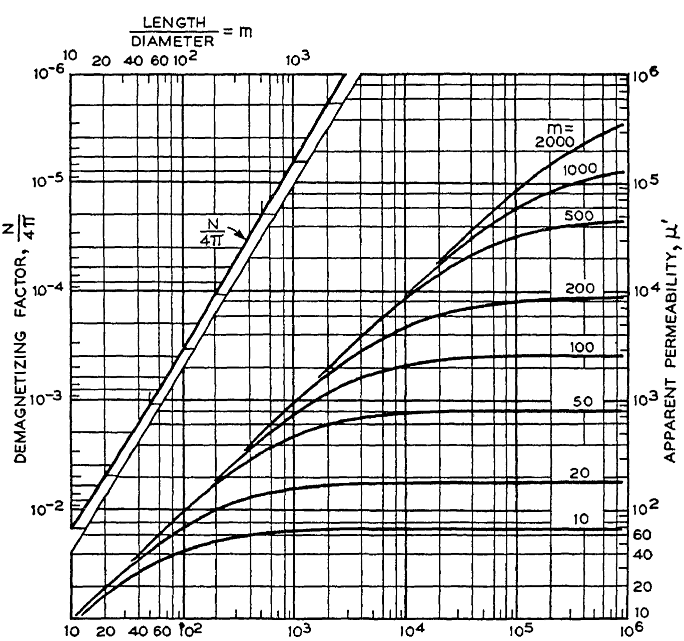

FIG. 19. Relation of the Apparent Permeability to the True Permeability for Cylindrical Rods of Various Ratios, m, of Length to Diameter. Also, Demagnetizing Factors, $N/4\pi$, as Dependent on m.

Various types of permeameters are also used with the circuit shown in Fig. 18. They are especially useful for measuring permanent-magnet materials. Permeameters usually are designed to test straight bar samples clamped against a yoke of very low reluctance. Measurement of samples of high permeability, so tested, are subject to error due principally to the effects of the air gaps in the circuit. Only a few of the many types will be described.

The *Fahy permeameter* is commonly used for testing materials like iron and silicon-iron as well as some of the magnet steels of relatively low coercive force. It is suitable for tests at magnetizing forces up to 300 oersteds. This instrument, shown in Fig. 20, has one large magnetizing winding on a yoke of silicon-iron. Pole pieces extending from either end of the yoke are arranged so that bar samples can be clamped to them. The magnetizing force is measured by an air-core solenoid (*H* coil) mounted across the ends of the pole pieces and above the sample. A winding enclosing the sample acts as a secondary (*B* coil) and measures the induction with the aid of a galvanometer as in Fig. 18.

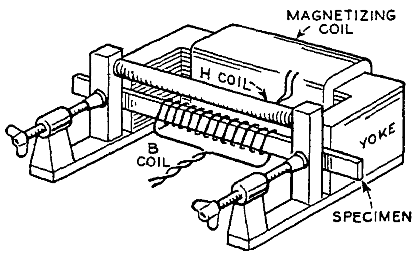

FIG. 20. Descriptive Drawing of the Fahy Permeameter

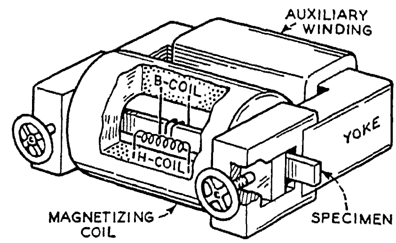

FIG. 21. Descriptive Drawing of the Babbitt Permeameter

The *Babbitt permeameter* (see Fig. 21) can be used for testing at magnetizing forces as high as 1000 oersteds. Several different high-permeability materials are used in the yoke to give low reluctance over a wide range of magnetizing force, and the magnetizing coil encloses the sample instead of being wound on the yoke alone as in the Fahy. Smaller windings are placed on the yoke to compensate for the reluctance of the air gaps. Magnetizing force and induction are measured with *H* and *B* coils placed near and around the middle of the sample.

More accurate tests of high-permeability materials can be made by means of the *Burrows permeameter*. This type requires two samples clamped between two connecting yokes of high-permeability material completing the magnetic circuit. In addition to the magnetizing coils around the samples, there are compensating coils around each end of the samples to give more adequate corrections for the effect of the air gaps at the joints. *B* coils are wound around the middle of each sample, and two search coils are placed on either side of each *B* coil. With proper adjustment the conditions of test more nearly approach those in the ring test, but the test is time-consuming because of the number of adjustments required.

Small air gaps are not very important when testing permanent-magnet alloys, but modern magnet materials require permeameters that can produce very high magnetizing fields. The saturation permeameter and the high-*H* permeameter are frequently used for this purpose.

The *saturation permeameter* is very similar to the Babbitt permeameter except that the magnetizing coil is larger and artificially cooled, and no compensating coils are used on the yoke. Magnetizing forces as high as 2500 oersteds are readily obtained with this instrument.

The *high-H-permeameter* developed by the Bureau of Standards can produce even more powerful fields and can be used to test any of the modern permanent-magnet alloys. In this permeameter four large coils are used. Two are wound on the yokes and two on the pole pieces clamped to the specimen (see Fig. 22). The induction is measured in the usual way with a coil wound around the center of the sample. A small rotatable *H* coil is arranged so that readings can be taken at different distances from the surface of the sample; the data so obtained give a curve of the variation in *H* and indicate by extrapolation the true value of field at the center of the sample.

In practice, magnetic materials are often subjected to alternating fields, and it is, therefore, important to measure magnetic permeability and energy losses by a-c methods. These include the use of a-c bridges, wattmeters, cathode-ray oscilloscopes, and various other instruments, a few of which will be described.

One of the common bridge circuits is the *Maxwell bridge.* The simplest form of this bridge consists of a pair of resistances for ratio arms, a variable resistor and variable inductance to balance the impedance of the sample, and a detector which may be a galvanometer, a sensitive voltmeter, or a telephone receiver (see Fig. 23). The bridge is useful for measuring apparent permeabilities and losses for low inductions at frequencies in the audio range. It is not suitable for testing at high inductions because of errors introduced by wave-form distortion.

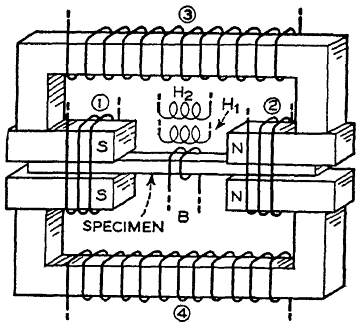

FIG. 22. Schematic Diagram of the High-H Permeameter

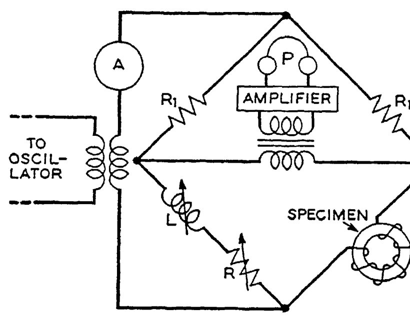

FIG. 23. Simplified Maxwell Bridge Circuit for Determining Equivalent Series Resistance, R, and Inductance, L, of a Coil Containing a Specimen of Magnetic Material

Incremental or superposed permeability measurements can also be made with the Maxwell bridge, by using an additional winding on the sample connected in series with a large inductance and a source of direct current. The inductance in the d-c circuit must be large enough to keep the alternating current in this circuit at a negligible value. Incremental permeability is important in the transformers of vacuum-tube amplifiers and in polarized apparatus such as telephone receivers where the material is subjected to both d-c and a-c fields (see Fig. 24).

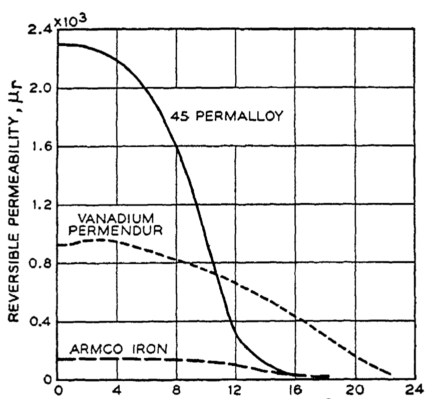

FIG. 24. Change in Reversible Permeability with Polarizing Induction for Several Materials

Properties are often determined at frequencies above the audio range with a-c bridges of the resistor-capacitor type, and Q-meters. For further information on a-c bridge methods, see Measurement of Inductance and Effective Resistance, Section 11.

For magnetic materials in sheet form, it is convenient to test samples made of sheared strips. The *Epstein test,* in common use for testing the core loss of materials such as silicon-iron sheet, uses samples of this form. Primary and secondary windings are placed on four hollow square forms mounted in the form of a square. The primary exciting current is measured with an a-c ammeter, A, and the induction is indicated by an "average" voltmeter, sometimes called a *flux* voltmeter, connected across the secondary as indicated in Fig. 25. The core loss is determined from the reading of a wattmeter, W. The test strips used in the Epstein are usually stacked with overlapping joints for permeability tests but may be stacked with butt joints for core-loss tests. This method gives reliable data up to

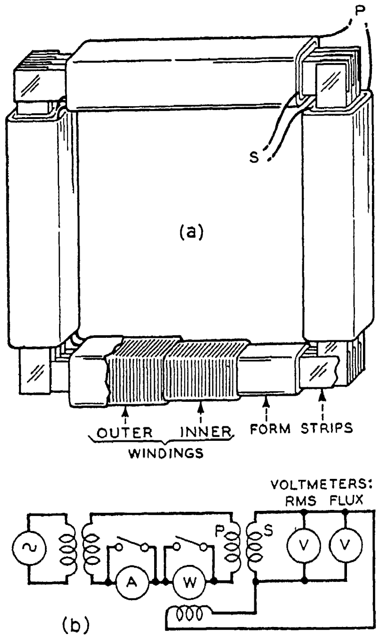

FIG. 25. Descriptive Drawing and Simplified Circuit Diagram for the Epstein Test for Determining Watt Loss

high inductions, and it is particularly useful for studying grain-oriented materials. For details of this test and other test methods, the latest issue of ASTM specifications should be consulted.

Cathode-ray oscilloscopes are sometimes used to give rapid indications of the a-c properties of materials. By means of a simple integrating circuit, hysteresis loops can be produced on the screen. A simplified circuit of this type is shown in Fig. 26. This test is

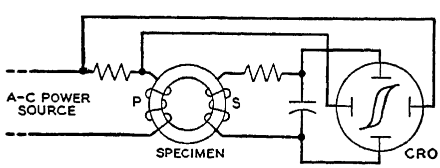

FIG. 26. Simplified Circuit for Producing Hysteresis Loops on Cathode-ray Screen

not as precise as those described above, but because of its rapidity it finds frequent application in certain types of production testing.

SECTION 3

RESISTORS, INDUCTORS, CAPACITORS

RESISTORS, INDUCTORS, CAPACITORS

RESISTORS AND RHEOSTATS

By Paul S. Darnell and Arthur H. Schafer

1. GENERAL

DEFINITIONS. A *resistor* is a circuit element whose primary function is to introduce electric resistance into an electric circuit.

A *rheostat* is an adjustable resistor which is provided with mechanical means for changing its resistance value without opening the circuit in which it may be connected. Its primary function is to adjust the current in a circuit or portion of a circuit in which it is connected. It may be in the form of a three-terminal potentiometer as defined below, or it may have only two terminals.

A potentiometer is defined by American Standards Association as a measuring instrument by means of which an electromotive force in one of the arms of the circuit may be measured in terms of one or more other electromotive forces and the constants of the potentiometer circuit. However, the term potentiometer is most commonly used to refer to any adjustable resistor having three terminals, two of which are connected to the ends of the resistance element and the third to a contact which traverses the resistance element without discontinuity. Its primary function is to convert an impressed voltage into a source of voltage which can be adjusted from a small percentage of the impressed voltage to approximately the magnitude of the impressed voltage.

PHYSICAL AND ELECTRICAL CONSIDERATIONS. Numerous factors, which will determine the type as well as the physical size and shape, must be considered in the design or selection of the proper resistor or rheostat for a specific application. The most important of these are: (1) resistance value and tolerance; (2) power dissipation under normal and trouble operating conditions; (3) frequency characteristic, phase angle, and change in resistance over a frequency range; (4) stability with age and changing conditions of temperature, humidity, and voltage; (5) mounting arrangements—space and shape requirements; and (6) relative cost of available resistor structures which will fulfill the circuit requirements in whole or in part.

Resistance Value. In general two classes of material are used for resistors: (1) pure metals and metal alloys in which resistance value for any given metal is determined largely by its physical dimensions, and (2) a composition or mixture of a carbon or metallic conductor with an insulating material in which the resistance value is determined by the relative proportion of conductor and insulator.

In the first group the element is usually a wire or strip having relatively low resistivity, which places a definite limitation on the resistance value that can be achieved for a given volume. The advantages are high stability with age, low temperature coefficient, low voltage coefficient, and low microphonic noise level. Its disadvantages are relatively high cost for higher resistance values, corrosion hazard under adverse conditions of voltage and humidity, limitation on high resistance values, and usually poor frequency characteristics at higher frequencies. Resistance range is normally from about 0.1 ohm to 1 megohm. In addition to the wire-wound resistors in this class are the metallic or carbon precision film-type resistors (to be discussed later) which circumvent some of the disadvantages enumerated here, since they permit attainment of high resistance in small space and have greatly improved frequency characteristics.

In the second group of resistors, since resistance value becomes a matter of composition of a mixture, the entire range of resistors in general use (10 ohms to 22 megohms) can be made in the same physical form and volume, so that size is determined largely by power dissipation desired. Other advantages are low cost, improved performance at high frequency, and, when wattage is not a factor, small size, light weight, and ease of mounting. Disadvantages are lesser stability with time, temperature, and humidity compared with wire-wound resistors, broader manufacturing tolerances, and higher noise level.

A third class of resistors, namely varistors and thermistors (see articles 8 to 10), is currently finding wide application as special-purpose circuit elements that are characterized chiefly by their high sensitivity to temperature and voltage and their relatively high resistivity. In this group the elements consist of semiconductor materials in the range between metallic conductors and insulating materials.

Resistance Tolerance. The matter of manufacturing tolerance with respect to the limits of resistance value within which a resistor shall initially be held is important from the standpoint both of the proper functioning of the circuit involved and of the design of the resistor itself. Practical tolerances of low-cost resistors commercially available are of the order of ±5 per cent to ±20 per cent for composition type, and ±1 per cent to ±10 per cent for wire-wound and precision film types.

Of equal importance to the initial manufacturing tolerances is the desired stability of the resistor during its life. To obtain stability of a lesser order of magnitude than the original manufacturing limits can be fairly simple at even the closest limits of the ranges indicated above but will probably become the major problem or even an impossibility for units adjusted to initial tolerances of one-quarter to one-tenth of those figures, for example.

ENERGY DISSIPATION—TEMPERATURE RISE—POWER RATINGS. Since normally the total electrical energy supplied to a resistor is dissipated in the form of heat, the resultant temperature rise will, under adverse conditions, constitute a potential hazard both to the resistor itself and to the materials of surrounding objects. Industrial Control Standards (NEMA, July 1, 1946, IC4-22) state that the temperature rise for bare resistive conductors shall not exceed 375 deg cent as measured by a thermocouple in contact with the hottest spot on the bare conductor, and for resistive conductors imbedded shall not exceed 300 deg cent as measured by a thermocouple in contact with the hottest spot on the surface of the imbedding material. The establishment of such maximum power ratings is possible only for power-type resistors constructed entirely of inorganic materials not adversely affected either physically or chemically by the heat generated. Ratings for other resistors are normally established on the basis of the maximum temperature at which they can operate continuously without deterioration of their performance or their component parts. Since power ratings under the various standards are predicated on operation in still air and free space at an ambient temperature of the order of 25 deg cent, a status seldom realized under actual operating conditions, good engineering practice dictates derating the resistor to reflect the specific conditions of use. In the absence of exact data to indicate the amount of derating necessary, a figure of 50 per cent is commonly applied. In addition to consideration of the normal wattage at which the resistor will be required to operate, it is frequently advisable to determine the power the resistor must dissipate under predictable abnormal or trouble conditions, and when possible, to select a resistor that will operate safely under such conditions as well.

FREQUENCY CHARACTERISTIC. In considering the behavior of a resistor over a frequency range, it must be remembered that in any practical design in which the element has finite dimensions it will necessarily contain components of all three parameters (Fig. 1—R, L, and C) and will approach the characteristics of a pure resistor over a limited frequency range. The problem of design is to approach a pure resistance with the inductance and capacitance regarded as parasitic values, useful only to the extent to which they can be made to nullify each other over the frequency range in which the resistor is to be used. A typical resistor may be represented as a two-terminal network comprising three elements as shown in Fig. 1.

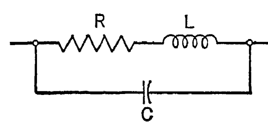

FIG. 1. Equivalent Network of a Resistor Having Inductance and Distributed Capacitance

The impedance Z of this circuit may be expressed in terms of effective inductance L' and effective resistance R' of the system as follows: $Z = R' + j\omega L'$. It can readily be shown that in terms R, L, and C the following relations hold:

$$R' = \frac{R}{1 - \omega^2 C(2L - CR^2) + \omega^4 C^2 L^2} \tag{1}$$

$$L' = \frac{L - CR^2 - \omega^2 CL^2}{1 - \omega^2 C(2L - CR^2) + \omega^4 C^2 L^2} \tag{2}$$

Also the phase angle $\Phi = \tan^{-1}(\omega L'/R')$, from which

$$\text{Tan } \Phi = \frac{\omega(L - CR^2 - \omega^2 CL^2)}{R} \tag{3}$$

Since in a resistor both L and C are small, eqs. (1), (2), and (3) may be rewritten:

$$R' = R[1 + \omega^2 C(2L - CR^2)] \tag{4}$$

$$L' = L - CR^2 \tag{5}$$

$$\text{Tan } \Phi = \frac{\omega(L - CR^2)}{R} \tag{6}$$

It will be observed that the phase angle will be zero if $L - CR^2 = 0$, but that the change in resistance will be zero only if $C = 0$ or if $2L - CR^2 = 0$. It follows then that both the phase angle and the change in resistance with frequency can be zero simultaneously only for the conditions $C = 0$, $L = 0$. These are important relations, for it means that a resistor may be designed with a small or zero phase angle over a considerable frequency range merely by keeping to a minimum the quantities L/R and CR and making them as nearly equal as is warranted for the particular design under consideration.

A second factor causing change of resistance with frequency is the so-called skin effect, which arises from the fact that elements or filaments of current at different points in the cross-section of the conductor encounter different components of inductance. This is because of the greater mutual inductance between elements at the center of the conductor. These unequal inductances over the cross-section tend to produce unequal current densities, with the minimum at the axis and the maximum at the periphery. Such unequal current densities reduce the effective cross-section of the conductor and tend to increase its effective resistance. Since the determination of skin effect by computation is involved, it is sufficient to observe that this effect may be kept to the minimum by (1) using a conductor of small cross-section, (2) using a conductor of high specific resistance, and (3) for a wire-wound resistor, winding the wire to have the minimum effective inductance. It will be seen that these are also conditions for other good characteristics in an alternating-current resistor. (For a more detailed description of skin effect and methods of computation, see *National Bureau of Standards Circular* 74.)

Small Phase Angle over a Frequency Range. As stated previously, to insure small phase angle over a given frequency range requires that residual inductance and capacitance be held to the minimum, zero phase angle being realized when one is made to compensate the other. Such compensation is achieved by satisfying the equation $L = CR^2$. The major problem for low resistance is the reduction of inductance; for high resistance it is the reduction of capacitance. In actual practice it is found that for values up to about 100 ohms the problem is one of inductance; for values over several thousand ohms the problem is mostly capacitance; for values in between, both capacitance and inductance must be considered. Of course these figures show merely the broad boundaries, and considerable variation will be encountered due to differences in structure, type of winding, and capacitance to ground.

STABILITY WITH AGE, TEMPERATURE, AND HUMIDITY. *Aging* may be defined as any permanent change in resistance value with time, measured under the same conditions of temperature and humidity. It is generally caused by strains set up in the resistor element, either in the original manufacturing process as when wire is wound tightly on a core or when the element is pressed or molded into shape, or during the life of the unit when the supporting structure is distorted as the result of aging of the structure itself. In a composition resistor it is also brought about by chemical and physical changes in the materials of composition, particularly in the deterioration of the insulating materials used in the binder and filler. Strains in the winding may often be relieved by a preaging treatment (generally baking from 1 to 24 hours). To prevent warpage of the structure, and to guard against other effects discussed later, resistors are protected against moisture in various ways. Impregnation with wax, varnish, or asphalt compounds is common practice, and frequently an exterior covering of moisture-resistant material is used. Proper selection of structural materials is probably the most important single factor in aging protection. Metal, which appears to be the ideal material for this purpose, usually cannot be used, partly because of its effect on the residuals, and partly because proximity to the winding would be an added hazard in promoting electrolytic corrosion.

Temperature Variations. Stability with change in temperature is obtained by a proper selection of the resistive material. For composition-type resistors this material is at present limited almost entirely to carbon or graphite for the conducting portion of the mix; a wide variety of insulating materials is used for binder and filler, and frequently the choice is controlled by considerations other than temperature coefficient. For wire-wound resistors the desired temperature characteristics are determined largely by the wire selected.

Humidity Conditions. In addition to warping of structural materials two other humidity effects must be considered in resistance design: the effect on residual inductance and capacitance, and the effect on corrosion. When moisture gets into a resistance structure it causes a change in the dielectric properties of the materials used therein, and a consequent change in the residual capacitance. This will often change the phase angle by an appreciable amount. The danger of corrosion which takes place when impurities and moisture are present is generally the more serious consideration in protection against humidity, especially where fine wires are used.

CLASSIFICATIONS. Resistors have been variously classified in terms of performance, power dissipation, structure, usage, and manufacturing tolerances. Broadly, the following classifications are in general use today and have been adopted, with proper subdivisions, by the various standards agencies: (1) fixed wire-wound, (2) fixed composition type, (3) precision film type, (4) rheostats and potentiometers (wire-wound and composition), (5) special-purpose types (chiefly thermistors and varistors). Each of these categories will be treated separately below.

RESISTOR TESTS AND SPECIFICATIONS. Aside from a marked quality improvement of the resistor product, one of the major benefits derived from the past war was the promulgation and adoption by the armed services, and to a lesser extent by industry, of resistor standards of performance, size, resistance value, and tolerance. These can be found by reference to the following specifications:

JAN-R-11	Resistors, Fixed Composition.
JAN-R-26	Resistors, Fixed Wire-Wound, Power Type.
JAN-R-93	Resistors, Accurate, Fixed, Wire-Wound.
JAN-R-184	Resistors, Fixed, Wire-Wound (Low-power).
JAN-R-22	Rheostats, Wire-Wound, Power Type.
JAN-R-19	Resistors, Variable, Wire-Wound (Low Operating Temperature).

Specifications include tests of both mechanical and electrical qualities, including measurement of strength of leads, strength of resistor, resistance load life, load characteristics, voltage characteristic, temperature coefficient, microphonic noise, and effects of humidity, overload, and aging. In addition the Radio Manufacturers Association is in the process of preparing corresponding specifications for commercial usage, less severe and exacting. (See also Section 11.)

2. WIRE-WOUND RESISTORS

The many varieties of wire-wound resistors in use are classified in numerous ways, some by the manufacturer and some by the application to which the resistor is put. Thus we have power type, high-frequency resistors, precision type, flat type, tubular, plate, ballast, cord type, lead mounting, ferrule type, spool type, sectionalized bobbin type, and many others. As might be expected there is a great deal of overlapping in categories, and the descriptive terms are of course relative and at times misleading. Wire-wound resistors will be arbitrarily subdivided here into the several main classifications currently accepted by most manufacturers and users.

POWER-TYPE RESISTORS. Power resistors consist of that class of resistor whose primary function is to dissipate relatively large amounts of power in a comparatively small space. In this group, materials of construction are selected first because of their ability to withstand heat. Normally temperature rise is limited to 300 deg cent which with 25 deg cent ambient means a hot-spot temperature of 325 deg cent. Where organic materials are used (usually to obtain increased resistance to humidity or to facilitate construction of special features requiring machined or molded parts) temperature rise is limited to 125 deg cent and wattage ratings are reduced to about one-third of maximum values obtainable with complete inorganic construction. Typical construction consists of a cylindrical ceramic-core tube with encircling band terminals at each end, with a single inductively wound layer of wire made of resistance material selected for the qualities desired. Because of corrosion hazards and considerations of mechanical strength, choice of wire size is usually limited to minimum 0.002-in. diameter (0.0025 in. in JAN specifications), although most manufacturers will wind wire down to 0.001 in. or less in diameter if requested to do so. The resistor winding is protected against mechanical injury and the effects of moisture. Electrical insulation is obtained by applying a cover coat of either vitreous enamel or cement. A typical assortment of sizes commercially available in this type is shown in Table 1.

Table 1. Ratings and Dimensions

Nominal Ratings, watts	Range of Resistance Values, ohms	Approximate Core Sizes, in.	
		Diameter	Length
5	0.5 to 1,600	5/16	1
10	0.3 to 5,000	5/16	1 3/4
20	0.3 to 10,000	9/16	2
25	0.3 to 13,000	5/8	2
30	0.5 to 23,000	3/4	3
40	0.6 to 28,000	3/4	3 1/2
50	0.8 to 40,000	3/4	4 1/2
75	1.2 to 50,000	1 1/8	4 1/4
115	1.9 to 90,000	1 1/8	6 1/2
160	2.6 to 120,000	1 1/8	8 1/2
200	3.6 to 150,000	1 1/8	10 1/2

Maximum resistance value is based on use of 0.002-in.-diameter wire. With 0.001-in. wire, values up to eight times these maximum figures may be obtained. Wattage ratings are based on a permissible 300 deg cent temperature rise. Maximum voltage which may be applied is properly held within about 500 volts per inch of length, subject, of course, to permissible power dissipation.

Other varieties of power-type resistors include the following: strip type, plaque type, disk type, plate type, supported ribbon, ferrule or axial terminal, adjustable type,

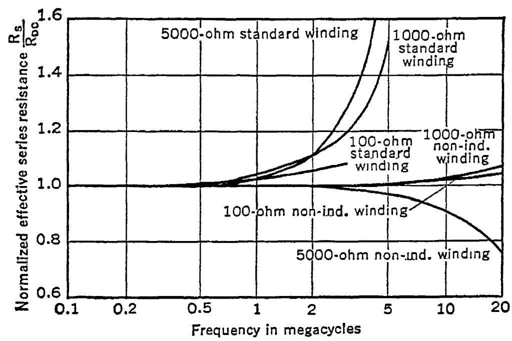

FIG. 2. Resistance Frequency Characteristics of Several Wire-wound Vitreous Enamel Resistors—50 Watts, 9/16 in. Diameter x 4 in. Core (Courtesy Ohmite Mfg. Co.)

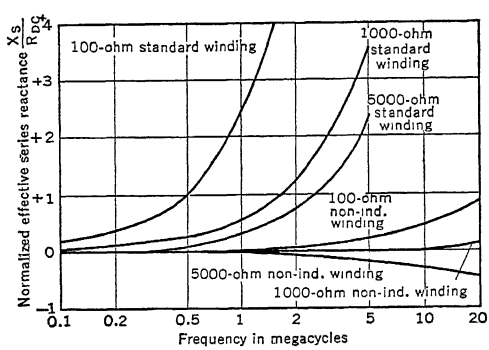

FIG. 3. Reactance Frequency Characteristics of Several Wire-wound Vitreous Enamel Resistors—50 Watts, 9/16 in. Diameter x 4 in. Core (Courtesy Ohmite Mfg. Co.)

molded type, and those with multiple or tapped windings. The adjustable type has a lengthwise strip of winding bared down one side of the core tube, and the resistor is provided with an extra encircling band terminal for clamping down on and tapping the winding at any point along its length.

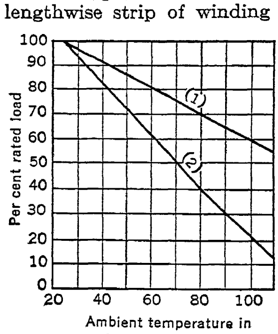

FIG. 4. Resistor Derating for High Ambient Temperatures as Specified in JAN-R-26. Curve 1—Nominal rating based on 250 deg cent temperature rise. Curve 2—Nominal rating based on 125 deg cent temperature rise.

Close-tolerance Resistors. Although usual manufacturing tolerances available are either ±5 or ±10 per cent, closer tolerances down to about ±1 per cent can usually be obtained at increased cost. Tolerances closer than 1 per cent are not generally furnished in power-type resistors since self-heating frequently changes the resistance value by at least 1 per cent. In the case of vitreous enamel resistors the high firing temperatures involved in applying the protective coating and the consequent resistance changes during manufacture make closer adjustment impracticable. Sometimes varnishes, lacquers, or asphalt coatings are substituted for the high-temperature coverings to facilitate initial adjustment, to permit use of low-temperature-coefficient wires without loss of desirable characteristics brought about through additional heat treatment, and to provide further protection against weathering in service. Such special coatings may necessitate derating as much as 80 or 90 per cent.

Layer Windings. Power-type resistors are occasionally wound in layers to achieve a greater range of resistance value. Resistance wire having insulation capable of withstanding high temperatures as well as having a high degree of mechanical strength must be chosen for this type of resistance winding.

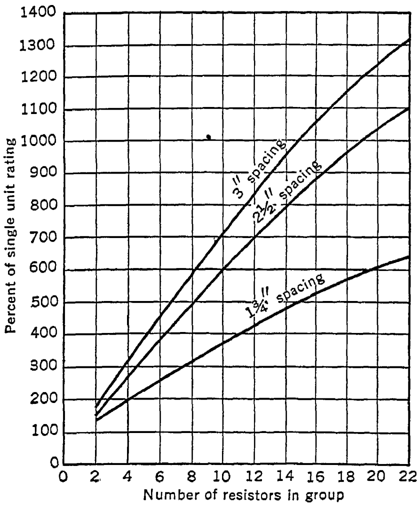

FIG. 5. Resistor Derating When Mounted in Groups. Spacings are centerline to centerline of resistors mounted horizontally—1 1/8 in. diameter core tubes. All resistors of equal length and power rating. (Courtesy Ward Leonard Electric Co.)

Non-inductive Windings. Many of the power-type resistors may be obtained with windings of low inductance. Generally the Ayrton-Perry winding is used (see description under "Precision-type Resistors"), which has the added advantage of low distributed capacitance and greatly increases the frequency range over which the resistor can be used effectively, particularly for low resistance values (up to about 10,000 ohms). Figures 2 and 3 show plots of the normalized effective series resistance and normalized effective series reactance against frequency for both standard and non-inductive (Ayrton-Perry) windings on 50-watt core sizes for resistance values of 100, 1000, 5000 ohms, and are representative of the improved performance that may be expected from this type of winding. Normalized resistance or reactance is to be considered as the ratio of resistance or reactance to the d-c resistance of the resistor.

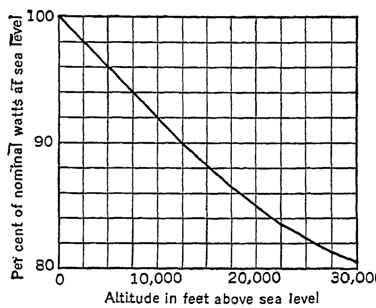

FIG. 6. Resistor Derating When Operated Above Sea Level (Courtesy Ward Leonard Electric Co.)

Typical behavior and characteristics of some power-type resistors are shown in Figs. 4 to 10. Figures 4 to 7 show the required derating of resistors operated under unfavorable conditions; Figs. 8, 9, and 10 show behavior under overload and intermittent duty.

LOW-POWER AND PRECISION-TYPE RESISTORS. This category is made up of those resistors in which power dissipation is a minor consideration; it comprises a wide variety of shapes and sizes. Since power dissipation is not an important factor, many more materials are available for body structures and protective coatings, including plastics and molding compounds, which are more readily adaptable to the form of unit required.

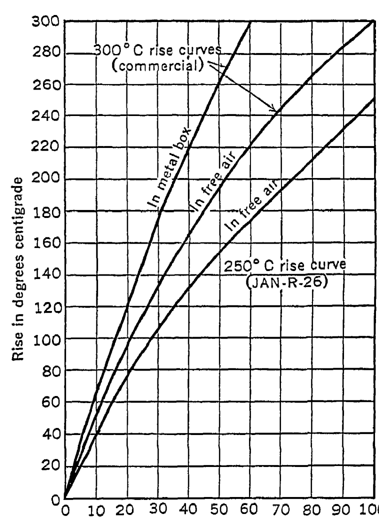

FIG. 7. Temperature Rise of Resistors in Free Air, and Enclosed in a Metal Box. Unit mounted in unventilated metal box reaches maximum permissible temperature when dissipating only about 60 per cent of normal rating. (Courtesy Ward Leonard Electric Co.)

Precision resistors fall within this category and are usually considered to be resistors which are manufactured to tolerances of ± 1 per cent or less and which are stable during their normal life and operating conditions to within toler-

ances of something less than the initial adjustment. A few of the types in general use today are the following:

Spool Type, in which the winding is applied to a core body in the form of a spool, either molded or fabricated, to the dimensions necessary to accommodate sufficient wire for maximum resistance value desired and to dissipate rated watts with the minimum of self-heating. The spool may be divided into sections to control the voltage gradient between individual turns and between sections of winding and to permit some improvement in frequency characteristic over a winding applied in a single section. Typical sizes available are shown in the tabulation.

Spool Dimensions, in.		Watts Rating	Maximum Resistance Value, megohms Minimum 0.0015 in.-diameter Wire
Diameter	Length		
19/32	19/32	0.5	0.15
19/32	1 1/32	0.75	0.4
25/32	1 9/32	1.0	1.0

Flat-type resistors (card-type) usually consist of a single layer of bare or insulated wire, wound on a flat card of insulating material. The wound card is either encased in molding compound or is given a protective coating of lacquer or varnish. Maximum resistance value is typically of the order of 5000 ohms per inch of length and wattage dissipation about 1 watt per square inch of radiating surface.

Pad-type resistors consist of multiple windings on a spool or card to form resistor networks suitable for use as attenuators.

Plug-in type resistors are provided with terminations at one end in the form of a vacuum-tube base, providing means for inserting attenuator pads in a circuit.

Flexible resistors are made in the form of a helix wound on a flexible insulating cord which in turn is insulated with a flexible sleeving.

WINDING TYPES. Numerous types of winding are commonly used in resistors in an effort to attain low residuals of capacitance and inductance or simply to achieve the desired resistance value in the most economical way. Some of these winding types are shown here. Typical residuals obtained are shown in Table 2.

Table 2. Net Residuals of Typical Resistor Windings

Winding Type	Resistance, ohms	Approximate Net Residual
Continuous (flat-card type)	0–4.5	0–1.5 μh
	4.5–20	0.5–3.5 μh
	20–600	3.5–15 μh
	1,000	70 μh
	10,000	±3 μμf
Continuous (tubular power type)	0– 200	2–15 μh
	200– 800	15–60 μh
	800–2,000	60–130 μh
	2,000–5,000	130–500 μh
Bifilar	10	0.5 μh
	100	1.5 μh
	1,000	100 μμf
	3,500	300 μμf
Reverse layer	1,000	10 μμf
	3,500	30 μμf
	10,000	100 μμf
Reverse section	1,000	100 μh
	3,500	300 μh
	10,000	±5 μμf
Reverse half-section	1,000	±5 μμf
	3,500	±5 μμf
	10,000	30 μμf
Mandrelated filament	1,000	1–2 μμf
	3,500	1–2 μμf
	10,000	1–3 μμf
	35,000	2–4 μμf
	100,000	2–5 μμf
	200,000	3–8 μμf
Parallel opposing (Ayrton-Perry)	100	0–1 μh
	1,000	1–2 μh
	10,000	1–2 μμf

Continuous Winding. The simplest of all windings is one in which the wire is wound on a core continuously in one direction, known generally as a continuous or inductive winding. If the wire is wound in layers, the residuals of both capacitance and inductance are large and the resistor can be used merely for very low frequencies or direct-current applications. By winding in a single layer on a core of small cross-sectional area such as a flat card or small-diameter core, the inductance and capacitance are reduced. By spacing the turns and keeping the wire size to the minimum almost any desired residual may be achieved with the obvious limitation that short lengths of wire become increasingly difficult to adjust.

Bifilar Winding. This winding is used most generally where low inductance is required. In this winding the wire is bent back on itself at the midpoint so that the two half-lengths are side by side, separated by the insulation only. In this straight form any given wire has the minimum possible inductance. This minimum inductance L may be computed from the formula:

$$L = 0.005l(2.303 \log_{10} \frac{2D}{d} + 0.25)\ \mu\text{h}$$

where l = total length of wire in inches, D = distance apart, between centers, d = diameter of the bare wire, and μh = microhenries. D and d are expressed in the same units.

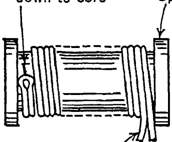

FIG. 11. Bifilar Winding.

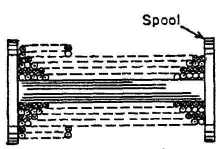
In practice this loop is generally wound on a core (see Fig. 11), often in several layers, with the result that L is increased slightly. The bifilar winding has the disadvantage of high distributed capacitance. Next to a straight inductive winding, it is the cheapest winding to apply.

A modification of the straight bifilar winding is the series-bifilar winding in which the total length of wire is divided into sections, each wound separately as a bifilar loop and the sections connected in series. This has the advantage of maintaining minimum inductance and of reducing the capacitance by any desired amount, inasmuch as the capacitance is approximately inversely proportional to the square of the number of sections. This results in a good resistor, but it is expensive to apply, and since simpler windings generally give practically the same results it is seldom used in regular production.

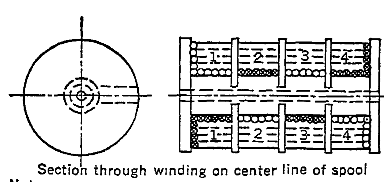
Reverse Layer Winding. The reverse layer winding (see Fig. 12) is used where the frequency range is low enough to permit appreciable residuals and where the spool is not divided into sections for a sectional winding. The direction of turns is reversed for each layer. It approximates the series-bifilar winding, but, because each layer must be secured in place before reversing turns, it is expensive where a large number of layers are applied. To be non-inductive it must have an even number of full as well as partial layers.



Section through winding on center line of spool

Notes:
1. Section shows alternate full layers and final partial layers wound in opposite directions. o indicates layer wound towards observer. ● indicates layer wound away from observer.
2. Winding always consists of even number of full and partial layers.

FIG. 12. Reverse Layer Winding



Section through winding on center line of spool

Notes:
1. ⊙ indicates section of winding wound toward the observer.
   ● indicates section of winding wound away from observer.
2. Approximately the same number of turns are wound in each of the sections.
3. Figures indicate winding order.

FIG. 13. Reverse Section Winding

Reverse Section Winding. The reverse section winding (see Fig. 13) is used largely for high resistance values. This winding is divided into two or more adjacent sections of equal size and number of turns. As in the series-bifilar winding, the distributed capacitance is approximately inversely proportional to the square of the number of sections. The turns in adjacent sections are wound in opposite directions to reduce the inductance, thereby approximating the reversed layers of a reverse layer winding. Generally the spool is sectionalized to simplify the winding. However, if the wire is large and the turns correspondingly few, the same effect is attained in a bunch-type winding in which the wire is wound in successive bunches around the core.

Reverse Half-section Winding. Although the reversed section winding gives excellent results for capacitance reduction, the magnetic coupling between adjacent sections is so low that in spite of reverse turns the inductance is often too high. This is especially true for values ranging from 1000 to 4000 ohms. Although above this upper limit high residual inductance still obtains, tolerable phase angle results because of the increasing effect of higher resistance value in the $L - CR^2$ relationship of eq. (6). Reversing by half-sections has the effect of increasing the capacitive and decreasing the inductive residuals. This winding is somewhat more expensive to apply than the reverse section type.

Parallel Opposing (Ayrton-Perry) Winding (See Fig. 14). This type of winding consists of two inductive windings on a core with turns equal and in opposite direction. A spaced layer of either insulated or bare wire is first applied in one direction. The second wire is wound in the opposite direction between the turns of the first winding. When bare wire is used, the cross-overs must be at exactly diametrically opposite sides of the core so that contact occurs at points of equal potential on each wire. The two windings are connected in parallel. The distributed capacitance is low, and the opposing currents in the two wires produce the minimum of magnetic effect. It has the disadvantage of requiring four times as much wire of any given size to obtain the same value produced from a normal single-wire winding.

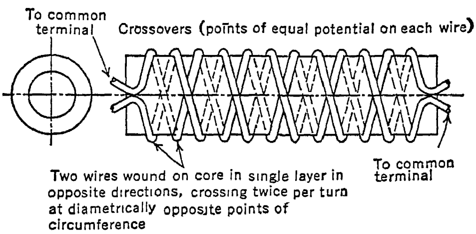


FIG. 14. Parallel Opposing (Ayrton-Perry) Winding

Mandrelated Filament Winding. This is an adaptation of the continuous winding discussed earlier, in which a single layer of resistance wire is wound on a flexible core. The helical filament so formed can then be handled in much the same manner as ordinary resistance wire. A number of such filaments have been developed with resistance wire, dimensions, and turn spacing so selected that for any straight length of filament the inductive component L/R is substantially equal to the capacitive component CR. The effect of winding on a form and terminating the filament is to increase the capacitance slightly. Because of the excellent frequency characteristics and the high resistance per linear length of filament (up to 2400 ohms per inch in 0.030-in. diameter of insulated filament), this type of winding is widely used for high resistance values in many of the designs developed for use in the communications field.

Miscellaneous Windings. Numerous other windings have been developed for use at high frequency that serve satisfactorily but are not in general commercial use except in precision-type measuring apparatus and in resistance standards. One of these is the "woven type" in which wire is woven into a cloth or ribbon pattern giving the effect of a continuous winding on a card of infinitesimal thickness. Rather intricate patterns are sometimes used to obtain low phase angle. Constructions such as "reversed turn" and "Curtis" windings require handling of each turn individually and therefore do not lend themselves to economic manufacture in mass production. Occasionally zero phase angle is achieved by adding the necessary amount of capacitance or inductance to a completely wound unit.

3. COMPOSITION CARBON RESISTORS

FIXED RESISTANCE RESISTORS. The designation "composition resistor" denotes a type of resistor that has very wide application in electronic equipment and apparatus because of its light weight, compactness, wide range of resistance values covered, and ease of mounting. It is primarily used in circuits where drift and variation in resistance value with time, temperature, humidity, and applied voltage are not of particular significance. In general, the resistive element in a composition resistor is a combination of finely divided carbon or graphite, a non-conducting inert material or filler such as talc, with synthetic resin as a binder. These substances are proportioned so as to yield the proper resistance value in the finished product.

Composition resistors are available in insulated and non-insulated types. In general, the large majority of composition resistors used in electronic equipment is of the insulated type. In this type the resistive element of the unit is surrounded by a substantial housing of insulating material, such as mineral-filled Bakelite, so that there is no possibility of contact with the element other than through the wire terminal leads of the resistor. The usual form of insulated resistors for wattage dissipations of 2 watts and less is a cylindrical body provided with axial terminals. In the uninsulated resistor, a cylindrical rod of resistive material is generally equipped with radial leads and the unit is painted.

SIZES AND RATINGS. Typical sizes in general usage of fixed insulated axial lead resistors with cylindrical bodies are as listed in Table 3.

Table 3. Sizes of Cylindrical Insulated Resistors

Nominal Wattage Rating at 40° C	Maximum Body Length, in.	Maximum Body Diameter, in.	Lead Length, in.	Min. Lead Diameter, in.
0.25	0.438	0.125	$1\frac{1}{2} \pm \frac{1}{8}$	0.028
0.50	0.438	0.156	$1\frac{1}{2} \pm \frac{1}{8}$	0.028
1.0	0.750	0.280	$1\frac{1}{2} \pm \frac{1}{8}$	0.032
2.0	0.750	0.344	$1\frac{1}{2} \pm \frac{1}{8}$	0.036

The resistors listed in Table 3 are available in resistance values ranging from a few ohms to 22 megohms on a manufacturer's standard basis, with the qualification that the 0.25-watt unit may not be obtainable in values as low as for the other units. These resistors are furnished in accordance with the RMA preferred number system for the values and tolerances shown in Table 4.

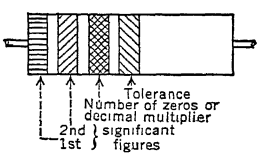

FIG. 15. Standard Color Coding

The resistance value is indicated by a color code applied to the resistor as shown in Figs. 15 and 16 and Table 5. The exterior body color of insulated resistors may be any color except black. It is recommended that the maximum continuous working voltage, either d-c or rms a-c, should not exceed 250 volts for the 0.25-watt unit; 350 volts for the 0.5-watt unit; and 500 volts for the 1- and 2-watt units.

Table 4. Nominal Resistance Values

(RMA preferred number system)

Nominal Resistance					Available in Tolerances ± per cent
ohms				megohms	
10	100	1,000	10,000	0.10, 1.0, 10	5, 10, 20
11	110	1,100	11,000	0.11, 1.1, 11	5
12	120	1,200	12,000	0.12, 1.2, 12	5, 10
13	130	1,300	13,000	0.13, 1.3, 13	5
15	150	1,500	15,000	0.15, 1.5, 15	5, 10, 20

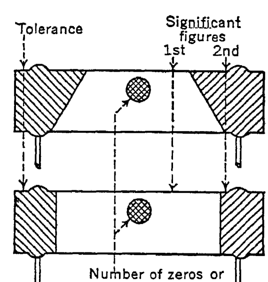

FIG. 16. Alternate Color Coding for Radial-lead Resistors

PERFORMANCE CHARACTERISTICS. In addition to obvious requirements on the mechanical properties of a resistor, such as ruggedness, security of terminals, legibility of color code, and its d-c resistance value and tolerance as established by a suitable d-c resistance measurement, the following properties are of interest for commercial uses.

Resistance-temperature Characteristic. Table 6 indicates the range within which an insulated composition resistor may be expected to vary at the temperatures indicated.

Table 6. Insulated Composition Resistor Variations Due to Temperature

Nominal Resistance Value	Maximum Per Cent Change in Resistance from Value at Ambient Temperature of +25 ° C			
	To −15° C Ambient	To −55° C Ambient	To +65° C Ambient	To +105° C Ambient
10 ohms to 1000 ohms	−0, +3.5	−0, + 6.5	±3	±5
1010 ohms to 10,000 ohms	−0, +5	−0, +10	±4.5	±8.5
10,100 ohms to 0.1 megohm	−0, +6.5	−0, +13	±4.5	±8.5
Over 0.1 megohm	−0, +10	−0, +20	±5	±10

Voltage Coefficient. This coefficient relates to the percentage change in resistance value per unit change in voltage with applied voltage as distinguished from any effects caused by heating at the applied voltage. It arises from a change in the conducting properties of the resistive material as the applied voltage is varied. Voltage coefficient is usually determined for resistors of 1000 ohms and above as follows:

$$\text{Voltage coefficient (per cent)} = 100\,\frac{R_1 - R_2}{R_2} \times \frac{1}{E_1 - E_2}$$

where E_1 = rated continuous working voltage, E_2 = 0.1 rated continuous working voltage, R_1 = resistance at rated continuous working voltage, and R_2 = resistance at 0.1 continuous working voltage. For resistors rated at $^1/_4$ and $^1/_2$ watt, the voltage coefficient should not exceed 0.035 per cent per volt, and for higher-wattage resistors it should not exceed 0.02 per cent per volt.

Humidity Effects. Test data indicate that molded-housing-type insulated resistors which have been thoroughly dried and then subjected to a condition of 90 per cent relative humidity at an ambient of 30 deg cent for 200 hours may in general be expected to stay within a limit of about 5 per cent, the magnitude of the change depending upon resistance value. The product of certain manufacturers is also capable of withstanding exposure to 100 per cent relative humidity at an ambient temperature of 66 deg cent for 250 hours without changing in resistance value by more than 10 per cent.

Noise. Current noise arises within the resistive element of a composition resistor primarily because of the microphonic nature of particle-to-particle conduction of current in the structure. In some resistors noise may also originate at the junction between the lead wire and resistive element because of imperfect contact.

It has been found that the product of certain manufacturers will have root-mean-square values of current noise with rated d-c voltage applied to the resistor terminals less than 3 rms microvolts per volt for $^1/_2$-watt units up to a resistance value of 1 megohm, and 6 rms microvolts per volt for resistance values above 1 megohm. For 1- and 2-watt resistors, the noise level may be expected not to exceed 1.2 rms microvolts per volt.

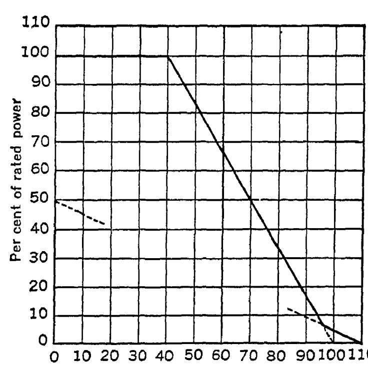

FIG. 17. Derating Curve for High Ambient Temperatures

Load-life Characteristic. D-c load tests conducted at 40 deg cent have shown such extremely wide variations in resistance change in 1000 hours that no general statement is of value. Units have been found to age either positively or negatively, the film-type resistor usually showing an increase in value and the body type a decrease in value. Hence the manufacturer should be consulted for specific information on the performance of his product. However, resistors are available which will not change more than 10 per cent under this 1000-hour load test.

For resistors designed to carry 100 per cent of rated load at 40 deg cent ambient, it is recommended that the derating curve shown in Fig. 17 be followed to prevent undue aging.

It will be noted, for example, that resistors functioning in an ambient of 85 deg cent should be operated at not more than 25 per cent of rated load. Resistors are also available which may be operated at full wattage at 70 deg cent with a derating to zero wattage at 150 deg cent.

Effect of Soldering. Care must always be taken to prevent the quality of a composition resistor from being seriously impaired and its resistance value and stability affected significantly by excessive heating during the operation of soldering its terminal leads to apparatus or equipment terminals. The leads should be left as long as possible and preferably not less than $^3/_8$ in.

Additional Characteristics. In addition to the properties and tests described above, other characteristics of interest in military work and of possible importance in certain commercial application may be mentioned: voltage breakdown strength of the insulation on insulated-type resistors; high-altitude flashover voltage; performance after salt-water-immersion cycling; effects of thermal shock under temperature cycling in air; effect of mechanical vibration on mounted resistors; performance under other types of load-life tests; short-time overload performance; and ability to withstand specific mechanical tests on the security of terminals. Further details on tests and expected performance may be found in Specification JAN-R-11.

FREQUENCY CHARACTERISTIC. In general the inductance associated with composition resistors is sufficiently small to be disregarded. At low frequencies the value of resistance R is the same as the d-c resistance, but as the operating frequency is raised the value of R starts to decrease and may reach a value which is only a few per cent of the d-c value. The frequency at which R begins to show a significant decrease in value depends upon its d-c value; that is, the greater the d-c value of a resistor, the lower the frequency at which departure from the d-c value is observed. Incidentally, parallel capacitance C shows a similar decline in value, but the amount of change is significantly less than the reduction in resistance.

Figure 18 shows the variation in resistance with frequency of two different 1-megohm insulated resistors of $^1/_2$-watt rating. These resistors are practically identical in physical size, but one has a resistive element in the form of a composition film on the surface of a glass tube and the other has a resistive element of the body type. Resistors that have been found to show the least decrease with frequency have a very thin uniform resistive film on a rod or tube of low-loss dielectric material in which the ratio of length of element to its diameter is large and in which no exterior covering or coating material is in contact with the surface of the element.

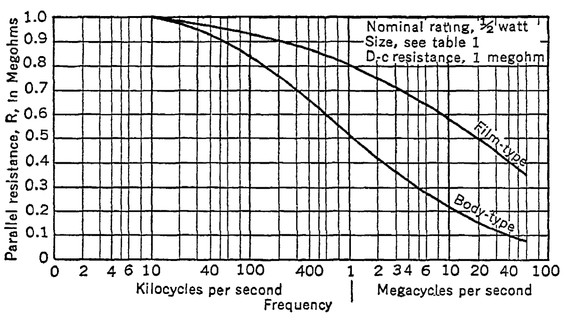

FIG. 18. Variation of Parallel Resistance R with Frequency for 1-megohm Molded Insulated Housing Type of Resistor

It has been observed that, in a given specific type of resistor, the ratio of parallel a-c resistance to the d-c resistance is approximately constant for a fixed value of the product of operating frequency and d-c resistance value. That is to say the ratio is approximately the same for a 10-megohm unit operating at 0.1 mc, a 1-megohm unit at 1 mc, and a 0.1-megohm unit at 10 mc. In each instance the product of megohms and megacycles is unity. Applying this example to the curve given for the body-type resistor in Fig. 18, and noting that at 1 mc the 1-megohm resistor has 53 per cent of its d-c resistance, a resistor having a value of 10 megohms (d-c) and being of the same construction as the 1-megohm unit for which the curve is drawn would have a parallel resistance of around 5.3 megohms at 0.1 mc. Also a 0.1-megohm unit (d-c) at 10 mc would have a value of about 53,000 ohms parallel resistance. It is very important to observe that this relationship is only approximate and also must be established for each specific type of resistor. This is evident from the fact that, for a product of unity for the film type of resistor shown, the parallel resistance is about 80 per cent of the d-c value, as compared to 53 per cent for the body-type unit.

Table 7 indicates the approximate frequency at which a 1-megohm resistor will have a parallel resistance of 0.5 megohm for 0.5-, 1- and 2-watt resistors within the dimensional limits stated in Table 3. With the product relationship discussed above, the data in Table 7 may be used to estimate the frequencies at which other resistors of the same size and type will drop to values of parallel resistance equal to half of the d-c resistance.

The parallel capacitance C associated with these resistors is also a function of resistor construction, resistance value, and frequency. Considerable variation in capacitance value for different samples of the same type has been noted, but the value appears to be in the order of 1 to 3 $\mu\mu f$, falling with frequency to around 0.5 to 1 $\mu\mu f$.

HIGH-FREQUENCY AND HIGH-VOLTAGE TYPES. Another line of composition-type resistors is available which is designed for high-voltage and high-frequency applications. These have various wattage ratings from less than 1 watt to about 100 watts.

In general the high-frequency type consists of a continuous film of resistive element on the surface of a ceramic tube. In size, as typified by the product of one manufacturer, these resistors range from units about $1/8$ in. in diameter and $1/2$ in. long with wire lead axial terminals to units about 2 in. in diameter and 20 in. long overall, including ferrule terminals. Resistance values of a few ohms to several megohms are available, depending upon the physical size of the resistor.

Table 7. Resistance-frequency Characteristics of Specific Resistors

1-megohm Resistor Nominal Wattage Rating	Frequency in Megacycles for R of 0.5 Megohm	
	Film-type Element	Body-type Element
0.5	20	1.2
1.0	3.0	0.8
2.0	....	0.4

High-voltage composition-type resistors are of similar construction to that described for the high-frequency type, except that the resistive element is usually in the form of a spiral or ribbon to provide a long conducting path. They are available in sizes ranging from units $5/16$ in. in diameter and about 2 in. long rated at 2 watts and 7500 volts maximum, to units 2 in. in diameter and about 20 in. long rated at 150 watts and 100,000 volts maximum. Resistance values obtainable range from a few thousand ohms to a million megohms.

4. DEPOSITED-CARBON RESISTORS

GENERAL DESCRIPTION. "Deposited-carbon resistor" denotes a kind of resistor in which the resistive element is a film of carbon deposited on the surface of a suitable ceramic core by the thermal decomposition of gaseous hydrocarbons at high temperatures. This film is extremely thin and by proper control of the coating process may be varied in thickness within the range from 1×10^{-4} to 5×10^{-8} in. The resistance of such films ranges from about 5 ohms per unit square to about 10,000 ohms per unit square. "Ohms per unit square" denotes the resistance as measured between opposite edges of a square of resistance film of the thickness indicated.

Electrical connection is made to the carbon film by applying low-resistance electrodes of either graphitic or special metallic paint. These electrodes are cured by suitable heat treatment, and then metal caps with integral lead wires are forced over them. Since the carbon film is sensitive to abrasion and also needs protection from contamination, the resistance structure is coated with a suitable baking varnish or housed in an enclosure. Resistors having resistance values up to a few thousand ohms are formed of uniform films. High-ohmage units are obtained by cutting a helical groove through the carbon film to form a ribbon of film wound around the core between the end electrodes. The surface perfection of the ceramic core and its other physical and chemical properties have a marked effect on the electrical characteristics of the resistor.

USAGE. Deposited-carbon resistors provide exceptional resistance stability and compactness in high values of resistance. Also, because of low residual inductance, the power-type varieties are of value as load resistors in testing high-frequency equipment. Special shapes of deposited-carbon resistors in the form of suitably terminated small rods and disks are available for assembly in coaxial-type attenuator units for use in making accurate attenuation measurements up to frequencies of several hundred megacycles.

SIZES AND RATINGS. Typical figures for the product of one manufacturer are given in Table 8. These resistors have cylindrical bodies. The resistors with the shell enclosures have axial leads and are intended for general-purpose use. The glass-enclosed units are hermetically sealed with an inert gas in the enclosure and are provided with ferrule end caps as terminals; they are intended for applications in which high stability in resistance value or high levels of power dissipation are involved.

PERFORMANCE CHARACTERISTICS. The general-purpose resistors and the glass-enclosed types for high-stability application are available in tolerances as close as ±1 per cent. The large power dissipating units are available in tolerances of ±5 per cent.

Table 8. Ratings and Sizes of Deposited-carbon Resistors

Rating Nom. at 30° C	Wattage, Maximum *	Approximate Overall Size, in.		Resistance Range, ohms		Short-period Peak Voltage †	Protective Enclosure
		Diameter	Length	Minimum	Maximum		
0.15	0.5	11/64	13/16	1	5×10^6	5,000	Shell
0.5	1.5	11/32	1	200	10^6	8,000	Shell
1.0	3.0	11/32	2 1/16	200	5×10^7	15,000	Shell
1.0	10	7/16	2 1/4	200	10^7	2,000	Glass
2.0	20	7/16	3 1/4	200	1.5×10^7	6,000	Glass
	60	5/8	4 11/16	20	10^7	10,000	Glass
	300	1 1/4	8 3/4	20	5×10^6	20,000	Glass
	600	1 1/4	14 3/4	40	10^7	40,000	Glass

* At maximum wattage, resistance may differ from 30 deg cent value by decreases of 10 to 15 per cent.
† Not to exceed that required for maximum power rating.

Temperature Coefficient. The temperature coefficient of the carbon film depends upon its thickness and ranges from about −180 parts per million per degree centigrade for very heavy coatings to about −500 parts per million per degree centigrade for light coatings. Furthermore, the application of protective lacquer to the film may modify its temperature coefficient by virtue of mechanical effects on the film. The physical properties of the ceramic base also affect this coefficient. Hence the temperature coefficients of these resistors range from about −0.02 to possibly −0.10 per cent per degree centigrade, depending upon resistance value and constructional features. The resistance-temperature curve is approximately linear over the temperature range of −40 deg cent to +60 deg cent.

Voltage coefficient is in general negligible for deposited-carbon units. Occasionally an individual resistor may show a slight resistance variation with voltage but probably not more than 0.002 per cent per volt.

Humidity effects depend upon the structure of the resistor and in hermetically sealed units become a matter of leakage across the surface of the housing. The following figures are indicative for general-purpose units with shell enclosures. After exposure to a condition of 90 per cent relative humidity at an ambient of 30 deg cent for 200 hours, the maximum change in resistance may be expected to be less than 1 per cent, with an average change of less than 0.5 per cent.

Noise. At low levels of voltage, deposited-carbon resistors exhibit pure thermal noise, but as the voltage is raised other electrical noise may be observed. This may be some form of contact noise due to imperfections or loose contacts in the carbon film. However, at rated load the noise level, excluding thermal noise, may be expected not to exceed 0.25 rms microvolt per volt.

Load-life Characteristics. General-purpose-type deposited-carbon units when operated at their normal wattage rating may be expected to show average changes in resistance value of not more than 1 per cent after 2000 hours. Occasional units may age as much as 1.5 per cent. Hermetically sealed resistors operated at high power levels may show more rapid aging. For example, the 7/16 × 3 1/4 unit in Table 8 may change in resistance value up to 3 per cent after 3000 hours of operation at 10 watts. Load aging may cause either a positive or negative change in resistance but generally results in a positive change. In using power-type resistors, care must be taken to insure that the voltage gradient within the resistor is not sufficient to give rise to corona or cause flashover between adjacent turns of a spiraled element and thus damage the unit.

Like composition resistors, when deposited-carbon units are operated in high ambient temperatures they should be derated. For types which are not hermetically sealed, it is recommended that the maximum operating surface temperature of the carbon film not exceed 120 deg cent. Since their normal rating is established at 30 deg cent, the wattage ratings for these units should be decreased by about 1 per cent for each degree centigrade that the ambient exceeds 30 deg cent. For glass-sealed units, which under maximum power ratings may operate at surface temperatures up to 450 deg cent, the ratings can be regarded as independent of ambient temperature up to about 80 deg cent. The manufacturer should be consulted for further derating information for the specific conditions of application. The ratings of power units can be increased several fold by forced air cooling, and, for a-c application, resistors are available which may be liquid cooled through direct contact of the coolant with the film. Anodic oxidation of the film precludes the use of water cooling on d-c applications.

The effect of soldering is negligible on lead-type units, provided, of course, that the resistor is not damaged by direct contact with the soldering tool.

No-load Aging. Under conditions of no-load or shelf-aging, deposited-carbon resistors of the general-purpose type may be expected to drift in value not more than 0.1 to 0.2 per cent per year. Hermetically sealed units appear to have a stability in resistance value of the order of 0.005 per cent per year, which is about the limit of error in measurements extending over such a time period. In fact the stability of high-quality hermetically sealed carbon film resistors, particularly in the megohm region, appears to be at least as good as, if not better than, that of equivalent resistance wire-wound units.

FREQUENCY CHARACTERISTIC. Deposited-carbon resistors exhibit a decrease in parallel resistance with frequency. However, the rate of decrease does not appear to be as rapid as in the insulated-type composition resistor, and it is less for the glass-enclosed type than for the varnished or shell-protected unit in which the protecting material is in contact with or very close to the carbon film. A 1-watt varnish-coated 1-megohm unit, $9/32$ in. in diameter and $2\ 1/16$ in. long, drops to 0.5 megohm parallel resistance at about 12 mc.

Whereas the inductance of an unspiraled film is negligible, the inductance of a spiraled unit may be appreciable. For example, the inductance of a 1-megohm resistor of the $7/16$ in. $\times$ $3\ 1/4$ in. size in Table 8 is about 1.1 microhenries. Though spiraling increases inductance, the ratio of inductance to resistance remains essentially unchanged. Since the effects of distributed capacitance are changed only slightly by spiraling, the alteration in high-frequency behavior of a resistor which is spiraled to a high resistance value is largely that associated with the resistance increase alone.

5. METAL FILM RESISTORS

These resistors are formed by coating a base of suitable material with a very thin film of metal or metallic alloy. This film may be applied to the base by cathode sputtering or metal evaporation processes, and by chemical methods. It is quite thin, being of the order of 10^{-7} in. thick. The material used for the base may be ceramic, glass, or an organic body such as Bakelite.

In one construction, a thin film of palladium is deposited by a chemical process on a ceramic-core tube. The ends of the film are coated with silver or some other metal to form electrodes for the attachment by soldering of radial lead wires. The film is covered by a form of vitreous covering to afford protection against oxidation and corrosion as well as against mechanical damage. High values of resistance are obtained by cutting a helix through the metal film into the core, in the same fashion as deposited-carbon film resistors are helixed. For further protection the whole unit, including the portion of the lead wires in contact with the resistor body, is lacquered. Resistors made in this way are available over a range of resistance values in several sizes corresponding to different wattage ratings. They possess good electrical stability under aging and load conditions, and they have good heat-dissipating properties. As determined from observations on a limited number of samples with a nominal rating of 1 watt, aging under d-c rated load is predominately positive as regards resistance value and may be of the order of 1 to 5 per cent after 1000 hours, depending upon resistance value. The temperature coefficient is negative and varies to some extent with resistance value. It also shows considerable departure from linearity over the temperature range of -40 deg cent to $+80$ deg cent. Referred to resistance value at 20 deg cent, resistors increase in value by about 5.5 per cent at -40 deg cent, and at 80 deg cent they decrease in value by about 3 per cent.

In another construction of metal film resistor, a resistance alloy such as Nichrome is evaporated to form a very thin film on the surface of a glass tube or rod. A layer of protective material is placed over this film, and lead wires are attached in the same general manner as described above. An advantage of this type of construction is that the low temperature coefficient of the resistance alloy is retained in the resistor.

6. POTENTIOMETERS AND RHEOSTATS *

Potentiometers and rheostats in general use in the communications and electronics fields may be classified as wire-wound and composition types. Those most extensively used are the continuously adjustable type, where a movable contact traverses a resistance-wire winding or a composition resistance element in small increments of their lengths. In most instances the movable contact is controlled by a rotatable shaft, although in some the resistance element is rotated. It is standard practice to have terminals for both ends

* Article 6 was contributed by A. H. Volz.

of the resistance element in addition to a terminal for the movable contact so that they may be wired either as potentiometers or rheostats.

Most of the potentiometers and rheostats hereinafter described may be obtained in tandem arrangement either with a common shaft which adjusts each unit simultaneously or with concentric shafts which permit independent adjustment of the tandem units.

WIRE-WOUND POTENTIOMETERS AND RHEOSTATS. **Low-operating-temperature potentiometers** find application as voltage- and current-adjusting devices in low-energy circuits. The power ratings are based on operation in free still air at an ambient temperature of 40 deg cent with a maximum temperature rise of 60 deg cent. A power derating curve is shown in Fig. 19. When potentiometers are enclosed and in close proximity to other components it is considered good practice to limit the power dissipation to about one-half the rating.

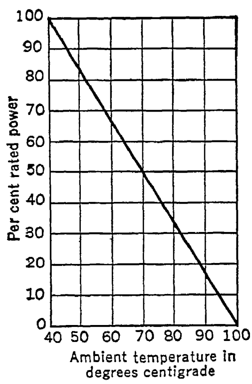

FIG. 19. Power Derating Curve for Continuous Duty

The types that find the widest application are the small circular potentiometers that range from about 1 1/4 in. to 2 in. in diameter and are rated from about 2 to 4 watts. In this type bare wire is space wound on a flat strip of insulating material, usually a laminated phenolic, which is then formed into a circular shape and set into a housing or case. The contact shoe or brush is made of a base metal or an alloy of base metals, supported on a spring member. The force exerted on the resistance wire by the base-metal contacts usually ranges from about 100 to 200 grams, sufficient to keep the contact resistance below 1 ohm, providing a satisfactory level of contact noise for most applications and a useful life of 25,000 to 100,000 cycles of operation. Individual potentiometer designs may show changes in resistance from 1 to 10 per cent over the ranges of temperature and humidity usually encountered.

In general it is desirable to use no smaller than 1.75 mil wire (usually similar to Nichrome), resulting in maximum resistance of about 50,000 ohms for the 2-in.-diameter size and 10,000 ohms for the 1 1/4-in. size. Standard tolerances on resistance are ±10 per cent. Closer tolerances and higher resistance values can be obtained on a custom basis. Finer wire is more susceptible to wear and electrolytic action.

Various resistance-rotation characteristics are available, the most extensively used being the linear type wherein the rate of change of resistance between the contact terminal and one of the end terminals is approximately constant with angular rotation. In these small types the degree of linearity is usually of the order of ±5 per cent of total resistance. This type of characteristic is illustrated by curve *A* of Fig. 20.

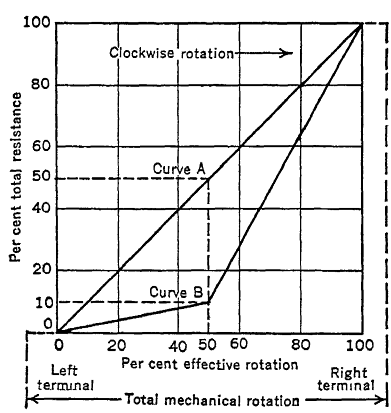

FIG. 20. Clockwise Tapers

For special applications, non-linear or tapered potentiometers can be obtained. This non-linear characteristic is effected by changing the pitch of the winding at certain points in the range of rotation or by changing wire size or by a combination of both. Curve *B* of Fig. 20 illustrates a clockwise and non-linear characteristic in which there are two sections differing in their rates of change of resistance. As a high percentage of the total resistance may be concentrated in a small portion of the resistance element, it is recommended that non-linear controls be rated at about half of the rated power of linear controls of the same designs.

For continuous operation of linear types, the maximum current through the entire resistance element or through any portion thereof should not exceed the value given by the following equation:

$$I = \sqrt{\frac{W}{R}}$$

where W is the wattage rating, R is the total resistance, and I is the maximum permissible current. The maximum current for each section of a non-linear control should be determined from the above expression except that R, instead of being the actual total resistance, should be that value which would obtain if the entire resistance element were wound with the same size wire as the particular section.

There is another group of circular, wire-wound, low-operating-temperature potentiometers which are approximately 3 in. in diameter and range from about 1 $^1/_4$ in. to 2 $^5/_8$ in. in depth, and in power rating from 8 to 15 watts. The winding is usually clamped around a molded phenolic base. This class of potentiometer is usually provided with a winding of a higher degree of uniformity than the smaller types, owing to the use of higher-precision winding methods. As a result linearly wound potentiometers are obtainable with linearity ranging from 1 to 0.3 per cent. Non-linear types are usually produced by shaping the card or strip on which the wire is wound, which is possible because of the greater depth of the winding. The amount of taper is limited by the maximum slope (angle between winding axis and shaped side of card) that can be wound without having the winding collapse which for close winding is about 40 deg. The deepest linear unit of this group can be wound to about 200,000 ohms without resorting to Nichrome wire finer than 1.75 mil in diameter. These types are readily obtainable with low-temperature-coefficient wire such as Advance, which, however, will wear more rapidly than Nichrome since it is softer. An idea of the performance capabilities of potentiometers of these two groups can be obtained by referring to the Joint Army-Navy Specification JAN-R-19.

Very special high-precision, low-operating-temperature wire-wound potentiometers have been developed for military applications. Some of them have winding cards shaped to provide special resistance-rotation characteristics to an accuracy represented by two turns of the winding at any point in the range of rotation. Some types have been provided with closed windings for continuous rotation; in one such type an input d-c voltage is applied through two fixed taps 180 deg apart and the output voltage is obtained from two rotating brushes diametrically opposed to each other. If the winding is linear, varying the position of the brushes varies the output voltage in accordance with a linear sawtooth wave.

Many of these types have been provided with precious-metal contacts developed specifically to obtain low contact resistance with low contact pressure. Contact resistance of a few hundredths of an ohm with contact pressures of about 50 to 80 grams has been obtained, and a life of the order of a million operations has been realized. One type of contact alloy widely used is Paliney No. 7, which consists of platinum, palladium, gold, silver, copper, and zinc.

In another type of low-operating-temperature wire-wound potentiometer, known as a multiturn potentiometer, the resistance wire is wound on an insulated metal mandrel about $^1/_8$ in. in diameter which is then formed into a helix. The diameter and number of turns of the helix vary, and potentiometers have been produced commercially with 2, 10, 15, 25, and 40 turns and with overall diameters of approximately 2, 3, 4, and 6 in. The contact is arranged to follow the path of the helix. With this type very fine adjustments are possible because of the comparatively long winding. By maintaining close tolerance on the diameter of the mandrel and on the resistivity and diameter of the wire, linearity of the order of ± 0.1 per cent or better can be provided.

The straight winding type potentiometers heretofore described are not very suitable for high-frequency applications. At frequencies above the audio range the straight winding controls are affected by distributed capacitance and inductance. For higher-frequency applications the characteristics of the individual control should be investigated.

POWER-TYPE RHEOSTATS. Toroidal Winding Type. This type is the most extensively used for applications from 25 to 1000 watts in the communications and electronics fields. Adjustable resistors of this type generally consist of a toroidal ceramic form which is wound with either round or ribbon-type wire over an arc of approximately 300 deg. The wound form is then placed in a suitable ceramic base, and the entire unit, except for the contacting surface of the wire, is given a coating of vitreous enamel under high temperature. This form of construction permits a high wattage rating in a relatively small volume of space.

Rheostats of this type are available in sizes ranging from approximately 1 $^1/_2$ in. to 12 in. in diameter and in rated wattage from 25 to 1000 watts. They are wound to resistance values from a fraction of an ohm up to 10,000 ohms. The power rating of rheostats is based on temperature rise in free still air. For those rated at 100 watts or less, the temperature rise is limited to 300 deg cent; for those rated above 100 watts the permissible temperature rise is 350 deg cent.

These rheostats are available with either linear or tapered windings. Specific uses for tapered rheostats are: (1) to provide a more uniform degree of control for all positions of the contact, (2) to make possible the use of a smaller control, (3) to make it possible to wind a higher resistance on a small control for specific applications, (4) to provide a particular controlled effect. An example of this last might be to provide a linear relationship between control setting and motor speed in the case of motor speed controls, or to give linear control of light output from a lamp. Figure 21 shows how the current varies (in three typical rheostats) with per cent rotation of the contact.

For special applications, controls can be obtained with continuous 360-deg windings, built-in toggle switches, or off positions at either end of the rotation.

Metal Type. Another power type of rheostat utilizes mostly metal in its construction. The wire or ribbon is wound on a strip of aluminum with asbestos as insulation between the wire and aluminum strip. The winding is formed into a circular shape and is assembled in a die-cast aluminum base with mica separating the winding from the base. Owing to the close proximity of the winding to the aluminum parts, the heat is carried away from the winding more rapidly than in the ceramic types. As a result, for the same wattage dissipation the temperature rise is somewhat lower.

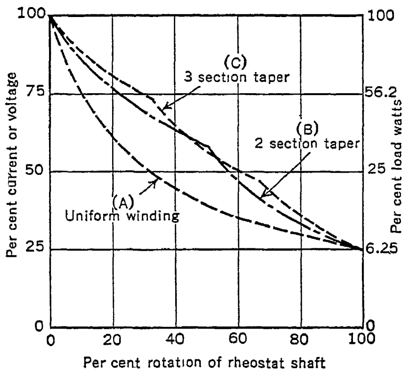

FIG. 21. Typical Curves of Current, Voltage, or Wattage Relative to Shaft Rotation for Uniformly Wound and Taper-wound Rheostats (Courtesy Ohmite Mfg. Co.)

Standardization requirements and performance capabilities of power-type rheostats for use in military applications are contained in Joint Army-Navy Specification JAN-R-22.

Tubular Slide-wire Type. The tubular slide-wire type of rheostat is used extensively for general laboratory applications, particularly for precision measurements. They are not generally used in commercial applications, inasmuch as they require considerably more mounting space for equivalent wattage ratings and are not as convenient as the toroidal type.

STEP-TYPE POTENTIOMETERS, RESISTANCE BOXES, AND ATTENUATORS. **Potentiometers.** This type consists of a rotary-type switch wired with fixed wire-wound resistors between successive contact positions. A brush or blade rotated by a shaft makes contact with contact studs or clips to which the fixed resistances are wired. The resistors of each step may be all of equal resistance value or they may differ, depending upon the nature of the application. The use of finite resistance steps permits a high degree of accuracy, especially in low- and medium-frequency applications. The accuracy at higher frequencies is dependent upon the frequency characteristics of the individual resistors and the type of switch structure. Likewise, the amount of power that can be dissipated is governed by the fixed resistors and the type of switch used.

Decade Resistance Boxes. Many laboratory measurements and test instruments require the adjustment of resistance in a circuit in accurately known steps of pure resistance. A decade resistance box consists of a number of individual resistance units equipped with switching so that the total resistance is adjustable in decade units. Resistance units are connected in series, and as many units can be connected as are required. To keep minimum inductance and distributed capacitance, card-wound or spool-type resistor units are used. Shielding and careful wiring arrangement also help keep capacitance low between resistor units. Where residual inductance of the resistors must be considered, a switching arrangement introduces a compensating winding as the resistance is adjusted to maintain constant inductance.

Attenuators. Attenuators are used to insert known amounts of transmission loss in circuits either for testing purposes or for volume level control. Step-type attenuators basically consist of rotary-type switches and fixed resistors, as in step-type potentiometers. They are arranged, however, to introduce various types of balanced or unbalanced resistive networks into a circuit. They are designed electrically to be inserted between specific input and output impedances, and only when so used will they insert the desired loss (see Section 5).

CARBON COMPOSITION TYPE POTENTIOMETERS. Carbon composition potentiometers are widely used in the communications and electronics fields on account of their low cost, the higher resistance values in which they can be obtained, and their excellent high-frequency characteristics. The types generally available are physically similar to the small single-hole mounting, low-operating-temperature wire-wound controls previously described. Two types of composition resistance elements are used, namely, the film-coated type and the molded type. In the film-coated type, the carbon, filler, and binder mixture are applied as a film on a ring of insulating material. The film is specially processed so as to minimize abrasion of the contact surface of the resistance element. In the molded type the carbon composition is molded into a phenolic base. The contact is a carbon brush, giving a carbon to carbon contact.

Linear and non-linear resistance rotation characteristics are obtainable in the composition types. The non-linear or tapered characteristic is produced by varying the proportion of the conducting material to the insulating material in the mixture as the element progresses over its length. It is possible by blending in this manner to obtain a rather smooth rate of change of resistance with angular rotation. Typical resistance-rotation characteristics of composition-type potentiometers are shown in Fig. 22. Curve *A* represents a clockwise linear characteristic except for a small range at each end of the rotation. Curve *B* illustrates a clockwise taper in which the first 50 per cent of the rotation introduces only 10 per cent of the resistance into the circuit, whereas the second half of the rotation inserts the remaining 90 per cent of the resistance. Curve *C* represents a clockwise taper in which the first 50 per cent of the rotation introduces 90 per cent of the resistance and the second half of the rotation inserts the remaining 10 per cent of the resistance. Curves *D*, *E*, and *F* illustrate counterclockwise tapers of similar characteristics to curves *A*, *B*, and *C*, respectively.

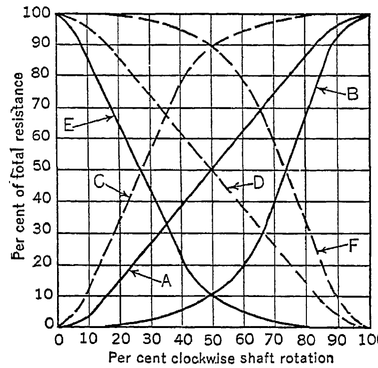

FIG. 22. Nominal Resistance-rotation Characteristics (Courtesy Ohmite Mfg. Co.)

Film-type composition potentiometers are available in a variety of sizes ranging from about 5/8 to 1 1/2 in. in diameter and in wattage ratings from about 0.05 watt to 1 watt. The available molded types are about 1 1/8 in. in diameter and are rated at about 2 watts. Resistance values obtainable range from about 50 ohms to 10 megohms.

For film and molded composition-type potentiometers, the voltage coefficient and the effects of overloading, aging, temperature changes, and exposure to high humidity are about of the same order as for film and molded fixed composition resistors. The molded are inherently more stable in resistance than the film types. The tabulation below obtained by tests compares typical film and molded types of 1-megohm resistance with respect to their stability of resistance under varying atmospheric conditions. The tabulation is in terms of average percentage change in resistance from that measured at room conditions in successive tests on the same set of samples.

Per Cent Change in Resistance from Initial Resistance at 20° C under Varying Atmospheric Conditions

	After 4 Hr at −18° C	After 4 Hr at −50° C	After 72 Hr at 50° C	After 72 Hr at 65° C	After 96 Hr at 40° C and 95% relative humidity	After 72 hr at 90° C
Film type	+3.0	+7.0	−7.0	−10.0	+14.0	−17.5
Molded type	+3.5	+5.5	−4.0	−5.5	+6.5	−5.5

Owing to their low inductance and capacitance, composition potentiometers are finding wide use in high-frequency applications; an example is a common shaft tandem arrangement of three rheostats, two of which are the series arms and the third the shunt arm of a continuously adjustable T type attenuator for level control in television transmission over telephone circuits at frequencies up to 4 megacycles.

7. SPECIAL-PURPOSE RESISTORS

In addition to the many resistors described so far, numerous special-purpose resistors designed for particular applications should at least be mentioned here. In this category are resistor standards such as those used in various measuring circuits and bridges which are discussed in Electrical Measurements, Section 11 of this handbook. Thermistors and varistors are used in an increasing number of applications in communications circuits, and they are fully described in the following articles. Resistors used primarily for heating as in furnace elements and heavy-duty power controllers are covered in the Electric Power volume of the *Electrical Engineers' Handbook*. A few other kinds are:

Resistance Lamps. In this type a special lamp filament having a high positive temperature coefficient serves either as a current-limiting, current-regulating, or protective device in communication circuits. Those used to maintain constant current, as in the heater circuits of vacuum tubes, are referred to as ballast lamps.

Dummy Antenna Loads. These may be in the form of (*a*) special space-wound resistance elements enclosed in an evacuated glass bulb, (*b*) a wound mica card mounted between metal castings to assist in carrying off the heat, or (*c*) a water-cooled film-type resistor in which water is circulated through or over a ceramic core on which a resistor film has been deposited.

RESISTORS IN PRINTED CIRCUITS. Printed circuit structures are a comparatively recent development in which a network of resistors, in combination with capacitors and inductors, is applied in the form of bands or ribbon to one or both sides of a supporting structure, usually a thin ceramic plate. The necessary capacitors are also mounted on the plate, and the plate itself may serve as the dielectric spacer and support for the capacitor. Connections to both resistors and capacitors are made by lines of conducting paint. Thus a complete coupling or filter circuit or even an entire amplifier circuit having several stages of amplification may be assembled on a thin plate of 1 or 2 sq. in. of surface area. The network is suitably terminated with wire leads, and the whole structure is given a suitable protective covering. The resistors may be of metallic or carbon film or of the composition film type. For composition and metal film type resistors produced by chemical means, the material may be applied in the desired pattern by painting or silk-screen process. For resistors applied by the metal-evaporation process, suitable stencils may be used to limit deposition to the desired areas. Where a high dielectric body serves both as the dielectric for the capacitors in the circuit and as the supporting panel for the resistors, note that the increased distributed capacitance brought about in the resistor due to the intimate contact with the high dielectric material may have a very marked effect on its performance at high frequency. Printed circuits are finding increasing applications in devices such as hearing aids, miniature radios, or wherever space is at a premium. Obvious advantages are compactness and small size. Disadvantages are difficulties in manufacture due to the necessity for processing all elements of the circuit at one time, which makes close tolerance adjustment of individual elements impracticable and lessens the likelihood of attaining the desired characteristics in all components. Also, in service, it is usually necessary to replace the entire unit when a single element becomes defective.

VARISTORS AND THERMISTORS

By N. Y. Priessman

GENERAL. The term varistor, from the words variable and resistor, is applied to a group of circuit elements broadly classified as non-ohmic resistances. The application of the term varistor is restricted to devices in which the property of variable resistance is provided by solid semiconductor materials. The semiconductors that have proved useful as stable circuit elements are those in which the current carriers are electrons as distinguished from those in which ions are transferred through the solid.

These non-ohmic resistors may be divided into two broad classes, depending upon whether the resistance change is an electric field effect (varistors) or a temperature effect (thermistors). The field-effect varistors may further be divided into rectifier varistors and symmetrical varistors. Rectifiers, such as copper oxide, selenium, silicon, and germanium, exhibit quite different values of resistance depending on the polarity of the applied voltage. Symmetrical varistors such as Thyrite, Metrosil, Atmite, and silicon carbide show no rectifying properties. Thermistors (see article 10) change resistance markedly with changes of temperature but do not, independently of temperature change, possess a non-linear resistance characteristic.

8. COPPER-CUPROUS OXIDE VARISTOR

The copper-cuprous oxide varistor consists essentially of a piece of sheet copper about 0.050 in. thick in the form of a disk, washer, or plate which has been oxidized so as to form on its surface a layer of red cuprous oxide. A thin layer of conducting material is applied to the exposed surface of this oxide to provide a contact, known as the outer contact. The mother copper provides the other electrode. Figure 1 shows an enlarged and out-of-scale cross-section of such a varistor cell.

The manufacturing techniques, although differing in detail with various manufacturers, depending on the particular qualities in the product they are interested in, have in common the following: the desired form of cell is blanked from sheet copper (usually the grade known as Chile copper), chemically cleaned, oxidized in air atmosphere at a temperature in the neighborhood of 1000 deg cent for some 10 to 20 minutes to form a layer of cuprous oxide 0.003 to 0.004 in. thick, held for some minutes at a temperature of about 550 deg cent, and then quenched in water. At this stage the cuprous oxide (red) is covered with a thin layer of cupric oxide (black) which must be removed by chemical action. The means of providing an outer contact vary with the manufacturer. The following means are in common use: (*a*) painted-on contacts of "aqua-dag" (colloidal graphite), (*b*) electroplated contacts, and (*c*) contacts of gold or silver produced by the well-known techniques of evaporation in vacuum.

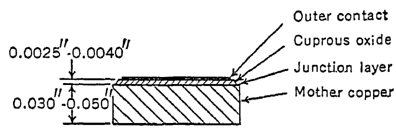

FIG. 1. Copper Oxide Varistor Cell

The electrical properties of the varistor may be altered significantly by suitable variations in the fabricating processes, as for example by the addition of metallic impurities to the copper (such as thallium); by changes in time, temperature, and atmosphere of the heat treatments; or by changes in rate of cooling and quench temperature, etc.

The current-voltage characteristics of a varistor cell commonly used in communication circuits is shown in Fig. 2 in the "Chile copper" curves. The "forward characteristic" exhibited by the cell with the mother copper negative and the outer contact positive is the flatter branch of the two curves. The "reverse characteristic" which obtains when the copper is positive and the outer contact negative is shown by the steeper branch. Considering in detail the forward characteristic curve the varistor behaves very much like an ohmic resistor at voltages below 0.05. As the voltage increases above this the current increases rapidly; that is, the resistance decreases. The seat of this potential dependent resistance as well as of the rectifying property is in the interface between the cuprous oxide and the copper. This interface is variously called blocking layer, junction layer, barrier layer, etc. As the voltage increases above 0.5 volt the current increases less rapidly and the resistance approaches a limiting constant series resistance, which is mainly the body resistance of the oxide layer itself. The series resistance of the outer contact is small compared with the body resistance of the cuprous oxide layer and is non-rectifying. The thallium-copper cell behaves similarly but with reduced currents in both directions.

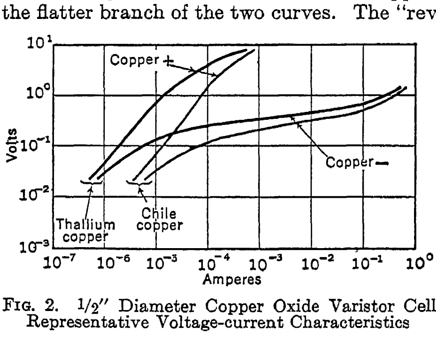

FIG. 2. 1/2″ Diameter Copper Oxide Varistor Cell Representative Voltage-current Characteristics

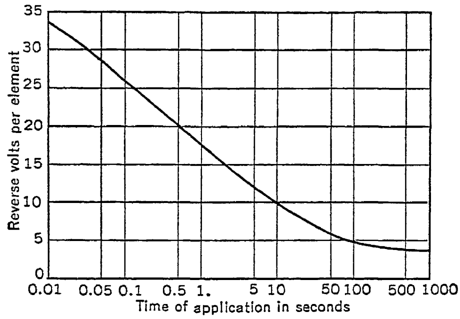

FIG. 3. Relation of Safe Reverse Voltage to Time of Application for Typical Copper Oxide Cells at Ambient Temperatures below 100° F and for Applications Spaced at Least 1 Minute Apart

The forward current at a voltage is proportional to the area of the cell or, more accurately, to the area of the outer contact. The reverse current is not simply related to the geometry of the cell. The characteristics of cells in series may be obtained by sliding the characteristic curves parallel to themselves along the voltage axis, and the characteristics of cells in parallel by sliding the curves along the current axis. In practice large areas may be obtained most economically by large-area plates.

Large deviations from the typical characteristic curves shown are inherent in the commercially manufactured product even when produced under the best controlled conditions of present practice. Moreover these characteristics change with time and use. While the forward resistance increases with time and temperature, the reverse resistance decreases with

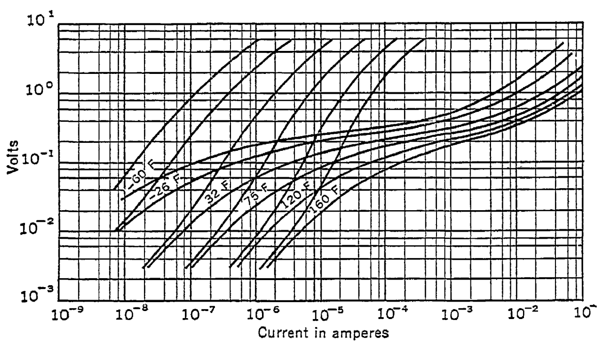

FIG. 4. Representative D-c Characteristic of $^3/_{16}$-in.-diam. Copper Oxide Varistor Cell (Chile Copper)

continued application of reverse voltage. In general this should not exceed 4 volts (see Fig. 3). These effects again vary from batch to batch.

Large negative temperature coefficients of resistance both in the forward and reverse direction are characteristic of these devices. No simple law such as holds for metallic conductors is applicable, and the variation of resistance with temperature may best be displayed graphically as in Fig. 4.

The effect of exposure to moisture is to reduce the reverse resistance of all types of cells. This is especially troublesome in the small-diameter, very-high-reverse-resistance cells. The forward resistance of cells with aqua-dag contacts is increased by exposure to moisture. It is customary in the use of varistors as circuit elements to provide substantial moisture-proofing in the form of organic coatings, potting in wax, etc.

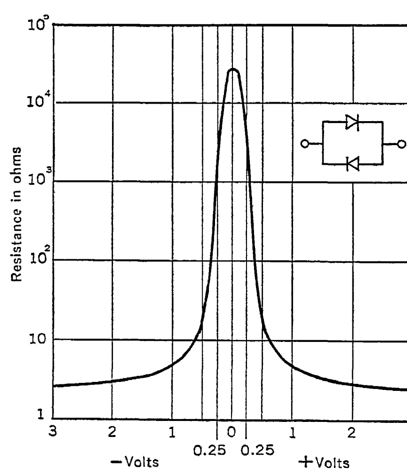

FIG. 5. Voltage Limiter, Two $^1/_2$-in.-diam. Copper Oxide Varistor Cells (Copper plus Thallium)

Structures. The $^3/_4$-in.-diameter and larger cells are usually made in the form of a washer and clamped together with wiring terminals on an insulated bolt. The $^1/_2$-in.-diameter and smaller cells are usually assembled with wiring terminals and pressure spring in cylindrical cavities in insulating blocks.

Ratings. When copper oxide varistors are used as current-supply rectifiers their ratings are based on four factors on which definite specifications should be made, with allowance for aging. These factors are (1) the d-c voltage and current output, (2) the a-c voltage input, (3) the ambient temperature, and (4) the means for cooling the varistor cells.

APPLICATIONS. Voltage Limiter. It may be seen from Fig. 2 that as the voltage in the forward direction increases from 0.1 to 1.0 volt the current increases more than 1000 fold. A varistor may be connected across the input terminals of a network to act as a bypass when applied voltages are substantially above the normal level. Figure 5 shows the resistance-voltage characteristic of such a varistor in which two 1/2-in.-diameter cells of thallium copper (see Fig. 2) are connected in parallel opposing so that the combination has a symmetrical resistance-voltage curve. The resistance is greater than 10,000 ohms for voltages up to 0.1 volt and drops to about 5.0 ohms at 1.0 volt. As the voltage increases above 1.0 volt the resistance decreases but little; it is being limited by the body resistance of the copper oxide layer.

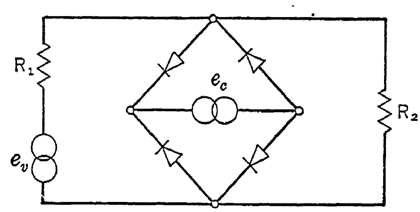

Fig. 6. Bridge Connected Modulator

Modulator. Copper oxide varistors are extensively used both as modulators and demodulators in carrier telephone systems. A bridge-connected modulator is shown in Fig. 6. The carrier voltage e_c is made large compared with the signal voltage e_v. When the carrier voltage is of such polarity as to bias the varistors in the forward direction they will all be low in resistance, offering substantially a short circuit to the signal current. When the carrier voltage reverses the varistors all have a high reverse resistance and the signal current appears in R_2. It is desirable to prevent unmodulated carrier current from appearing in R_2, and this is done by selecting the four varistors in the arms of the bridge to have voltage-current characteristics very closely alike so that the bridge is balanced throughout the cycle of carrier voltage. (A complete discussion of the varistor modulator is given by Caruthers, *Bell System Technical Journal*, Vol. 18, 315 [1939].)

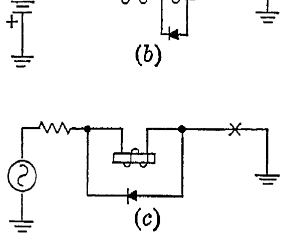

Fig. 7

Control of Telephone Relays. Various configurations of relay windings and varistors may be used to modify the response characteristics of relays. Several such arrangements are shown in Fig. 7: (*a*) delayed release with practically no effect on operate time; (*b*) delayed operate with practically no effect on release time. Steady operation of relays from an a-c source is obviously possible using the varistor as a rectifier. In the simple arrangement shown in Fig. 7(*c*), the reverse half-cycle is bypassed through the varistor which also affords a path for the slow decay of current established in the winding during the previous positive half-cycle.

Varistors are used in a circuit network known as a "compandor"—a contraction of the words "compressor" and "expandor." A compressor is a non-linear transmission network in which the range of signal power output is compressed relative to the range of power input. An expandor is a network which provides the inverse action. Detailed discussion of such circuits, also called "vario-lossers," may be found in Bennett and Doba, *Trans. A.I.E.E.*, Vol. 60, 17 (1941).

9. SILICON CARBIDE VARISTORS

It has long been known that silicon carbide will, under suitable conditions of contact, exhibit a non-linear relationship between current and voltage. This may readily be demonstrated by measuring the voltage-current characteristic of a mass of small particles of silicon carbide compressed between metallic electrodes. As the voltage is increased from zero the current increases, at low voltage in direct proportion to the voltage and then much more rapidly. If the number of particles in the mass is large and the distance between electrodes large compared with the dimensions of the particles the non-linear resistance of the device is independent of polarity.

Experiments upon single particles with suitably made contacts indicate that the body resistance of the particle is small, ohmic, and independent of polarity.

The non-linear conduction exhibited by the mass of particles results from the voltage-dependent resistances at the point-to-point contacts between the granules of silicon carbide. The overall resistance characteristic may be thought of as due to large numbers of non-linear resistance contacts arranged at random in series and parallel. In a statistical sense the aggregate displays no dependence upon the direction of current flow. This varistor is an example of a "symmetrical non-linear resistor."

The simple device of containing a mass of silicon carbide particles under pressure between electrodes does not have the stability of characteristic under use conditions to afford wholly reliable circuit elements.

In 1930, McEachron (see *Journal A.I.E.E.*, Vol. 49, 410 [1930]) described a silicon carbide ceramic non-linear resistor to which the name Thyrite was given. The material consists of silicon carbide particles bonded in a ceramic matrix. Similar materials are known under various names such as Metrosil and Atmite.

The essential steps of manufacture are these: suitable silicon carbide particles, clay and water, sometimes with a minor constituent such as carbon, are mixed to form a plastic mass. The mass is partially dried and forced through screens to obtain a slightly damp granular powder. This material is compressed under high pressure into desired shapes, generally flat disks or rods. These pieces are further dried and heat treated in a reducing atmosphere at a temperature in the neighborhood of 1200 deg cent. The fired pieces are hard and strong and have mechanical properties quite similar to those of dry process porcelain. Electrodes on the opposite plane faces are provided by spraying or Schooping a layer of metal such as brass, copper, aluminum, or tin. The piece is then usually impregnated with a moisture-repellent organic substance to prevent pickup of water, which adversely affects their electrical stability.

The electrical properties of the product are profoundly affected by the parameters of process: materials, particle size, moisture content, forming pressure, and especially temperature, time, and atmosphere of the heat treatments. The products of different manufacturers differ somewhat in electrical properties, most importantly in the degree of non-linearity, and the characteristics of Fig. 8 are to be taken only as generally indicative. The current-voltage characteristic shown is closely represented by the equation

$$I = C_1E + C_2E^n$$

where I = current through the piece, E = voltage applied to the piece, C_1 and C_2 are constants depending on the material and geometry of the piece, and n is an exponent the value of which depends on various factors in the manufacturing process and generally lies between 3.5 and 5.0. Some manufacturers indicate values of n as high as 7.0 but only for pieces having resistances much above the range indicated in Fig. 8.

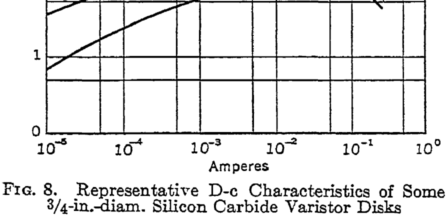

FIG. 8. Representative D-c Characteristics of Some 3/4-in.-diam. Silicon Carbide Varistor Disks

The variation of characteristic through control of manufacturing processes and geometry of the piece permits coverage of an enormous range of current and voltage. This range may be further extended by connection of pieces in series or parallel. It is to be noted from Fig. 8 that as the resistance of the piece decreases the value of n decreases also, and this being typical of all manufacturers' products may be considered an inherent characteristic of the presently made material. In consequence it is not possible with this device to obtain marked non-linearity at low voltage.

In common with semiconductors the silicon carbide varistor exhibits a negative temperature coefficient of resistance. The coefficient does not have a single value but varies both with the material and with voltage and temperature. The values of the coefficient at constant voltage cover a spread of from 0.3 per cent to 0.9 per cent per degree centigrade in the normally used range of temperature. The higher values of temperature coefficient are observed at the lower voltages.

At high frequencies consideration should be given to the presence of a capacitance effectively in parallel with the non-ohmic resistance. The exact value of this capacitance is determinable only by measurement, but the order of magnitude may be calculated by assuming the material to have a dielectric constant of 30 to 200.

Commonly used shapes are rods and disks. Small disks and rods may be furnished with leads soldered to the metallic electrodes on the faces of the piece. Disks are also made with holes in the center and clamped together with wiring terminals by means of a central bolt. Disks and rods of all sizes are used with spring clip mountings which furnish mechanical support and electrical connections.

When used under high humidity conditions, or at low currents, the organic impregnant, referred to in the description of the fabricating process, may not be sufficient protection against moisture and further precautions may be necessary.

Approximate values of mechanical and thermal properties of importance in circuit element design are as follows:

Bulk density....................	2.35 grams per cu cm
Compression strength............	15,000 to 23,000 lb per sq in
Specific heat....................	0.17 to 0.21 cal per gram per deg cent
Thermal conductivity............	0.0034 cal per cm per sec per deg cent

Requirements on the current-voltage characteristic for a particular application may be stated in a number of ways; the following are commonly used.

(*a*) The voltage E_1 at a current I_1 shall be greater than some value, and the voltage E_2 at a current I_2, where I_2 is greater than I_1, shall be less than some value. This statement of requirements contains implicitly a requirement as to the minimum value of n.

(*b*) The voltage at a given current I shall be equal to a value $E \pm X$ per cent, and the value of n shall lie within certain limits throughout a range of current.

It is to be noted that considerable differences in characteristic may exist between pieces meeting a set of such requirements. In commercial manufacture the range of voltage at a given current commonly runs ±20% about the average. Accuracy of meters used in checking requirements is important since errors in voltage readings are to be multiplied by n in determining their effect on current readings.

Self-heating resulting from power dissipation in the varistor lowers its resistance (negative temperature coefficient of resistance), but this effect is in general reversible; that is, no permanent effects on the characteristic are produced by moderate heating, say from 100 to 150 deg cent. The safe upper limit of heating is oftentimes determined by the moisture-resistant organic compound used as an impregnant. As shown in Fig. 8, 1.0 watt for a disk of $^3/_4$-in. diameter suspended in free air at 50 deg cent is a limit recommended by one manufacturer. Very heavy transient currents may alter permanently the characteristic, usually in the direction of decreasing the resistance.

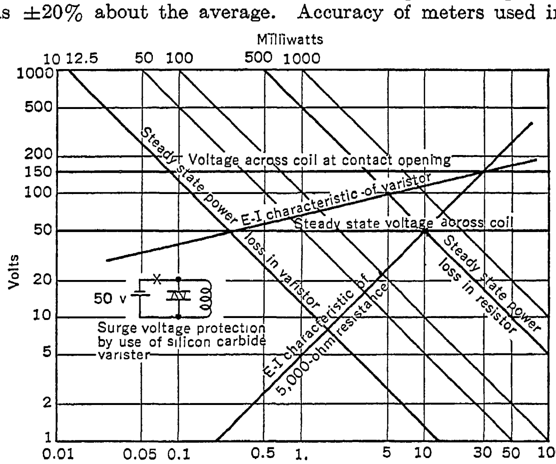

FIG. 9. Surge Voltage Protection by Use of Silicon Carbide Varistor

APPLICATIONS. (1) A silicon carbide varistor connected across the terminals of an electromagnetic winding acts to limit the surge voltage generated when the field is opened.

As shown in Fig. 9 the maximum value of voltage across the varistor may be determined from the point on the voltage-current characteristic corresponding to the steady-state value of current I_0 in the winding. As compared with an ordinary resistance shunt across the winding to secure the same voltage-limiting effect, the varistor dissipates much less power when the coil is steadily energized.

(2) In certain carrier telephone system filters exposed to high incoming voltage, the condenser of a high-Q combination of coil and condenser has been protected by a varistor in shunt.

(3) Some of the smaller telephone switchboards have line lamps connected directly in the subscriber's loop for signaling. These line lamps are exposed to electrical disturbances that may be impressed on the outside lines, and if the disturbances are severe enough the lamps may be burned out. Silicon carbide varistors have been used very effectively in parallel with the lamp to bypass large incoming surges. The high resistance of the varistor at the normal signaling level has no appreciable effect on the lamp illumination.

(4) Use is made of varistors to protect contacts controlling inductive circuits from the deleterious effect of sparks resulting from the opening of such circuits. Usually the varistor is connected across the winding rather than across the contact to avoid continuous current drain. Though such an arrangement is useful it is not a satisfactory general solution of the problem. The varistor increases the release time of the relay or switch magnet, though not to the extent that an ohmic resistance of equivalent spark quenching action would do, and it does not entirely eliminate high-frequency oscillations across the opening contact due to the associated wiring.

10. THERMISTORS

Thermistors or thermally sensitive resistances are devices made of solid semiconductors the electrical resistance of which varies markedly with temperature. This phenomenon has long been known, Faraday having observed that the resistance of silver sulfide decreased rapidly as the temperature increased. Since that time it has been determined that a great number of materials classed electrically as semiconductors exhibit high negative temperature coefficients of resistance. Semiconductors have specific resistances at room temperature much greater than those of metallic conductors and much less than those of insulators. This very wide intermediate range of resistivities is not bounded precisely but may extend from 0.1 ohm cm to 10^9 ohm cm. Materials commercially employed in thermistor circuit elements have a much narrower range of resistivity, roughly from 10 ohm cms to 100,000 ohm cm.

The materials of thermistor construction include a wide variety of metallic oxides. In common use are the oxides of uranium and various mixtures of the oxides of magnesium, manganese, titanium, iron, nickel, cobalt, zinc, etc. The common method of fabricating is to heat the oxides in the form of compressed powders to a temperature at which they will sinter. At the sintering temperature the powders recrystallize to form a dense, hard, ceramic-like solid of homogeneous composition. The sintered-powder process permits the mixing of various oxides in suitable proportions to produce a wide range of electrical and thermal characteristics and permits as well the fabrication of a great variety of shapes and sizes of the completed piece.

Forms. Three forms of thermistors are common—disks, rods, and beads. A thin plate or flake form has also been described and is in limited use (see Becker et al., *Bell Sys. Tech. Jour.*, January 1947). Disks range in diameter from 0.125 to 2.0 in. and in thickness from 0.030 to 0.250 in. Rods are made in diameter from 0.030 to 0.250 in. and in length from 0.050 to 2.5 in. Bead diameters range from 0.006 to 0.060 in.

Properties. The relations between specific resistance and temperature of several thermistor materials are shown in Fig. 10 and for comparison the resistance-temperature relation of platinum. In Fig. 11 the log of the specific resistance is plotted against the reciprocal of the absolute temperature. It is seen that the curves are very nearly straight lines, and so to a close approximation

$$\log \rho = \text{const.} + \beta \cdot \frac{1}{T} \quad \text{or} \quad \rho = \text{const.}\ e^{\beta/T}$$

from which

$$\rho = \rho_0 e^{(\beta/T - \beta/T_0)}$$

where T = temperature in degrees Kelvin, $\rho = \rho_0$ when $T = T_0$, β is numerically proportional to the slope and is of the dimensions degrees Kelvin. From the definition of temperature coefficient $\alpha = (1/R)(dR/dT)$ it is seen that

$$\alpha = -\frac{\beta}{T^2}$$

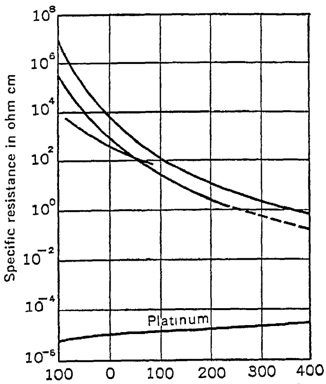

FIG. 10

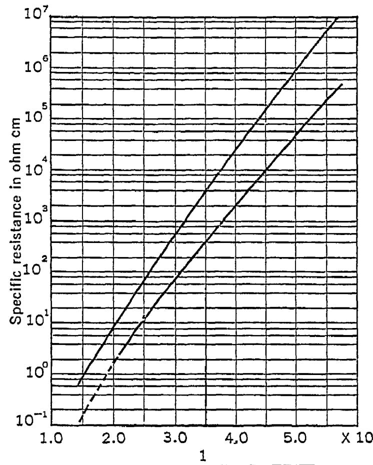

FIG. 11

THERMISTOR APPLICATIONS. Direct utilization of the resistance-temperature relation is a broad field of use including resistance thermometry, compensation for the positive temperature coefficient of other resistive circuit elements, temperature control, and the like. In all these applications the self-heating effect of any current in the thermistor is kept small so that the resistance is fully controlled by the ambient temperature.

The equation previously given for the relation between resistance and temperature may for purposes of general calculation be considered independent of temperature. Table 9 shows temperature-resistance characteristics of a typical thermistor thermometer. With an ordinary Wheatstone bridge and galvanometer and a suitably calibrated thermistor thermometer a precision of 0.001 cent deg is readily obtainable.

The use of thermistors in conjunction with relays, valves, etc., for temperature control is closely akin to their use in thermometry. The larger currents required for relay operation necessitate design consideration of the self-heating effects in the thermistor.

Thermistors are used to compensate for changes in resistance of electrical circuits caused by ambient temperature variations. Shunting the thermistor by a parallel resistance sometimes improves the accuracy of the compensation. Consideration should be given to like temperature exposure of the thermistor and the compensated circuit element, and also to the effects on both of power dissipation.

Table 9. Temperature-resistance Characteristic of a Typical Thermistor Thermometer

Temperature, deg cent	Resistance, ohms	Temperature Coefficients	
		B, deg cent	α, per cent per deg cent
−25	580,000	3,780	−6.1
0	145,000	3,850	−5.2
25	46,000	3,920	−4.4
50	16,400	3,980	−3.8
75	6,700	4,050	−3.3
100	3,200	4,120	−3.0
150	830	4,260	−2.4
200	305	4,410	−2.0

Dissipation constant in still air, approximately 4 milliwatts per degree centigrade; thermal time constant in still air, approximately 70 sec; dimensions of thermistor, diameter approximately 0.11 in., length approximately 0.54 in.

Small thermistors have been used extensively to measure power in very high-frequency test sets. Suitably mounted in a properly terminated waveguide a thermistor bead absorbs effectively the entering power, and the consequent heating of the bead produces a change in resistance which may readily be measured with high accuracy. Calibrating may be done with d-c or low-frequency power.

The self-heating effect of current through a thermistor, primarily the bead type, results in interesting and useful non-linear relationships between current and voltage. Figure 12 shows a "steady-state" characteristic of a particular form of bead thermistor. At small currents the power dissipated is too small to heat the thermistor appreciably, and the resistance remains constant. With increasing current the effects of self-heating become evident; the temperature of the thermistor rises and the resistance decreases. As the current continues to increase, the slope of the curve changes from positive to negative and in this latter region the thermistor exhibits a negative value of dv/dI, that is, a negative resistance. The numbers along the curve give the rise in temperature in degrees centigrade above the ambient. The change in resistance of the thermistor does not occur instantaneously with current change because of its thermal mass.

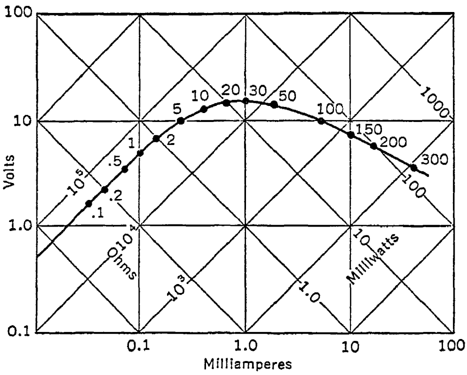

FIG. 12

The heating and consequent reduction of resistance by the continued passage of current is used to obtain delayed response circuits as well as non-response to short-duration surges by connection of the thermistor in series with a relay.

Figure 13 shows a combination of thermistor and resistances to obtain either a speech volume limiter or a volume compressor. The speed of response of the thermistor is adjusted to syllabic frequency or slower to eliminate the wave-form distortion and peak chopping common to quick-acting non-linear devices.

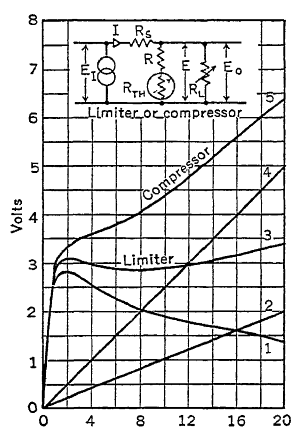

FIG. 13

Curve 1, thermistor characteristic
Curves 2 and 4, ohmic resistor characteristics
Curves 3 and 5, combined characteristics

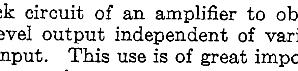

FIG. 14

Figure 14 shows a thermistor in the negative feedback circuit of an amplifier to obtain constant level output independent of variations of signal input. This use is of great importance in telephone carrier systems to correct for variations in overall line loss. The simple bead structure previously described is not adequate for this purpose since its resistance and hence the amount of feedback would be subject to change with changes in ambient temperature. Temperature compensation is economically obtained by associating a heater winding with the bead and regulating the input current to the heater to produce a constant temperature surrounding the bead.

INDUCTORS WITH AIR CORES

By L. M. Hershey

Of the many different types of air-core inductors in communications equipment today, the solenoid and the universal winding are most widely used. Torroidal windings, and other types such as the bank winding, spiral winding, and basket weave, are sometimes found.

The single-layer solenoid is used in untuned or tuned circuits, for resonant circuits, chokes, and in various other applications where a high Q, low distributed capacitance, mechanical strength, or ease of construction is of importance. More space is required to accommodate a single-layer solenoid than a universal winding of any type, for a given inductance; at frequencies below about 1 or 2 mc, space considerations frequently prevent the use of the single-layer solenoid.

The universal winding is popular in applications similar to those listed above for the single-layer solenoid but generally at frequencies below about 2 mc. It produces a coil having fairly high Q with low distributed capacitance, and mechanical strength. The distributed capacitance of a universal winding can be decreased by winding it on a narrower cam or by building it in a number of sections, each of which is a universal winding, with these sections connected in series. This multisection universal winding also can be adjusted to close inductance tolerance requirements by moving one of the end sections (sometimes called a "pi") nearer to, or away from, the adjacent section.

Many special types of windings are in use as tuned loops in the broadcast band (540 to 1600 kc). Among these types are the multilayer solenoid, basket weave, single-layer solenoid, and spiral winding.

Air-core inductors are used at frequencies up to about 200 mc, or up to a frequency where a transmission line becomes more convenient. The transition region between coils and transmission lines appears to be extremely broad.

The choice of the type of inductor is generally dictated by such practical considerations as available space or cost as well as by circuit considerations. Untuned primary coils and chokes of less than about 10 to 20 μh are usually solenoid windings. When greater inductance is required, the universal winding is used.

11. PROPERTIES OF AIR-CORE INDUCTORS

FIGURE OF MERIT. The figure of merit of an inductor is the ratio of its effective reactance to its effective resistance. This factor is called the Q of the inductor.

POWER FACTOR. The reciprocal of the Q of the inductor is equal to the power factor of the circuit within very close limits for values of Q above about 20. The power factor is more convenient than the Q to use in the calculation of certain circuit phenomena. For instance, the power factor of a circuit formed by an inductor shunted by a capacitor is the sum of the power factors of the two branches of the circuit, while the Q of the circuit is the reciprocal of the sum of the reciprocals of the Q's of each branch.

Like resistance and conductance, both the power factor and the Q are useful concepts, and the choice depends upon their application to the particular problem.

TIME CONSTANT. The time constant of an inductor in series with a resistor (the resistor may represent the internal resistance of the inductor) is L/R; it is the time in seconds required for the current, through an inductor of L henries in series with a resistor of R ohms, to reach 0.632 of its final value if a voltage is applied suddenly, or for the current through the series circuit to fall to 0.368 of its initial value if the inductor and resistor are short-circuited suddenly.

COIL LOSSES. The principal losses in an air-core inductor are those due to I^2R loss in the conductor and the dielectric losses in the coil form, wire insulation, impregnating material, etc. Eddy-current losses also occur in the conductor. At very high frequencies the losses due to radiated power may be appreciable. Additional losses occur outside the coil itself whenever any magnetic, dielectric, or conducting material is within the field of the coil.

The attainment of a maximum Q in a given space is one of the most common problems. At the lowest frequencies, the problem is to obtain the lowest d-c resistance for a given inductance. As the frequency becomes higher, skin effect (the tendency of an alternating current to flow along the outside surface of a conductor) becomes apparent, and is measurable even at power-line frequencies. Dielectric losses also begin to be noticeable at very low frequencies. Throughout the radio-frequency spectrum these two causes of power loss are of extreme importance. For example, a well-designed coil operating at 1 mc might have a d-c resistance of less than 5 ohms and an apparent resistance greater than 10 ohms.

Coil losses may be minimized, and high values of Q realized, by careful choice of the type of wire (to increase the surface area of the conductor through which the r-f currents flow), by obtaining the optimum spacing between conductors, and by choosing the proper shape of the winding for the available space.

It is sometimes desirable to design a coil with a certain value of Q so that, for instance, a required band width can be produced without the use of an external damping resistance. Then the designer may reverse his usual thought processes and use a "poor" shape factor for his coil, a conductor either larger or smaller than the optimum value for maximum Q, or use a value other than optimum for the spacing between conductors. Frequently, the diameter of the coil form can be reduced until a desired low value of Q is realized.

DISTRIBUTED CAPACITANCE. Each turn of an inductor is coupled magnetically to other turns of the same inductor. A certain small amount of capacitance between the turns of a winding is unavoidably produced by their proximity. The effect of all these small series capacitances across the whole inductor at its working frequency is called the distributed capacitance of the coil. The values of the distributed capacitances of various common types of air-core inductors range from a small fraction of a micro-microfarad up to 10 or more $\mu\mu$f. In general, a coil having a large ratio of length to diameter has a low distributed capacitance, and it is obvious that finer wire and greater spacing between turns will result in lower distributed capacitance.

Dielectric losses generally are decreased by a reduction in distributed capacitance. However, the changes necessary to reduce the dielectric losses and distributed capacitance (reducing the wire size, increasing the spacing between turns) finally begin to increase the copper losses in the conductor faster than the dielectric losses are decreased. An optimum design is a compromise between all these factors, and in a resonant circuit the distributed capacitance is frequently of lesser importance than the Q of the inductor; therefore, the capacitance is disregarded, while efforts are directed toward the attainment of minimum total losses. In r-f choke coil design, a minimum value of distributed capacitance is usually desired, while a Q higher than 5 or 10 produces a negligible effect. Therefore, choke coils are frequently wound with a minimum wire size, on long slender forms, and with relatively large spacing between turns.

12. ELECTRICAL DESIGN CONSIDERATIONS

TYPES OF CONDUCTORS. Copper wire is most commonly used in inductors. Copper tubing, or strips, are sometimes resorted to at frequencies above about 50 mc. Litz wire, composed of a number of strands of fine enameled wire (from about No. 38 to No. 44), produces lower r-f resistance than a single wire of the same area of cross-section. It is most effective in the lower-frequency part of the radio spectrum, below about 2 mc. Above this frequency the r-f currents appear to flow along the outside of the *group* of conductors and the effectiveness of litz wire is not so apparent.

Bare copper wire is rarely used for inductors. Tinned wire is found occasionally on space-wound solenoids; silver plating is also used occasionally on the heavier conductors normal for this type of coil. Silver plating offers the advantages of high conductivity on the surface of the conductor where higher-frequency currents flow, soldering to the conductor is made easy, and an attractive and fairly durable finish is produced.

TYPES OF WIRE INSULATION. Silk and cotton have been the most common materials for wire insulation on air-core inductors. Coil wire is made with a spiral wrapping, adding about 0.002 in. to the diameter of the wire for silk or about 0.004 in. for cotton. This is called a "serving" of silk or cotton. A double serving may be used, with the second serving spiraling in a direction opposite to that of the first serving. This is known as double-silk or double-cotton insulation; it is usually designated D.S. or D.C. For instance, a No. 38 bare wire with double silk insulation could be described as 38 D.S. Celanese and nylon are rapidly replacing silk and cotton as insulation for coil wire. Braided fabric insulation is also used to some extent.

An enamel coating is used, either alone on wire for solenoids, or with one or more servings of silk or one of the other serving materials over it. The enamel adds about 0.001 in. to the wire diameter. Plastic coatings can be added to conductors, and almost any required outside diameter can be produced in this manner.

Litz wire, as it is made in this country, consists of three or more strands of enameled wire with one or more servings of silk, cotton, celanese, or nylon, around the group of wires. The strands are either twisted in a regular fashion as they are wrapped or simply placed side by side parallel to each other. The twisted method produces a slightly higher Q under some conditions.

BEST COIL SHAPE. Formulas are available which express the best shape factor and winding pitch of a single-layer solenoid under idealized conditions. In a practical design problem these formulas serve as a valuable guide.

It has been shown that with a given length of wire, wound with a given pitch, the single-layer coil which has the maximum inductance value is so shaped that the ratio Diameter $\div$ Width of winding = 2.46, approximately.

Brooks has determined that there is a most efficient multilayer coil form to produce the maximum inductance with a given length of conductor. This most efficient inductor was produced as a compact multilayer cylindrical coil with a mean diameter 2.95 times the side of the square cross-section. Other proportions varying somewhat from the optimum affect the inductance only slightly. It has been determined that, when the ratio of mean diameter to side of square cross-section is 2.80, the resulting inductance is only 0.04 per cent less than the maximum value. It is generally convenient and within limits of accuracy to consider the optimum form as having the dimensions: diameter equal to 3 times width, and width equal height of winding.

Precision design can be effected only when the inductor is solely for low frequencies. The problem then of constructing an inductor of definite inductance for radio frequencies resolves mainly into the problem of minimizing the resistance and distributed capacitance. A coil is designed for a certain range of frequencies, and generally an attempt is made to construct a coil with a uniformly high value of Q in this range. In consideration of these and other requirements, a coil design will generally depart from the optimum proportions indicated above.

It will be found that a practical coil is, in general, somewhat elongated in the direction in which distributed capacitance will be minimized. For instance, a practical solenoid is usually longer in proportion than is indicated by the formula above; a diameter-to-length ratio of slightly over unity is common. The universal winding is frequently elongated in the radial direction. A diameter-to-length ratio of about 0.7 was found to produce the maximum Q over the broadcast band for a progressive universal winding on a 0.5-in.-diameter Bakelite form.

Dielectric and eddy-current losses, which usually are neglected in the computation of "best" coil shapes, appear to be primarily responsible for the noticeable discrepancies between calculated and measured data.

SOLENOID WINDINGS. Single-layer solenoids are sometimes wound with each turn touching the preceding turn; this results in fairly high values of distributed capacitance and eddy-current and dielectric losses. The length of the winding, and consequently its inductance, vary considerably from coil to coil in this type of winding because of variations in wire size (unless the wire is selected to closer than the usual limits for its gauge) and because of the failure of each turn to lie snugly against the next throughout its length. Therefore, when the inductance tolerance of a coil is closer than a few per cent, it is customary to "spin" a few turns—about 5 to 10 per cent of the total on the end of the coil. These turns are wound with the same spacing as the main portion of the winding, but the group of wires in the spun portion is spaced about $^1/_8$ in. away from the balance of the coil. These "spun" turns can be moved on the coil form nearer to, or away from, the balance of the winding.

It is possible to wind a solenoid to very accurate length and inductance limits (on a form of accurate diameter) on a winding machine or lathe adjusted to produce the desired pitch per turn. This method allows uninsulated wire to be wound in a solenoid, if care is taken to secure the turns properly on the form to prevent slippage after the coil is wound. Depending upon the design requirements, the pitch may be chosen to give the minimum spacing necessary to assure mechanical and electrical uniformity with maximum variations in wire and insulation dimensions, or the spacing may be chosen for optimum electrical performance.

Solenoids are sometimes wound in a screw-thread groove in the coil form, but unless a molded form is used it is difficult to maintain an accurate effective diameter of the groove and inductance variations result. Also, winding the conductor in a groove may reduce somewhat the Q of a very efficient inductor because of increased dielectric losses in the material in the immediate vicinity of the conductor. A slight increase in distributed capacitance will also result.

A simple manner in which to wind a single-layer solenoid is to choose insulation of the proper thickness to space the turns properly when the insulated wire is close wound.

THE UNIVERSAL WINDING. This type of inductor is wound in single or multiple sections ranging in widths from about $^1/_{16}$ to $^1/_2$ in. On a simple type of winding machine, the width of the coil is controlled by a cam which oscillates the wire guide back and forth in a linear fashion on the periphery of the form or on the next lower layer of the same winding. The cam is geared to the main shaft of the winding machine. The main shaft holds the coil form and rotates the coil as it is wound. The number of teeth in the gear on the main shaft (or driven by the main shaft through a 1/1 gear ratio) over the number of teeth in the gear on the camshaft is called the gear ratio. The wire is wound on the form at an angle to the side of the coil form (winding angle) determined by the width of the cam, the diameter of the coil, and the gear ratio. Simon has stated that a practical limit of this winding angle is about 12 deg maximum. Above this value, the wire may slip on the coil form and a poor winding will result. The winding angle becomes smaller as the coil builds up, being approximately inversely proportional to the diameter of the winding at any point; when this angle is reduced to about 6 deg the turns cross each other at an angle which is too small and tend to align themselves in the spaces between adjacent turns on the previous layer. The coil will not build up properly after this point is reached.

When a coil must be wound up to an outside diameter about equal to, or greater than, twice its inside diameter, it is frequently necessary to tolerate some slippage of the wire on the form at the start of the winding. The winding problem is, of course, greatly facilitated when the designer restricts the height of the winding to a point within practical limits.

The winding angle is proportional to the cam width and also to the gear ratio, since the gears drive the cam at a rate depending upon their relative number of teeth.

If g', the pattern gear ratio, is the fraction q'/s', where both q' and s' are small whole numbers, a simple and practical winding pattern should result. The number of cam cycles per winding cycles is q', and the number of planes cutting the periphery of the winding where interlaced crossing of turns occur is $(s' - 1)$.

In order to have the winding pattern repeat on consecutive winding cycles with the required spacing between adjacent turns, the pattern gear ratio may be corrected by the amount $\pm g'xw/2cq'$, where x is the desired number of wire diameters between turns (usually about 1.25), and w is the diameter of the wire. The plus sign produces a retrogressive winding; the minus sign produces a progressive winding. The gear ratio, g, may be computed $g = g'(1 \pm [0.63w/cq'])$.

THE PROGRESSIVE UNIVERSAL WINDING. The progressive universal winding is a special type of universal winding in which the wire guide is moved parallel to the axis of the coil form as the coil winds. The machine for winding this type of coil is usually equipped with 100:1 reduction gears driving the set of gears on the rear of the machine which produce the progression. The pitch of the winding produced by a 1:1 set of progression gears is usually very close to 0.01 in., but not exactly so on all machines.

It is necessary to correct the gear ratio (which would be used for an ordinary universal winding) slightly in order to allow for the change in spacing which results from the progression. This can be done by reducing g' by the amount $-0.5g_pp/c$, where g_p is the progression gear ratio and p is the pitch. This factor is usually rather small.

The steps required to determine the winding machine setup for this type of winding follow:

First, determine the number of turns per inch by dividing the desired number of turns by the required length. For a relatively wide cam and short winding, it is desirable to subtract one cam width from the required length for this calculation in order to allow for the tapering off of the winding at its ends. At this point it is best to examine the result and determine the number of layers of wire which will be built up radially on the coil. If the number is less than about 2.5 a solenoid would be preferable; if it is more than about 5 layers, the progressive winding may not build up satisfactorily, and a plain universal winding of one or more sections may be better.

The cam for a progressive winding is usually as narrow as possible, since the distributed capacitance and dielectric losses increase with a wider cam. A wider cam, however, decreases the steepness of the slope of the pile of wire upon which a turn must be wound and, consequently, enables a coil having more layers to be wound.

The value of g' for a progressive winding is usually less than for a universal, since it is unnecessary to make provisions for winding the coil up to a height comparable to the form diameter. In this case it is desirable to choose q' and s', again fairly small whole numbers, but values such as $^9/_5$ or $^7/_{11}$, where q' and s' are larger, produce a better pattern on the surface of the coil. Landon and Joyner's "composite" winding is obtainable when a fairly complicated pattern is obtained.

SHIELDING. The successful operation of many of the modern communication laboratory devices and radio receiving sets depends upon the effectiveness of the shielding between the various parts, and so, in high-gain amplifiers, leads, vacuum tubes, transformers, and tuning coils are all shielded. This process generally requires the placing of a metallic shielding container around the individual parts. Shielding is attempted against both electric and magnetic fields and is particularly necessary in circuits carrying high-frequency currents.

As has been pointed out before, whenever material is brought into the influence of the electric and magnetic fields of an inductor there is a transfer of energy to that material. Parts of the inductor are generally at a potential higher than that of the shield, which is usually at "ground" potential. With this condition there is added to the distributed capacitance of the winding more capacitance to "ground." This further complicates the calculation of the actual inductance of the coil at high frequencies.

Shields are generally constructed of non-magnetic or magnetic metals such as iron, zinc, copper, and aluminum. In the shield used for the shielding of a high-frequency magnetic field, the efficiency of the screen depends upon the eddy currents produced in the shield. The energy involved in the circulation of these eddy currents is drawn from the field of the shielded inductor. Magnetic shielding is therefore always accompanied by an increase in the effective resistance of the shielded inductor.

When the resistivity and thickness of the metal shield remain constant and the frequency of the alternating electromagnetic field varies, the shielding increases as the frequency increases, owing to the increased flow of eddy currents. For a given kind of metal at any specified frequency the shielding efficiency increases as the shield thickness is increased. Under these conditions, a certain thickness of shield introduces a maximum resistance into the shielded circuit. The thickness of the shield which gives maximum added resistance to the shielded circuit decreases as the frequency increases. If shielding is to be obtained by eddy currents they must be free to flow as they will, which requires that there be no imperfect joints or breaks in the shield. A short-circuited coil may be used as a shield since the current induced in it by the field will set up an opposing field and give a zero local resultant.

In an "open"-circuit electrostatic screen, no eddy currents will flow, and the shield may be used to prevent the alternating field from reaching an impure dielectric and thus producing a loss. In this application the shield reduces the effective resistance of the electrical circuit.

Since the eddy currents in a shield set up a magnetic field opposing the field of the inductor, it is evident that there will be a reduction of the net field surrounding the inductor winding. There is therefore a change in the effective coil inductance, which results in a decrease of the inductance value.

Many investigators have attempted to state quantitatively the magnitude of the screening effects on coil inductance and resistance. An idealized mathematical solution of the problem (given in the *Wireless Engineer*) replaces the ordinary cylindrical screen by a spherical one, and the cylindrical coil by a dipole of the same magnetic moment placed at the center of the sphere. The development is possible because it has been found that the exact shape of the screening can is not important, and this permits the mathematical use of a sphere with a diameter the geometric mean of the three coordinates of the can. The expression developed shows the reduction of the effective inductance of the coil to depend upon the frequency, material constants, the screen thickness, and a linear dimension representing the can size

$$L = L_0\left(1 - \frac{2}{3}\cdot\frac{V_c}{V_s}\frac{a}{K}\right) \tag{1}$$

in which V_c equals volume of the coil (winding section $\times$ length); V_s equals volume of screening can; K equals a constant less than 1 ($K = 0.7$ when coil length = coil diameter); L_0 equals actual inductance of the short solenoid; and a equals factor depending upon f, dimensions, permeability, and resistivity of the screen can (a = almost 1 for non-magnetic materials).

A general interpretation which may be made of this expression is that the effect of the screen on the coil inductance varies inversely as the diameter of the screen can to the cube power.

This conclusion has been stated by Hayman, and the results of a simple expression of the effect have been accurately checked by experiment. The approximate expression which has been given for short coils is

$$L_{\text{screened}} = L_{\text{unscreened}} \left(\frac{D^3 - d^3}{D^3}\right) \tag{2}$$

where D = screen diameter and d = coil diameter. As the coil length approaches half the can length there is more influence from the ends of the can. This condition requires the use of a correcting factor which is expressed as

$$\text{End correction} = \left[1 - \left(\frac{l \text{ coil}}{2l \text{ can}}\right)^2\right] \tag{3}$$

The calculations with these expressions for coils which do not exceed half the can dimensions have checked experimental measurements within less than 1 per cent.

The effect of the eddy-current flow in drawing energy from the inductor results in an increase of the effective resistance of the inductor. If skin effect in the shield is negligible and the eddy currents are uniformly distributed through the screen, the effective addition to the coil resistance has been stated as

$$R_s = \frac{3}{2\pi} T^2 A^2 \frac{\rho}{tr^4} \tag{4}$$

in which A = cross-section area of coil, square centimeters; T = number of coil turns; t = thickness of screen, millimeters; r = radius of screen can, centimeters; and ρ = resistivity of the can material, ohms per cubic centimeter. When skin effect in the shield forces a non-uniform distribution of eddy current the above expression is modified to take the form

$$R_s = 0.95 \times 10^{-4} \, T^2 A^2 \frac{\sqrt{f\rho}}{r^4} \tag{5}$$

An indication of the presence of skin effect in the shield is gained from the expression

$$t\sqrt{\frac{f}{\rho}}$$

When this factor is less than 5000, the skin effect is negligible.

13. MECHANICAL DESIGN CONSIDERATIONS

FORM MATERIALS. Some of the factors to be considered in choosing a form material are its mechanical strength, dielectric properties, coefficient of thermal expansion, machinability, moisture absorption, power factor at the operating frequency, and cost. Sometimes the operating-temperature requirements will not permit the choice of an otherwise desirable material, or the heat required to solder leads to lugs on the coil form may soften the coil form and loosen the solder lugs.

It has been found advisable to select an extremely stable material, whenever frequency drift requirements are severe, rather than an unstable material with compensation elsewhere in the circuit for inductance changes. Glass coil forms are sometimes possible where only a very small thermal expansion can be permitted. The various kinds of glass, with coefficients of linear expansion of about 3 to 9 parts per million per degree centigrade, are among the best materials now available. Steatite and mycalex also exhibit good temperature stability characteristics.

While phenolic materials have been popular because of their adaptability for use as form materials and their relatively low cost, their coefficient of linear expansion is only fair, being about 30 parts per million per degree centigrade.

The coefficient of thermal expansion of materials which are not homogeneous (such as commercial laminated Bakelite tubing) frequently has different values for the radial and axial dimensions. Average values of these two coefficients can generally be furnished by the manufacturer or may be measured directly.

The coil form is usually much more rugged than the winding, and therefore the temperature instability of a coil is usually due to its form. Copper wire expands at about the same rate as Bakelite under varying temperature conditions. However, copper wire can be wound under tension on one of the more stable form materials and a stable coil will result; the form material must be sufficiently stronger than the wire so that the form is not distorted by the pressure of the wire.

Absorption of water by the coil form may result in loss of mechanical strength, a change in the distributed capacitance of the inductor, and consequent detuning of the circuit, and may produce conditions favorable to electrolysis or fungus growth. The various methods of treating coils, such as impregnating, varnishing, or the application of fungicides, may delay these harmful results, but it appears that the most certain way to avoid them is to choose materials which will not absorb water, if such materials are available and fulfill the other design requirements.

A partial list of the more important properties of some of the more frequently used form materials is given herewith.

Typical Properties of Form Materials *

Form Material	Dielectric Constant	Power Factor, % at 1 mc	Maximum Temperature, deg cent	Coefficient † of Linear Thermal Expansion	Water Absorption, % in 24 hr	Machinability
Bakelite, molded..	6.0	4.0	120	30.0	0.2	Fair
paper base......	5.5	4.0	120	30.0	0.2	Good
Glass............	6.0	0.4	Over 500	8.5	0	Very poor
Pyrex..........	4.5	0.2	500	3.5	0	Very poor
Magnesium silicate	6.0	0.3	1000	7.0	0.02	Very poor
Mycalex..........	7.0	0.3	300	8.5	0.04	Very poor
Polystyrene.......	2.6	0.03	75	70.0	0.01	Good
Porcelain.........	6.5	0.7	1000	4.0	0.5	Very poor
Rubber, hard.....	3.0	1.0	65	75.0	0.01	Fair

* Values given are subject to considerable variation.

† In parts per million per degree centigrade.

IMPREGNATION OF INDUCTORS. Coil impregnation serves two principal purposes: first, the impregnating material tends to seal out moisture; second, the impregnating material improves the mechanical strength of the winding and holds it more firmly in place on the coil form.

Either before or during the impregnation of the coil, it is necessary to drive out of the winding and form any moisture that may be present. This is accomplished either by baking the coil at a temperature slightly higher than 100 deg cent before impregnating or by maintaining the impregnating material at such a temperature while the coil is being impregnated. The maximum limit of the temperature used during baking or impregnating is the temperature that will damage some part of the winding or its form or the impregnating material.

There are many types and mixtures of different types of waxes which are used to imimpregnate coils. Resins also are mixed with waxes to improve their characteristics. The melting and softening temperatures, and the hardness of the wax, are determined by the kinds and amounts of the various kinds of waxes in the mixture. Some mixtures become extremely brittle at fairly low temperatures, which may be a serious disadvantage.

Varnish of good electrical quality, or polystyrene dissolved in a solvent, are sometimes used to impregnate coils. Vacuum impregnation (dipping the coil in the impregnating material while it is in a partial vacuum) is usually resorted to when varnish or some similar material is used to impregnate a coil.

The conditions under which the coil will be used determine the designer's choice of the method and material for impregnating the coil. Very often the economy of the method is a determining factor.

Coils which are designed for good conditions of temperature and humidity, such as in equipment to be used indoors in all but the most humid parts of the United States, are impregnated usually in a simple and inexpensive way. For instance, many coils are treated by baking in an oven until most of the moisture is driven out, followed by immersion in a wax, resin, or mixture of both, at a temperature slightly higher than the boiling point of water until all agitation of the liquid ceases. The coil is then cooled and finally "flash-dipped" to produce an even coating of the same or a different impregnant on the outer surface. The first (baking) operation is frequently omitted for the sake of economy.

Where more severe conditions of temperature and humidity are encountered, some better methods of impregnation and better materials are required. Two such impregnation procedures are described below. These methods were developed and tested by the Hazeltine Corporation for use on equipment for the Army and Navy during 1945. The two processes are:

Process 1. Q-Max A-27 diluted 1:1 with Toluene, applied by dipping and baking; recommended for Silicone-varnished Fibreglas-served wire.

(*a*) Bake the coil (on its form) for 1 hr at 110–120 deg cent.
(*b*) While still hot, immerse the coil until bubbling ceases in a solution consisting of:

1 part Q-Max Lacquer A-27
1 part Toluene ("technical grade")

(*c*) Drain and air dry for 1 hr.
(*d*) Bake for 4 hr at 140 deg cent.
(*e*) Apply two more coats per (*b*), (*c*), and (*d*) above, redipping immediately after (*d*).

Both processes described here require the use of combustible materials. Adequate ventilation must be provided and safety rules regarding fire hazards observed.

Process 2. Styrene Monomer N-100 and Q-Max A-27 diluted 1:1 with Toluene, applied by dipping and baking. Recommended for use on Fibreglas- or silk-served wire.

(*a*) Bake the coil (on its form) for 2 hr at 110 deg cent.
(*b*) While still hot, immerse the coil in styrene monomer for 20 min.
(*c*) Air dry the coil until dripping ceases.
(*d*) Bake for 24 hr at 125 deg cent.
(*e*) Redip in styrene monomer for 20 min.
(*f*) Repeat (*c*) and (*d*).
(*g*) Apply a thin coat of the Q-Max and Toluene solution.

Coils impregnated according to the two processes given above should withstand temperatures ranging from -65 to $+85$ deg cent with the relative humidity as high as 95 per cent at the highest temperature.

THE SPECIFICATION OF INDUCTORS. The materials and the method of construction of inductors can be shown readily by means of drawings and written specifications. However, it is sometimes difficult to specify the performance requirements of an inductor in an exact fashion. This is due to a lack of standardized measuring equipment in the industry capable of separating the effects of the distributed capacitance, inductance, and Q of the inductor in a practical and accurately measurable fashion, especially on the higher-frequency coils. It is possible, however, to compare one inductor to another with a higher degree of precision. Therefore, it has become a fairly widely accepted practice for the designer to adjust accurately one complete set of coils, which become the master standards. From these master standards, as many secondary standards as are required can be made and distributed to the coil adjusting and testing points. All performance specifications requiring very close tolerances are referred to these standards. If the standards are carefully prepared, stored, and handled, the variations in their performance over a period of time due to aging, etc., are minimized. It is desirable to obtain measurements, on the most stable equipment available, of all possible performance data of the standards so that the master standards themselves can be rechecked. If both the coil manufacturer and designer can measure the inductor, with similar equipment and by similar methods, the data and the inductors measured can be exchanged and the test equipment calibrated alike in both places. Even if this can be done, in view of the difficulty involved in obtaining standardized test equipment and conditions it is generally desirable to use the master standard as the basis of the specification of inductor performance.

14. INDUCTOR DESIGN FORMULAS

The formulas that follow have been found to be generally useful in the design of inductors. The inductance formulas are less accurate than those given in the *Bureau of Standards Circular* C74. They do, however, produce a result with approximately the same accuracy with which the usual range of radio-frequency inductors can be wound, using materials which are not selected to closer than normal limits. Their principal advantage is their simplicity.

The dimensions and symbols used in these formulas follow:

L = inductance of each section of a winding in microhenries.
d = form diameter in inches.
b = length of winding in inches.
c = throw of cam used to wind a universal section in inches.
w = outside diameter of wire, including covering insulation, in inches.
t = number of turns.
C_0 = distributed capacitance in micro-microfarads.
p' = pitch of winding in inches.
h = height of winding above coil form in inches.
a = mean diameter of winding in inches.

L_t = total inductance of a multisection universal winding in microhenries.
g_p = progression gear ratio.
y = number of sections in winding.
g = gear ratio.
g' = pattern gear ratio.
q' = small whole number, numerator of fraction g'.
s' = small whole number, denominator of fraction g'.
z = number of strands in litz wire.
L_a = apparent inductance in microhenries of coil with distributed capacitance.
ω = 2π times frequency in megacycles per second.
p = pitch produced by winding machine when 1/1 progression gear ratio is used.

SOLENOID AND PROGRESSIVE UNIVERSAL WINDING. Inductance.

$$L = \frac{d^2t^2}{18d + 40b} \tag{6}$$

Accurate to within about 1 per cent for solenoids with $b > 0.4d$.

Turns.

$$t = \frac{\sqrt{L(18d + 40b)}}{d} \tag{7}$$

Distributed Capacitance.

$$C_0 = \frac{2.2d}{\cosh^{-1} p'/w} \tag{8}$$

for single layer solenoids only, where w is the diameter of the bare wire. The dielectric constant of the coil form, wire insulation, and impregnating material will increase the distributed capacitance above the calculated value.

For progressive universal windings, the distributed capacitance is the minimum for the smallest cam throw; it is approximately proportional to the coil diameter.

EACH SECTION OF A UNIVERSAL WINDING. Inductance.

$$L = \frac{0.2d^2t^2}{3d + 9c + 10h} \tag{9}$$

Accuracy to within about 1 per cent when the three terms in the denominator are about equal.

Turns.

$$t = \log^{-1} (1.08 - 0.47d + 0.16c + 0.5 \log L) \tag{10}$$

to within 5 per cent approximately, for windings having more than about 100 turns. This is an empirically derived formula. If more accurate results are required, the result may be substituted in eq. (6) above, and a suitable correction obtained.

Height of Winding.

$$h = \frac{1.25w^2t}{c} \tag{11}$$

for wire which does not flatten appreciably during winding, and with 1.25-wire-diameter spacing. For litz wire, flattening of the insulation may reduce the calculated height by about 5 to 10 per cent.

Distributed Capacitance. The distributed capacitance of a universal winding is extremely variable; it depends upon many factors, including the pattern gear ratio (g'), the spacing between conductors, etc. It is approximately proportional to the throw of the cam and to the form diameter. It is fairly independent of the number of turns on the winding.

MULTISECTION UNIVERSAL WINDING. Inductance.

$$L_2 = L(2y - 1) \tag{12}$$

approximately, for each section with uniform spacing between sections about equal to the width of the section.

Distributed Capacitance. Slightly greater than the resultant of the distributed capacitances of the individual sections in series.

SPIRAL WINDING. Inductance.

$$L = \frac{(d + h)^2t^2}{16d + 44h} \tag{13}$$

where h is the difference between outside and inside diameters.

MEASUREMENT FORMULAS. Apparent Inductance.

$$L_a = \frac{L}{1 - \omega^2 L C_0} \tag{14}$$

Distributed Capacitance.

$$C_0 = \frac{C_1 - 4C_2}{3} \tag{15}$$

where C_1 and C_2 are the capacitances required to resonate the inductor at frequencies f and $2f$, respectively. When C_1 and C_2 are large, the value of C_0 obtained will be somewhat larger than that computed from the actual self-resonance of the coil.

FIGURE OF MERIT. The Q of an inductor is usually measured directly on equipment designed for that purpose. If such equipment is not available, a voltage can be induced in the inductor in a resonant circuit, with suitable precautions taken to avoid additional loading, and the resonant band width measured at the half-power point. The ratio of the test frequency to the distance between the half-power points is equal to the Q of the inductor.

UNIVERSAL WINDING GEAR RATIO CALCULATIONS

Minimum cam width = Approximately $3w$

Cam Cycles per Winding Cycle.

$$g' = \frac{q'}{s'} = \frac{d}{3c} \tag{16}$$

for forms of average smoothness; this was expressed first by Simon in terms of cross-overs (one-half cam cycle) per winding cycle:

$$g' = \frac{q'}{s'} = \frac{d}{4c} \tag{17}$$

for very smooth forms. Choose a small whole number for q' and s', with

$$s' < \frac{c}{3w} \tag{18}$$

Gear Ratio.

$$g = g'\left(1 \pm \frac{0.63w}{cq'}\right) \tag{19}$$

Set the calculated value of g on the C or D scale of a 10-in. slide rule, and locate the coincidence of two whole-number lines within the range of available gears on the C and D scales. These two coincident line numbers can be used as the number of teeth in the gears.

PROGRESSIVE UNIVERSAL WINDING GEAR RATIO CALCULATION. To determine whether progressive universal should be used, if

$$\frac{w}{g_p p} < 1 \tag{20}$$

a solenoid should be used, according to Landon and Joyner. To determine minimum cam throw:

$$c > \frac{4w^2}{g_p p} \tag{21}$$

which is Landon and Joyner's formula in the terms used here. To determine cam cycles per winding cycle:

$$g' = \frac{d}{4c} = \frac{q'}{s'} \tag{22}$$

Choose fairly small whole numbers for q' and s'; the more complicated patterns result when s' is made fairly large, and a proper choice of q' and s' can be made so that the wire is adjacent to a preceding turn in the pattern on both forward and backward strokes of the cam, producing Landon and Joyner's "composite" winding. To determine progression gear ratio:

$$g_p = \frac{b}{tp} \tag{23}$$

To determine gear ratio:

$$g = \left(g' - \frac{0.5 g_p p}{c}\right)\left(1 \pm \frac{0.63w}{cq'}\right) \tag{24}$$

This is essentially the original formula published by Landon and Joyner, in the form suggested by Simon. Use the minus sign after g' when the winding forms a right-hand screw thread. If a left-hand thread is formed, a plus sign should be used. The value of g may be computed in the same manner as for a universal winding.

FERROUS-CORED INDUCTORS

By A. J. Rohner

The utility of ferromagnetic cores in coils lies in the fact that such cores have a higher magnetic permeability than air. This permeability may be anywhere between 2 and 100,000. The use of a ferrous core may have the following beneficial effects:

(*a*) Increase of inductance. With a complete magnetic path of ferromagnetic material, this increase may be several thousand times the air-core value of inductance.

(*b*) Increase of Q. This results from the increased inductance, if the increase of loss due to core loss is not greater than the increase of inductance.

(*c*) Magnetic shielding. The magnetic field of the coil is constrained to follow to a large extent the path of the high-permeability core.

(*d*) Adjustability of inductance. Movement of the core in or out of the coil, or variation of an air gap in the core, gives mechanical means of adjusting the inductance.

The limitations of ferromagnetic cores in coils are due to certain undesirable qualities of ferromagnetic materials. Most important of these are:

(*a*) Magnetic saturation, which occurs at 7000 to 15,000 lines per square centimeter. These values depend upon the kind of core material and are for a magnetizing force of 10 oersteds.

(*b*) Non-constant permeability. Permeability varies with the direct current passing through the coil, the alternating voltage impressed across the coil terminals, and other factors.

(*c*) Core loss, which is a wattage loss additional to the copper loss of the coil; it determines the frequency range for which each type of core material may be used.

Core loss consists of two distinct parts, hysteresis loss and eddy-current loss. See Section 2, "Magnetic Materials," Spooner, "Properties and Testing of Magnetic Materials," or "Magnetic Circuits and Transformers" by staff of M.I.T. Hysteresis loss is a magnetic effect due to the magnetizing and demagnetizing of the core and is proportional to the frequency. Hysteresis loss can be reduced by using core material that is easily magnetized and demagnetized, i.e., a "magnetically soft" material. Eddy-current loss is an electrical effect due to induced currents within the core material and is proportional to the square of the frequency. Eddy-current loss can be reduced by using core material of high electrical resistivity, and by laminating or powdering the core.

At the higher frequencies, eddy-current loss becomes predominant and a finer subdivision of the core material is necessary.

Frequency Ranges. At frequencies below about 4 kc, the core usually consists of thin sheets, either in the form of flat plates or "laminations," as thin as 0.003 in., or in the form of ribbon, which can be made as thin as 0.001 in. Above 20 kc, the core usually consists of powdered material, the grains of which may average as little as 0.00012 in. in diameter. Between 4 and 20 kc, either sheet material or powdered material may be suitable. However, thin ribbon cores are useful up into the low- and medium-radiofrequency bands, while powdered cores, of larger grain size, are useful down to 1 kc or lower.

15. LOW-FREQUENCY, SHEET-CORE INDUCTORS

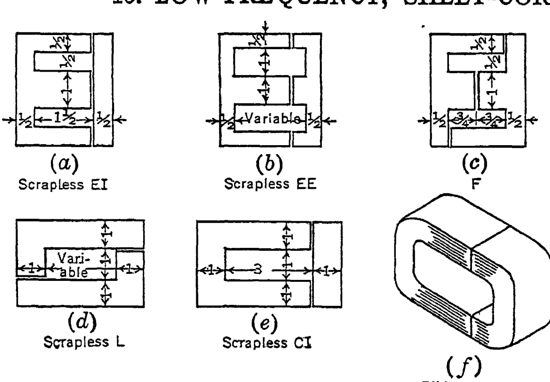

Fig. 1. Laminations and Ribbon Core

CORE CONSTRUCTION. Typical lamination shapes, and a ribbon core, are shown in Fig. 1. In general, all sheet-material cores form a complete magnetic path around the coil, except for small air gaps which may be purposely introduced, and the cross-section of this magnetic path is essentially uniform throughout the length of the magnetic circuit.

Assembly of laminated cores is illustrated in Fig. 2. A butt joint is actually a small air gap, because of oxide on the ends of the laminations, non-squareness of the ends, and imperfect meeting of the joint. This butt-joint gap may be from 0.0005 to 0.002 in. long. A value of 0.0015 in. per gap may be assumed for average design purposes. When there is an air gap, the magnetic flux usually must cross this separation *twice*. Thus, for example, if the air-gap spacer is 0.010 in. thick, the total length of air gap in the core, including the butt-joint gaps, is 0.023 in.

Usually, ribbon cores are cut in two after winding, forming two C-shaped pieces, and the ends of each C-piece are ground flat. When the two pieces are placed together, after adding the coil, the ends meet in tight butt joints, each joint being about 0.0005 in. long, so that the core as a whole approaches a continuous ferromagnetic path.

Stacking Factor. Because of oxide or other insulation on the sheet material, non-flatness of sheets, and stamping burrs on laminations, the magnetically useful cross-section of a sheet core is never 100 per cent of the measured cross-section. The ratio of the two is called the "stacking factor." Values that may be used as a guide are given in Table 1.

Table 1. Stacking Factors

Laminated Cores		Ribbon Cores	
19-mil.	0.94	14-mil.	0.65
14-mil	0.92	5-mil.	0.91
6-mil.	0.83	3-mil.	0.86
3-mil.	0.71	2-mil.	0.80

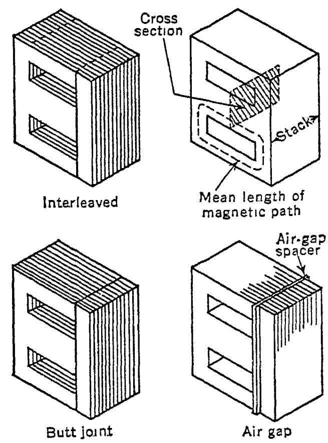

FIG. 2. Assembly of Laminated Cores

Materials most commonly used in sheet-material cores are:

(*a*) Silicon steel, especially the better grades, having silicon content from 2.5 to 4.75 per cent.

(*b*) Grain-oriented silicon steel. Hipersil and Silectron are trade names for this material.

(*c*) Nickel-iron alloys, of approximately 50–50 composition, variously known as Nicaloi, Hipernik, 4750, or 49-Alloy.

(*d*) Permalloy, an alloy of about 80 per cent nickel with iron. Hymu is a similar material.

(*e*) Mumetal, similar to permalloy, but with 5 per cent copper added.

For more detailed description of sheet-core materials, see Section 2, *Magnetic Materials*, Spooner, Chapter IV; Elmen, "Magnetic Alloys of Iron, Nickel, and Cobalt," *J. Franklin Inst.*, May 1929; Alleghany Ludlum *Bulletins* EM-11 and EM-12, and their *Magnetic Core Materials Practice;* Follansbee, *Electrical Sheet Handbook*, Magnetic Metals *High Permeability Alloys;* and Westinghouse, *Metals and Alloys*.

Thickness of Sheets. For inductors operating at 25 to 120 cycles, 25-mil-thick (U.S.S. gage 24) and 19-mil-thick (26-gage) laminations are useful. Sheet of 14-mil thickness (29 gage) is widely used, both for laminations and ribbon, for applications from 60 cycles to the middle audiofrequencies. Below 14 mils, sheet material can be obtained in almost any thickness down to 1 mil. However, stamped laminations, and preformed ribbon cores, of these thinner sheets became available largely as a result of war needs and are not yet standardized. Laminations can be purchased, of 7-mil silicon steel, 6-mil 49-Alloy and Hymu, 4-mil 4750, and 3-mil 4750, in a large variety of sizes. Hipersil ribbon cores are obtainable in 14-, 5-, 3-, 2-, and 1-mil sheet thickness.

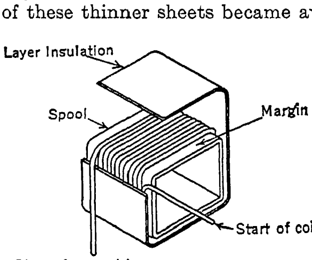

FIG. 3. Layer-wound Coil

COIL CONSTRUCTION. Low-frequency inductors usually have multilayer coils, with insulation between layers. See Fig. 3. The coil is wound upon a rectangular spool of spirally wrapped paper or fiber, 30 or 40 mils in total thickness, slightly larger in inside dimensions than the core over which it is to be placed, and slightly shorter than the core window. These clearances may be $^1/_{32}$ or $^1/_{16}$ in. Wire is usually solid copper, with enamel insulation. The length of the winding, or "wire traverse," is less than the length of the spool, to allow a "margin" of $^3/_{32}$ to $^3/_{16}$ in. at either end. Over each layer of wire is placed one turn of insulation, the same width as the length of the spool, which forms a smooth support for the next layer. Kraft paper, having a thickness about $^1/_5$ of the wire diameter, is a very satisfactory material for layer insulation. Glassine paper, of about the same thickness, is often used with wire of 24-gage (A.W.G.) or smaller. Layer-wound coils, of this construction, require no end boards to hold the wires in place.

Coils without layer insulation (random-wound) may also be used, allowing about 50 per cent more turns in a given space. There are several disadvantages to this type of winding, however. The wire must have more than ordinary enamel insulation to prevent shorted turns, which reduces the space advantage somewhat. End boards, or tape, are necessary to hold the wires in place. Multiple winding cannot be used.

After the coil is wound, flexible lead wires are attached if the wire of the coil is smaller than 20 gage. Then the coil, or the core and coil together, are impregnated with a varnish. wax, or asphaltic compound to exclude moisture and air and to strengthen the coil mechanically. See Belden Handbook 12, Anaconda "Magnet Wire and Coils," or Inca Bulletin 3.

Inductors having a three-legged core, Fig. 1(*a*), (*b*), (*c*), have a single coil, placed on the middle leg of the core. With two-legged cores, Fig. 1(*d*), (*e*), (*f*), two coils are sometimes used, one on each leg, the two coils being connected in series or in parallel. The use of two coils results in lower resistance and a smaller dimension over the coil.

DESIGN PROCEDURE is carried out by:

(*a*) Choosing a core material and core size.

(*b*) Choosing a wire size, and determining how many turns of this wire will fit in the core window. About 5 per cent allowance should be made for wires not lying tightly together. Also, the total calculated build of the coil, including spool, layer insulation, and outside wrapper, should not exceed 90 per cent of the core window height.

(*c*) Calculating the inductance, resistance, core loss, heating, capacity, and Q from the dimensions and the number of turns. Three or four trial designs may be necessary before the desired constants are arrived at.

Inductance. Since sheet material cores are characterized by high permeability, practically all the magnetic flux is confined within the core structure. The inductance of a sheet-core inductor, without air gaps, is given by

$$L = \frac{4\pi N^2 A k \mu_{ac}}{l} \times 10^{-9} \quad \text{henry} \tag{1}$$

in which N is the number of turns on the coil, A is the cross-section of the core in square centimeters, k is the stacking factor, l is the mean length of the magnetic circuit in centimeters, and μ_{ac} is the a-c, or "incremental," permeability of the core material.

When air gaps are present in the core, the inductance is given by

$$L = \frac{4\pi N^2 A k \mu_{avg}}{l} \times 10^{-9} \quad \text{henry} \tag{2}$$

in which μ_{avg} is the average permeability of the core, including air gaps. This average permeability is

$$\mu_{avg} = \frac{\mu_{ac}}{1 + (a/l)\mu_{ac}} \tag{3}$$

in which a is the total effective length of all air gaps, in centimeters.

At any air gap the magnetic flux spreads, so that the cross-section of the magnetic field is greater than the cross-section of the core. It is most convenient to treat this "fringing" as if the length of the air gap were effectively reduced. If m and n are the dimensions of the core cross-section at the air gap, and l_g is the actual physical length of the air gap,

$$\text{Effective length} = \frac{mn}{(m + l_g)(n + l_g)} \times l_g \quad \text{approximately} \tag{4}$$

Permeability. Incremental, or a-c, permeability is the kind of permeability of interest in connection with most inductors. See *Magnetic Circuits and Transformers*, p. 198. It is a variable, depending upon:

(*a*) The material of the core.
(*b*) The amount of d-c magnetization.
(*c*) The amount of alternating flux.
(*d*) Wave form of the a-c voltage.
(*e*) Previous magnetization of the core.
(*f*) Temperature.

Of these factors, only the first three are considered in practical design work, although the others are by no means negligible.

When a core has no air gaps, the d-c magnetization, H_{dc}, is given by

$$H_{dc} = \frac{0.4\pi NI}{l} \quad \text{oersteds (or gilberts per cm.)} \tag{5}$$

in which I is the direct current flowing through the coil, in amperes.

It is usually more convenient to express the amount of a-c magnetization of the core in terms of flux-density variation, which is a function of the a-c voltage across the coil, rather than in terms of magnetizing force, which is a function of the a-c current in the coil. The peak a-c flux density, $B_{\max}$, is given by eq. (6), if the a-c voltage is sinusoidal.

$$B_{\max} = \frac{E}{4.44NAkf} \times 10^8 \quad \text{gausses} \tag{6}$$

In this equation, E is the rms voltage across the coil, f is the frequency, and the other symbols have the same meaning as given previously for eq. (1). Equation (6) applies whether or not there are air gaps in the core. See Figs. 4, 5, and 6.

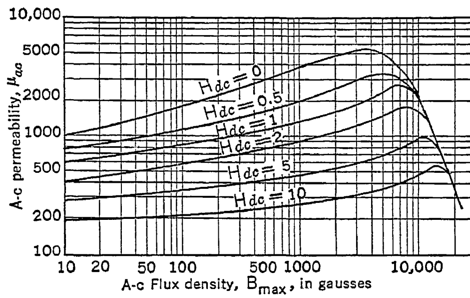

Fig. 4. A-c Permeability 3.6% Silicon Steel "58" Grade

D-c Magnetization with Air Gaps. D-c magnetization can be reduced by inserting an air gap in the core, improving the a-c permeability. See Figs. 4, 5, and 6. Up to a certain point, this results in an increase of inductance. See eqs. (2) and (3). Beyond that point, any further increase in the air gap causes a decrease of inductance.

The amount of d-c magnetization in the ferromagnetic core material, when there is an air gap in the core, can be determined by the graphical method shown in Fig. 7. See Karapetoff, *The Magnetic Circuit.* This method utilizes the normal magnetization or B-H curve of the particular core material, of which several are given in Fig. 8.

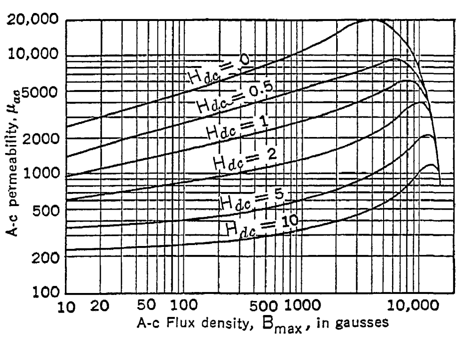

Fig. 5. A-c Permeability 50-50 Nickel-iron Alloys

The d-c magnetization of the core material and the a-c flux density [eq. (6)] having been determined, the a-c permeability is then found from curves such as Figs. 4, 5, or 6. This value of permeability is used in eq. (3) to compute the average permeability of the core, including air gaps, which is then used in eq. (2) to calculate the inductance of the reactor. It is usually necessary to try two or three values of air gap to discover the optimum one. This method of determining the optimum air gap, and the maximum inductance, may be called the "fundamental method."

A short-cut method of determining optimum air gap and maximum inductance was worked out by C. R. Hanna (Design of Reactances and Transformers Which Carry Direct Current, *Trans. A.I.E.E.*, February 1929). He showed that a curve can be drawn, for any particular core material, whose coordinates are NI/l and LI^2/V, V being the volume of the core. Such "optimum design curves" are shown for three commonly used materials in Figs. 9, 10, and 11. When using these curves it should be remembered that they apply only to a special case, in which maximum inductance for a given amount of direct current is the quality desired. If the reactor is to be used at several different values of direct current,

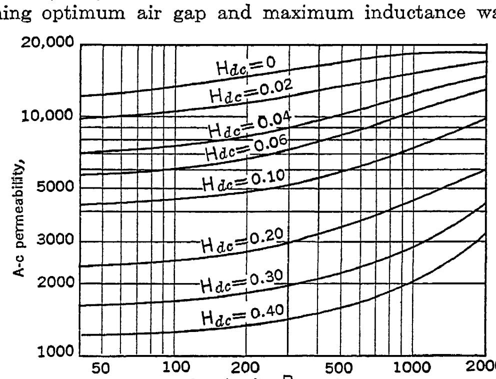

Fig. 6. A-c Permeability Mumetal

or if other considerations govern the design, the approach described previously should be used.

Saturation. If the sum of the d-c flux density and the peak a-c flux density approaches the saturation density of the core material, serious wave-form distortion occurs. This sum

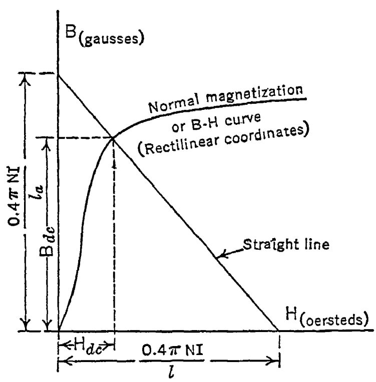

FIG. 7. Graphical Method of Determining D-c Magnetization of Core, when there is an airgap

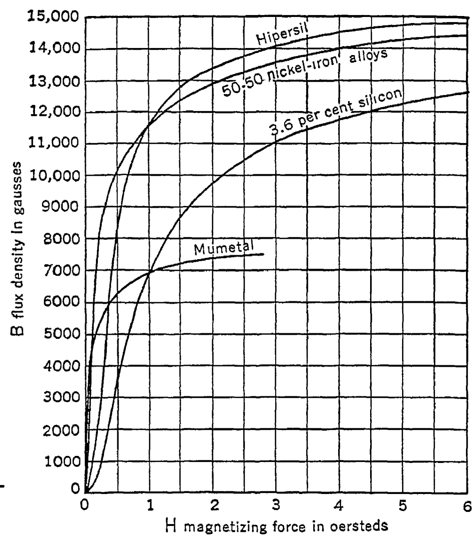

FIG. 8. D-c Magnetization Curves

should not exceed 12,000 gausses for silicon steel or for 50-50 nickel alloys. The d-c flux density may be found by the graphical method of Fig. 7, and the peak a-c flux density,

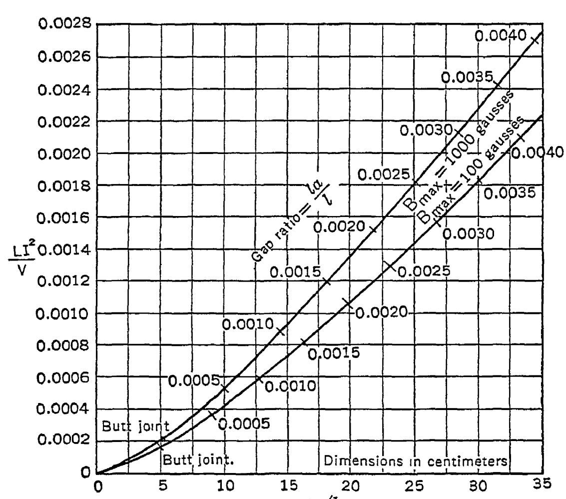

FIG. 9. Optimum Design Curves for Inductance with D.C. 3.6% Silicon

B_{max}, from eq. (6). If the total flux density is excessive, and the d-c flux density is the larger part, the air gap should be increased. If the a-c flux density is the larger part, the number of turns on the coil should be increased.

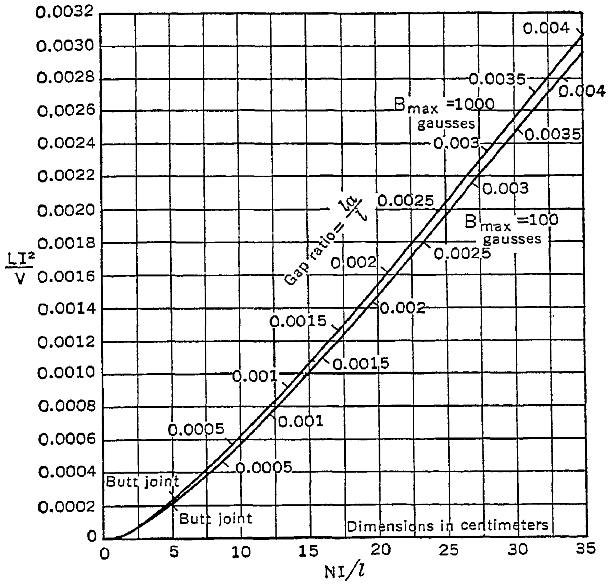

Fig. 10. Optimum Design Curves for Inductance with D.C. 50-50 Nickel-iron Alloys

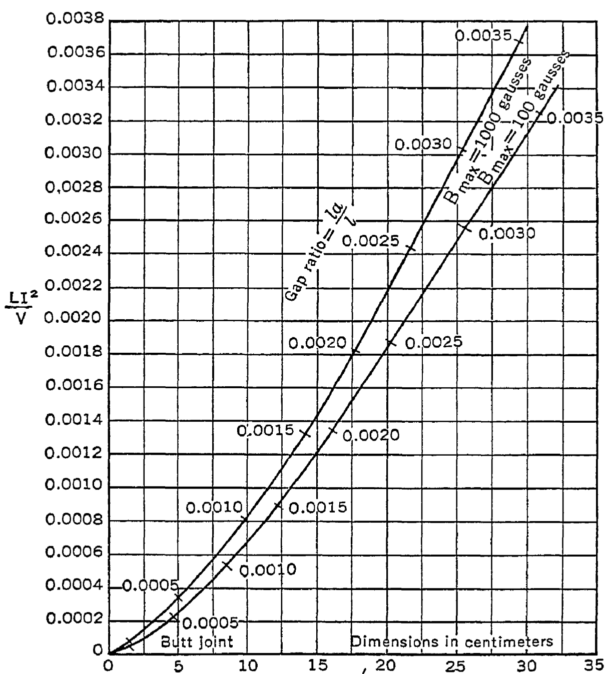

Fig. 11. Optimum Design Curves for Inductance with D.C. Hipersil

RECTIFIER-FILTER REACTORS AND AUDIOFREQUENCY PLATE REACTORS are examples of inductors for which maximum inductance at a given value of direct current is the most important quality desired. The "optimum design curves" are ideally suited for such designs.

THE SWINGING CHOKE is a reactor which must have a specified inductance at some large value of direct current, but which must increase rapidly in inductance as the direct current is decreased. An air gap is used which is optimum, not for the largest direct current nor for the smallest direct current, but rather for some intermediate value. An approximate design can be arrived at by using the "optimum design curves" for an intermediate value of direct current. Then the inductance should be calculated for the maximum and minimum currents by the fundamental method. In some cases, part of the core stack may have a large air gap to provide a good inductance at the largest current, while the remainder of the core may have a small air gap to give high inductance at the minimum current.

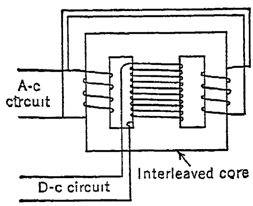

FIG. 12. Construction of Saturable Reactor

SATURABLE REACTORS are inductors the inductance of which is varied by means of a variable direct current. Interleaved laminations are used to get the greatest effect of the d-c magnetization. It is necessary to isolate the d-c circuit from the a-c circuit by means of separate windings. It is also necessary to prevent transformer coupling between the a-c and d-c windings. Figure 12 illustrates the construction of a saturable reactor. The a-c windings should always be connected in parallel. See Holubow, "D-C Saturable Reactors for Control Purposes," *Electronic Industries*, March 1945.

COIL RESISTANCE. The mean length of turn is calculated from the coil geometry, converted into feet, and multiplied by the number of turns. Reference to a wire table (Section 2, article 3) will give the d-c resistance of the coil, in ohms. Skin effect can be neglected, except for very large wire, above 1 kc. Allowance for temperature must be made. The resistance of a coil increases about 0.4 per cent per degree centigrade, above 20 deg cent. Thus, if an inductor operates at a coil temperature of 70 deg cent, its resistance will be 20 per cent higher than calculated for 20 deg cent.

CORE-LOSS curves are shown in Section 6, article 14. The core loss is determined in watts, which can then be added to copper loss watts to find the total heat dissipated in the reactor, and the temperature rise.

When the effect of core loss on the Q of the inductor, rather than heating, is the matter of interest, core loss can be represented by a resistor in parallel with the coil, of a value R_i ohms.

$$R_i = \frac{E^2}{W} \tag{7}$$

In this formula, E is the rms voltage across the coil, and W is the watts core loss. The core loss of most sheet-core materials varies very nearly as the square of the applied voltage, so that the ratio E^2/W is very nearly constant over a considerable range of voltage. Figure 13 gives core-loss curves of several materials at 2000 gausses. If P is the watts per pound, at 2000 gausses, and M is the weight of the core, in pounds, the core-loss resistance is

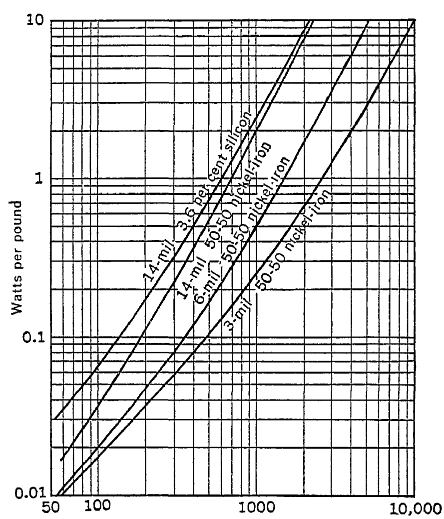

FIG. 13 Core Loss at 2000 Gausses (B_{max})

$$R_i = \frac{78.8(NAkf)^2}{PM} \times 10^{-10} \quad \text{ohm} \tag{8}$$

OPTIMUM Q. Q is often defined as the ratio of reactance to resistance. This is true when the only resistance present is in series with the coil, as is the case with the copper resistance of the winding. When there are both series and shunt resistances, as with a ferrous-cored inductor, Q is more clearly defined as the ratio of reactive volt-amperes to resistive volt-amperes.

For a particular core and coil, at a particular frequency, the shunt resistance of the core and the series resistance of the coil are practically fixed quantities. The reactance, however, can be varied by changing the air gap. There is a value of reactance which will produce the maximum Q. This problem is illustrated by the circuit shown in Fig. 14. In this circuit, R_c is the resistance of the coil, R_i is the resistance of the core, and X is the reactance of the inductor. Maximum Q is attained when

$$\frac{X}{R_c} = \frac{R_i}{X} \quad \text{or} \quad X = \sqrt{R_c R_i} \tag{9}$$

The air gap is adjusted so that

$$L = \frac{\sqrt{R_c R_i}}{2\pi f} \quad \text{for maximum } Q \tag{10}$$

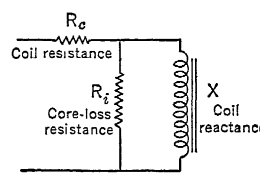

FIG. 14. Equivalent Circuit, Ferrous-cored Inductor

Equations (2) and (3) are used to compute the correct air gap. When the air gap and inductance are adjusted to optimum,

$$Q = \frac{X}{2R_c} \tag{11}$$

The maximum Q that can be obtained in a low-frequency, sheet-core inductor is practically independent of the inductance, the number of turns, the voltage, or the flux density. That is, a 10-henry reactor can be made with practically the same Q as a 1-mh reactor, by proper design. Maximum Q that can be realized depends only on the core material, the size of the core, and the frequency. See Fig. 15. For other sizes of core, the Q will

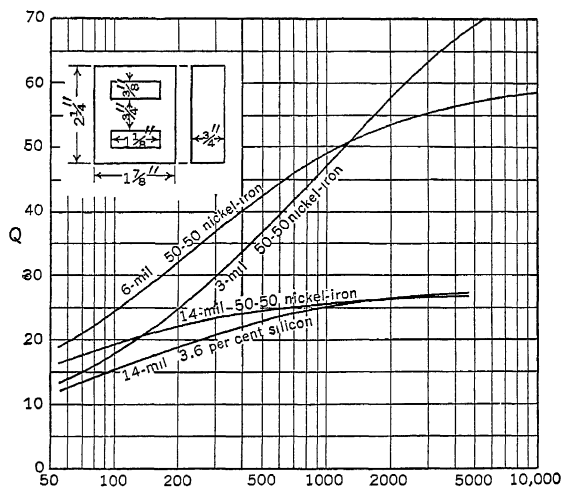

FIG. 15. Q vs Frequency, Various Core Materials

vary as the linear dimension if the proportions are the same, or as the cube root of the core volume if the proportions are different. Thus, a core having twice the linear dimensions of the one shown will have 8 times the volume but will give only twice the Q. For other core materials, the Q that can be realized will vary inversely as the square root of the relative core loss. Thus, a material having one-fourth the core loss will give twice the Q.

Air Gaps for Q should be located inside the coil, and preferably at the center of the coil length. There should be no air gaps outside of the coil. Fringing flux creates a magnetic field external to the reactor. When the reactor is placed in a metal can, or near a metal chassis, eddy currents are set up, which may reduce the Q of the reactor by a factor of 2 or 3 to 1.

Optimum Permeability for Q. For a particular core and coil, at a particular frequency, there is an optimum value of inductance which will give the highest Q. See eq. (10). This value of inductance requires a certain average permeability of the core. See eq. (2).

Practically all sheet-core materials have *too high* a value of a-c permeability to give the optimum inductance, so that it is necessary to *reduce* the overall permeability of the core by inserting an air gap. The use of an air gap to produce maximum Q in an inductor should not be confused with the use of an air gap to reduce d-c magnetization. The two purposes are different and distinct.

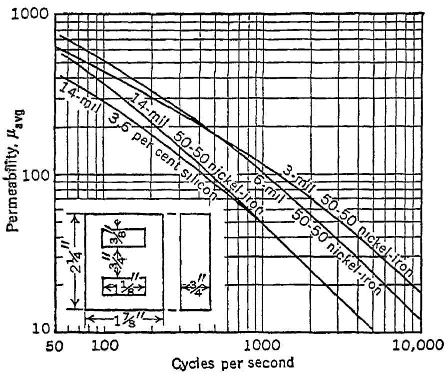

Fig. 16. Permeability for Maximum Q

The optimum overall permeability, μ_{avg}, required to produce maximum Q is a function of the core material, the core size, and the frequency. See Fig. 16. For other sizes of core, optimum permeability will vary inversely as the linear dimensions if the proportions are the same, or inversely as the cube root of the core volume if the proportions are different. For other core materials, the optimum permeability will vary inversely as the square root of the relative core loss.

A striking fact brought out by Fig. 16 is that the optimum overall permeability becomes less than 50 at frequencies above 4000 cycles. The high a-c permeability characteristic of sheet-core materials is of no advantage in this region. Permeability of the order of 50 can be realized with powdered-iron cores. This opens up the possibility of using powder cores at such frequencies.

16. HIGH-FREQUENCY, POWDERED-CORE INDUCTORS

Powdered cores differ from sheet cores in two important characteristics. They have, in general, lower core loss, particularly eddy-current loss, and they have much lower permeability. Both these characteristics are due to the subdivision of the core into minute particles, and both are desirable at high frequencies if the Q of the inductor is a major consideration. See above, "Optimum Permeability," and Fig. 16.

Material used for powdered cores are magnetite, a natural iron oxide, electrolytic iron, hydrogen-reduced iron, carbonyl iron, powdered Permalloy, and powdered molybdenum Permalloy. For descriptions of these materials and their method of manufacture, see Section 2, "Magnetic Materials"; H. G. Shea, "Magnetic Powders," *Electronic Industries*, August 1945; V. E. Legg and F. J. Given, "Powdered Molybdenum Permalloy," *B.S.T.J.*, July 1940.

Particle sizes range from about 50 microns diameter (0.002 in.) for audio-frequency cores to about 3 microns for cores useful at 100 mc. The particles making up a core are not all the same size. This is an advantage, as it gives a better packing of the magnetic material, the smaller particles filling in the spaces between the larger ones. Since eddy-current loss is proportional to the square of the particle diameter, the root-mean-square diameter of the particles making up a core is the particle dimension of greatest significance. Weight-average diameter is often given. This is a figure a few per cent higher than the root-mean-square diameter.

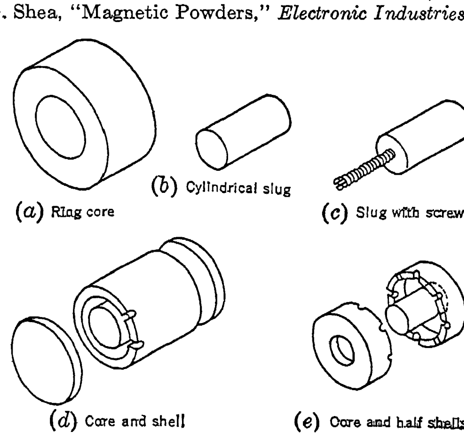

Fig. 17. Basic Types of Powdered-iron Cores

CORE CONSTRUCTION. Particles are coated with an insulating material, or treated in some manner to give them high surface resistivity, and mixed with a plastic binder. The mixture is compressed in molds at pressures of 50 to 100 tons per square inch, to form the desired core shape. The resulting core is a solid block of material resembling iron in appearance and somewhat lighter than iron in weight. Figure 17 illustrates a few basic styles. As better audiofrequency core materials are developed, cores of the shapes shown in Fig. 1 are also being offered.

COIL CONSTRUCTION, in general, follows the practice used for air-core coils of the same frequency range. Since powdered-iron cores are employed at the higher audiofrequencies and above, skin effect, coil capacitance, and coil dielectric loss are controlling factors in coil design, as with air-core coils. See Section 2, "Inductors with Air Cores." The presence of a core introduces two modifications of coil design. A somewhat longer coil, of less build-up, is desirable, to take better advantage of the core. Dielectric loss and dielectric constant of the winding form are of more importance when there is a core, especially if the core is grounded.

PERMEABILITY. "Intrinsic permeability" is the permeability of the magnetic particles. "Composite permeability," "ring-core permeability," or just "permeability" are terms used to describe the permeability of a core, made in the form of a ring sample, and wound with a toroidal coil. Such a sample has uniform flux density throughout its length and practically throughout its cross-section, and no end effects. Consequently, the ring-core permeability may be called the true permeability of the core material. The relation between ring-core permeability, μ, and intrinsic permeability μ_i, is given by

$$\mu = (\mu_i)^p \tag{12}$$

in which p is the "packing factor," or fraction of the core volume occupied by magnetic material. See Legg and Given, also analysis by H. Beller and G. O. Altmann, "Radio-Frequency Cores of High Permeability," *Electronic Industries*, November 1945. Table 3 gives values of ring-core permeability for a number of core materials.

The term "effective permeability" is used to describe the permeability of a cylindrical or slug-type core [Fig. 17(*b*)]. Such permeability is much lower than ring-core permeability of the same core material, because of demagnetizing effects at the ends of the cylinder. This matter has been investigated by R. M. Bozorth and D. M. Chapin, "Demagnetizing Factors of Rods," *J. Applied Phys.*, May 1942, and by W. J. Polydoroff and A. J. Klapperich, "Permeability of High Frequency Iron Cores," *Radio*, November 1945. Table 2 shows effective permeability versus ring-core permeability for various ratios of core length to core diameter. The coil is the same length as the core, in these data.

Table 2. Effective Permeability of Cylindrical Cores

Ring-core Permeability	Ratio Length/Diameter: 1	2	4	6	8
	Effective Permeability				
5	2.20	3.40	4.1	4.4	4.8
10	2.98	4.57	6.8	8.2	8.8
15	3.47	5.65	8.7	10.8	11.7
20	3.76	6.3	9.9	12.4	13.7
25	3.94	6.6	10.6	13.4	14.8
30	4.06	6.75	11.0	14.0	15.6

INDUCTANCE. The inductance of a toroidal coil on a ring core is given by

$$L = \frac{4N^2}{d}[A' + A(\mu - 1)] \times 10^{-9} \quad \text{henry} \tag{13}$$

in which N is the number of turns on the coil; d is the mean diameter of the core, in centimeters; A' is the mean cross-section of the coil, at right angles to the flux path, in square centimeters; A is the cross-section of the core, in square centimeters; and μ is the ring-core permeability of the core.

The inductance of a coil on a cylindrical, or slug-type core, if the coil is the same length as the core, is

$$L = L_0\left[1 + \left(\frac{b_i}{b_0}\right)^2\left(\mu_e - 1\right)\right] \tag{14}$$

In this equation, L_0 is the inductance of the coil without iron, b_i is the radius of the iron core, b_0 is the mean radius of the coil, and μ_e is the effective permeability, as given in Table 2. If the core is longer than the coil, the effective permeability is increased to a value

$$\mu_e' = \mu_e \sqrt[3]{\frac{l_i}{l_0}} \tag{15}$$

l_i being the length of the core, and l_0 that of the coil. This higher value should be substituted for μ_e in eq. (14).

Formulas are not available which apply to the various shell-type cores. The variety of shapes, non-uniform cross-section of the core, and square corners in the magnetic path offered by the core make any accurate analysis very difficult. The inductance of a coil, having a central core and a shell, will be greater than its inductance with the central core alone. On the other hand, its inductance will be less than that of a toroidal coil, of the same number of turns, on a ring core of the same average cross-section and the same mean length of magnetic path. See "Measurement of Iron Cores at Radio Frequencies," D. E. Foster and A. E. Newlon, *Proc. I.R.E.*, May 1941, and above reference by Polydoroff and Klapperich.

CORE LOSS AND Q. Core loss is of interest in high-frequency inductors primarily because of its effect upon Q, or quality factor. The addition of the core increases not only inductance but also resistance. A toroidal coil on a ring core has been analyzed by V. E. Legg, "Magnetic Measurements at Low Flux Densities," *B.S.T.J.*, January 1936. His formula for the increase of resistance due to core loss is

$$R = [(aB_m + c)f + ef^2]\mu L \quad \text{ohms} \tag{16}$$

In this, R is the resistance added to a coil by the core; a, c, and e are the hysteresis, residual, and eddy-current loss coefficients; f is the frequency, in cycles per second; B_m is the peak a-c flux density, in gausses; μ is the ring-core permeability; and L is the inductance of the coil with the core, in henries. Coefficients are given in Table 3 for a number of core materials.

The resistance added to a coil by a cylindrical core has been analyzed by Foster and Newlon, reference above, who give a formula

$$R = L_0 \frac{4\pi\mu_e^2 b_i^2 l_i \rho}{b_0^2 \sqrt{4b_0^2 + l_0^2}} \quad \text{ohms} \tag{17}$$

Symbols have the same meaning as for eqs. (14) and (15), ρ being the loss factor of the core material. The loss factor must be determined by measurements upon a sample of the particular core material. Published data are not available on the loss factor of cylindrical cores.

Table 3. Ring Permeability and Core-loss Coefficients

Material	Permeability	Hysteresis $\mu a \times 10^3$	Residual $\mu c \times 10^3$	Eddy Current $\mu e \times 10^6$

In Table 3, the figures for the permalloys are taken from Legg and Given. Figures for the other materials are General Aniline and Film Corporation data, published in the articles by H. G. Shea, and by Beller and Altmann, previously referred to.

PERMEABILITY TUNING, or "variable reluctance tuning," is the system of adjusting a circuit to resonance, at a desired frequency, by moving an iron core in or out of the coil. A simple arrangement for doing this is to mold a screw in one end of a cylindrical core as illustrated in Fig. 17(c). The screw passes through a tapped hole in the coil housing and is slotted at the end for a screwdriver. Rotation of the screw moves the core axially into or out of the coil, varying its inductance and the resonant frequency of the circuit. Such a system is ideal for a circuit tuned to some fixed frequency, such as an intermediate-frequency transformer circuit. See "Ferro-inductors and Permeability Tuning," W. J. Polydoroff, *Proc. I.R.E.*, May 1933.

Incremental permeability tuning is a system of adjusting the resonant frequency of a circuit by varying the permeability of the iron core without any mechanical motion. The permeability is varied by means of d-c magnetization on the same principle as the saturable reactor. Increase of d-c magnetization causes a decrease of inductance and an increase of frequency. By proper design, the increase of frequency, from some minimum value, may be made proportional to the direct current. "Incremental Permeability Tuning," W. J. Polydoroff, *Radio*, October 1944.

CAPACITORS

By James I. Cornell

A capacitor or condenser is an electrical device used primarily because it possesses the property of capacitance. Though *capacitor* is the preferred engineering terminology, the term *condenser* is still widely used.

Electrostatic capacitance is defined as the ratio of the electrical charge Q stored in the capacitor by virtue of the applied voltage (E_{dc}). That is, when a d-c voltage is impressed on two conductors insulated from each other, the voltage causes an electrical charge to flow into the system. One conductor assumes a positive charge and the other an equal negative charge, depending upon the polarity of the impressed voltage. The charge on the conductors produces electrostatic stresses in the region between them. The work done in charging the capacitor appears as stored potential energy. This energy is released when we remove the impressed voltage and short-circuit the capacitor electrodes. The capacitance is a measure of the charge or stored potential energy for a given voltage. In terms of physical units, a capacitor having a capacitance of 1 farad will store 1 coulomb of charge or 1 watt-second of energy for 1 volt of applied direct voltage.

17. CLASSIFICATION OF CAPACITORS

Capacitors may be classified according to *form*, *dielectric medium*, and *electrode structure*.

Generally, the classification of capacitors according to form is determined by whether the capacitance is *variable* or *fixed*.

Variable capacitors cover two essential types, namely:

1. *Variable capacitors* provide for continuous control of the capacitance and are used for varying the resonance frequency of a tuned circuit with which it is associated. The dielectric employed may be air, compressed gas, or liquid types. See Fig. 1.

2. *Adjustable capacitors* provide for limited control of the capacitance, and these capacitors are usually found in frequency-determining circuits for alignment purposes such as intermediate-frequency transformers, etc. The dielectric medium used in adjustable-type capacitors may be air, mica, or some form of ceramic.

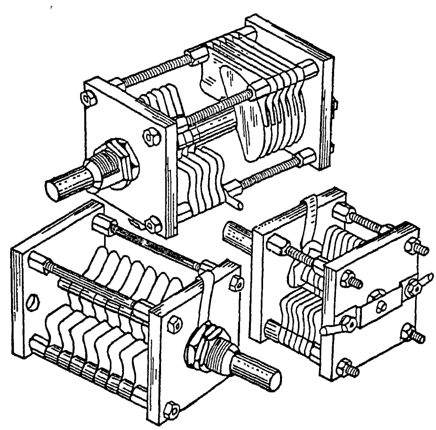

FIG. 1. Typical Variable Capacitors

Fixed capacitors employ a wide range of dielectric materials, and, because of the different dielectric media used, the form and usage of these capacitors must be evaluated according to their dielectric in terms of circuit requirements. The wide variation in the kinds of dielectric materials available for capacitors permits construction to meet practically all kinds of circuit requirements.

FIXED CAPACITORS CLASSIFIED ACCORDING TO DIELECTRIC MEDIUM.

Gas Dielectrics. Vacuum and compressed-gas-filled capacitors are designed for electronic power circuits where high voltage, high current, and high frequency requirements are encountered and where other types of dielectrics are inadequate because of excessive losses and resultant overheating.

Impregnated Paper. The most common form of solid-dielectric capacitors employed in electronic and communication circuits are impregnated-paper types. High-purity kraft paper may be impregnated with microcrystalline hydrocarbon waxes, chlorinated waxes, vegetable oil, mineral oil, Askarels or synthetic chlorinated oils, and plastics. Impregnated-paper capacitors are usually made up in a multiple-layer foil and paper structure of rolled construction and are impregnated after winding.

Plastic Film. Special design considerations such as low dielectric absorption or high operating temperatures have resulted in the development of plastic-film dielectrics, using such substances as polystyrene, acetate, or butyrate. These follow the general construction of the impregnated-paper types except that the plastic dielectrics are in final form and are impregnated only for the purpose of removing surface moisture and eliminating voids in the winding.

The principal virtue of polystyrene lies in the very low absorption characteristic and its low losses at radio frequencies. Its use is limited to an operating temperature of 85 deg cent. Other synthetic plastic films such as acetates and butyrates have been found useful for applications requiring operation at ambient temperatures exceeding 85 deg cent, and they have been operated experimentally at 150 deg cent. They usually have high r-f power factor, and their use is restricted to d-c or low voltage a-c circuits where high ambient temperature is the principal consideration.

Inorganic Dielectrics. Common inorganic dielectric materials are solid dielectrics consisting of mica, glass, and ceramic types; also liquid dielectrics such as silicone oils. The solid dielectrics are usually in sheet or plate form which require a laminated stacked construction. The electrodes may take the form of foil, or a silver coating deposited directly on the surface of the dielectric before the stacking operation.

Ceramic dielectrics are supplied in a variety of shapes other than laminal, and one of the most popular is a hollow cylinder with the electrodes placed on the inner and outer surfaces in the form of a silver coating. They form a capacitor whose capacitance is a function of the dielectric constant of the ceramic. Capacitance values are usually low or less than 2000 $\mu\mu$f. The dielectric constant and temperature coefficient of the ceramic body can be varied widely to give capacitors with negative, positive, or zero temperature coefficients of capacitance.

This form of capacitor is receiving more consideration in r-f circuits where a negative temperature coefficient is used to compensate for the positive temperature coefficients of other circuit elements with which they are associated.

The electrode structure used with a silicone oil dielectric is of the rigid grid type similar to that found in variable capacitors. Silicone oils will withstand high ambient temperatures and are characterized by low r-f power factor.

Oxide Film Dielectrics. Electrolytic capacitors owe their unusual characteristics to the oxide film dielectric layer which is produced electrochemically on aluminum, tantalum, and certain other metals. Details of this form of dielectric will be found under the subject "Electrolytic Capacitors."

CLASSIFICATION OF FIXED CAPACITORS ACCORDING TO PLATE STRUCTURE. Rigid multiple parallel plate structure used in connection with gas or liquid dielectrics. Under this classification may be found the silicone and compressed gas capacitors for high-power, high-frequency radio transmitting and dielectric heating circuits; also wet electrolytic capacitors for use in low-voltage receiver power-supply filters.

Interleaved foil or stack construction used in connection with mica, glass, ceramic, and plastic film solid dielectrics.

Helical or Rolled Plate Construction. The most common form of plate structure for solid dielectrics such as impregnated paper, plastic film, and electrolytic types is the helical or rolled plate construction. In this construction the electrodes are of very thin foil separated by a single- or multiple-ply dielectric layer and wound into a cylindrical roll.

Metallized plate construction where the electrodes are deposited on the surface of the dielectric. This construction is used with mica, ceramic, glass, plastic, and impregnated-paper dielectrics.

CAPACITOR CHARACTERISTICS. Variable Nature of Capacitance. Three principal characteristics of any dielectric medium influence the physical form of capacitors:

1. Dielectric constant or specific inductive capacity, denoted by K.
2. Dielectric strength.
3. Dielectric loss or power factor.

The dielectric constant is a numerical quantity, expressed as the ratio of the capacitance of the structure with a dielectric other than air to the capacitance with air as the dielectric. In other words, the higher the specific inductive capacity or dielectric constant (K), the smaller the size for a given capacitance. *Note:* Refer to Section 2 for the dielectric constant of various materials.

Dielectric strength may be defined as the property of the dielectric by which it withstands breakdown when a voltage is applied to it. The dielectric strength is expressed in volts per mil of dielectric thickness. The shape of the electrodes by which the voltage is impressed on the dielectric and the duration of the impressed voltage help to determine the rupture voltage. When the applied voltage is alternating, the wave shape and frequency of the voltage affect the dielectric strength. Because of these variables, the dielectric strength in volts per mil is not a constant and is usually expressed as a voltage range.

Capacitance varies inversely as the plate separation or dielectric thickness. The limiting minimum thickness is the voltage that the capacitor is required to withstand. Therefore, the higher the dielectric strength, or breakdown potential, of the insulating medium, the thinner the dielectric and the larger the capacitance value for a given electrode area. This can best be illustrated by comparing ceramic dielectric to the oxide film dielectrics of electrolytic capacitors. Most ceramic dielectrics are limited to a breakdown potential of less than 100 volts per mil, whereas the oxide film thickness of an electrolytic capacitor is measured in microns and will withstand a voltage stress equivalent to a million volts per mil of dielectric thickness.

D-c Leakage. Continued polarization of a capacitor by direct voltage after full electrification results in a flow of current termed the leakage current. Though the d-c leakage is negligible under most conditions of operation, it varies with temperature and should be taken into account in circuit designs, especially those involving grid coupling capacitors or similar circuits which are affected by the flow of conduction current in the capacitor.

Dielectric Polarization and Absorption. Capacitors with solid dielectrics take longer to charge than would be predicted from their theoretical constants, owing to a lag or delay in polarizing the dielectric medium. This is known as dielectric polarization. When a capacitor is discharged by short circuiting, all its energy is not released and it will build up a new charge with time which is known as the residual effect. This characteristic is known as dielectric absorption. Both are detrimental to circuits requiring rapid charge and discharge characteristics. Selection of a dielectric like polystyrene is dictated in circuits where dielectric absorption must be held to the absolute minimum.

Figure 2 illustrates schematically what takes place in a capacitor having d-c leakage and dielectric absorption. C represents the geometric capacitance based on a perfect dielectric. C_1 and r_1 represent the absorption effect. The pure conduction effect is represented by r_2.

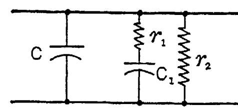

FIG. 2. Schematic Circuit of Capacitor

Power Factor, Q, or A-c Resistance. When a capacitor is operated under a-c voltage stresses, the dielectric will heat up, depending upon the frequency of the applied voltage. The a-c resistance or the power factor is a measure of the heat dissipated. It is more convenient in working with electrical circuits to use a ratio of the pure reactance to the effective resistance which is termed the Q factor. The Q factor can be employed for the purpose of comparing various capacitors quantitatively since it constitutes a figure of merit for a given design.

It is easily seen that, although so-called fixed capacitors may be made up using any one of the many different types of dielectrics, the actual capacitance is a variable depending upon the physical characteristics of the dielectric, which vary with:

A. *Voltage.* Capacitance will change with voltage. The voltage coefficient will vary with the magnitude of the d-c or a-c impressed voltages.

B. *Frequency.* The capacitance will change with frequency and is a function of the Q or power factor of the dielectric.

C. *Time.* Capacitance will change with time because of dielectric aging.

D. *Temperature.* Capacitance values will change with temperature since dielectrics change with temperature or have a temperature coefficient.

These characteristics serve to demonstrate the fallacy of considering a capacitor as an ideal fixed capacitance.

Inductance. In addition to the limitations imposed by the dielectric media, another limitation, which results from mechanical design, is inductance. All capacitors have a self-resonant frequency and behave like a circuit involving series inductance, resistance, and capacitance. Above the critical frequency, the reactance is inductive and not capacitive. In fact, capacitors behave like a complex impedance depending upon the operating frequency range.

18. VARIABLE AND ADJUSTABLE CAPACITORS

Capacitors designed for frequent adjustment by an equipment operator are usually termed variable or tuning capacitors. Capacitors of this type most often use an air dielectric, although other dielectrics are suitable for special circumstances. For example, compressed air or nitrogen dielectrics reduce the size of high-voltage capacitors in large transmitters. Mineral oil, silicone fluid, and other liquid dielectrics save space because of their higher dielectric constant. In addition, such capacitors have a higher breakdown voltage for the same interelectrode spacing.

Capacitance adjustment in variable capacitors is usually made by varying the effective plate area. The capacitor consists of two sets of parallel intermeshed plates, one fixed and one rotatable on a mounting shaft. Rigidity of the capacitor framework and freedom from warpage of the plates and the stator insulation are extremely important from the standpoint of circuit stability. For extremely stable circuits in high-grade electronic equipment, carefully designed Invar steel frames and plates may be used to minimize capacitance shifts with ambient temperatures. More commonly frames and plates are of aluminum or silver-plated brass. In the cheapest broadcast receivers, cadmium-plated steel has been used. To facilitate tracking of circuits in broadcast receivers, the outer rotor plates are sometimes slotted to permit small adjustments in the capacitance-rotation curve. The supporting insulation for the capacitor stator is usually phenolic or ceramic, depending upon circuit considerations. Electrically low-loss, dimensionally stable steatite or glass-bonded mica insulation is used in capacitors where high Q and low capacitance drift are important. In the highest grade of precision laboratory standard capacitors the insulation is quartz.

In certain highly accurate instruments, the "standard" variable capacitors consist of two co-axial cylinders, one fixed and one movable.

Capacitors intended for relatively infrequent adjustment of capacitance are termed "trimmer or adjustable" capacitors. Most common in broadcast receivers is the small mica trimmer capacitor. Such a capacitor consists of a fixed and a hinged movable metal electrode mounted on a phenolic or ceramic base with a mica spacer between the two electrodes. The movable leaf is raised or lowered by threading it on a screw. These capacitors are sometimes called "book mica trimmers."

In high-grade electronic equipment, especially for frequencies above the standard broadcast band, trimmer capacitors similar in construction to intermeshed plate variable capacitors are used. In many cases, they have a shaft positioning locking device such as a split tapered bushing and nut. Also found in such equipment are adjustable ceramic capacitors. These capacitors consist of two coaxial half-silvered ceramic disks, one fixed and one rotable. The ground unsilvered faces are kept in contact by spring pressure. The capacitance depends on the extent of overlap of the silvered faces. Through selection of various ceramic compositions an opportunity is provided for some degree of circuit temperature compensation.

Transmitter neutralizing capacitors are a special design of adjustable capacitors consisting of a fixed disk with rounded edges and a similar coaxial movable disk mounted on the end of a set screw. Capacitance adjustment is by turning the screw in and out of a threaded support.

In high-powered aircraft transmitters, adjustable vacuum capacitors are sometimes employed. These capacitors have a metal bellows to permit positioning the movable capacitor element.

The maximum capacitance of variable capacitors usually employed in electronic circuits is from 10 to 530 $\mu\mu$f. For use as a capacitance standard, units are made with capacitances up to 5000 $\mu\mu$f. Trimmer capacitors may have a maximum capacitance of 5 to 75 $\mu\mu$f.

Since air dielectric capacitors have very little loss in the dielectric and supporting insulation, they will show practically no change in capacitance with frequency. Accurate measurements of capacitance values at audio frequencies may therefore be depended upon at radio frequencies with a good degree of precision.

EFFECT OF STRAY CAPACITANCE. Units of variable capacitance generally are for relatively small values, and in a circuit, particularly at high frequencies, the capacitance effects of the various other parts of a circuit will be appreciable as compared with the capacitor unit. Every part of the apparatus has capacitance to other parts, and these small stray capacitances may be appreciable. The stray capacitances are particularly objectionable because they vary when parts of the circuit or conductors near by are moved, such as the hand or body of the operator. The disturbing effects may be minimized in practice as follows: (1) by keeping the capacitor a considerable distance away from conducting or dielectric masses; (2) by shielding the capacitor, that is, surrounding the whole capacitor by a metal covering connected to one of the sets of plates; (3) by using a capacitor of sufficiently large capacitance so that stray capacitances are negligible in comparison. The first two of these methods reduce only the stray capacitances of the capacitor itself to other parts of the circuit and to external moving bodies. Although the third procedure is workable for the lower radio frequencies, it fails at the very high and ultra-high frequencies, and an entirely different approach to the problem has been necessary.

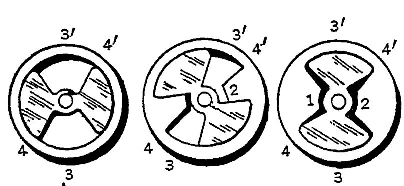

Fig. 3. Semi-butterfly Circuit

Karplus has described a variable capacitor design which includes the circuit inductance. In this design, wide tuning range with simultaneous change of lumped capacitance and inductance is obtained by rotation of a member that does not require any electrical connections. This arrangement is called the butterfly or semi-butterfly circuit, depending upon the configuration of the variable capacitor design. Figure 3 shows such a circuit.

Maximum and minimum capacitance of a butterfly circuit can be computed as in a variable air capacitor, but, owing to the butterfly shape, capacitance ratios are considerably less than in well-designed tuning capacitors.

CAPACITANCE FORMULA. The general expression for the capacitance of a multiplate capacitor is (in micro-microfarads)

$$C = 0.0885K\frac{(N-1)S}{T} \tag{1}$$

in which S is the area in square centimeters of a moving plate overlapping a fixed plate; T is the separation of plates in centimeters; K is the dielectric constant (for the air capacitor, $K = 1$); N is the total number of similar plates (fixed plus movable), alternate plates being connected in parallel. In eq. (1) no correction is made for the curving of the lines of force at the edges of the plates; this effect is negligible for most capacitors, when T is very small compared with S.

The numerous applications of variable capacitors in radio circuits place different requirements upon the capacitor in its characteristic variation with setting. For laboratory use a capacitor is usually designed with semicircular plates. With this form the capacitance increases linearly with the angular displacement of the movable plates. In other radio-circuit applications it is convenient to have the capacitance vary with the setting to some other power than the first, and these forms are noted below.

Plate Form, Semicircular. In a variable capacitor of the semicircular type the effective area of the plates is changed by rotating the movable plates. Throughout the entire plate rotation the capacitance is proportional to the setting, provided that the capacitor is well constructed and the distance between the two sets of plates is not affected by rotation of the movable set. When the plates are entirely unmeshed (no overlap), measurement usually will show that there is an appreciable capacitance between the capacitor terminals. For a 5000-$\mu\mu$f capacitor this may be as large as 75 $\mu\mu$f. This value is practically unaffected by the position of the movable plates on the rotor, and it represents the capacitance between the insulated binding posts and the small capacitance formed across the insulators which separate the plates. The capacitance of a variable capacitor cannot, therefore, be reduced to zero, and such relations as are developed for capacitance-rotor positions hold only when the plates are enmeshed a considerable amount. Throughout the range in which the capacitance curve is linear the capacitance is given by the expression $C = a\theta + b$, in which θ is the angle of rotation of one set of plates with respect to the other.

Plate Form, Logarithmic. In a special form of wavemeter, called the decremeter, the plates are so formed as to determine the logarithmic decrement of a circuit. This is measured by the percentage change in capacitance required to reduce by a certain amount the indication of an instrument in the circuit at resonance. In order that equal angular rotations may correspond to the same decrement at any setting of the capacitor, it is necessary that the percentage change in capacitance for a given rotation shall be the same at all parts of the scale. In order that each degree displacement give the same percentage increase in capacitance the following requirement must be satisfied:

$$\frac{dC}{C} = a\,d\theta \tag{2}$$

where a = constant = percentage change of capacitance per scale division. Integrating,

$$\log C = a\theta + b \tag{3}$$

where b = a constant

$$C = e^{(a\theta+b)} = C_0e^{a\theta} \tag{4}$$

where $C_0 = e^b$ = capacitance when $\theta = 0$.

Since the area must vary as the capacitance:

$$A = {}^1\!/_2\int r^2\,d\theta = C_0e^{a\theta} \tag{5}$$

using polar coordinates

$$\frac{dA}{d\theta} = \frac{r^2}{2} = C_0ae^{a\theta} \tag{6}$$

and

$$r = \sqrt{2C_0ae^{a\theta}} \tag{7}$$

The last expression is the polar equation of the bounding curve required to give a uniform decrement scale.

Plate Form, Wavelength. For certain applications it is desirable to have the wavelengths proportional to the setting of the capacitor. Since the wavelength varies as the square root of the capacitance, this will require that the capacitor plates be formed so that the capacitance of the circuit varies with the square of the setting. In designing the shape of these plates, allowance should be made for the stray capacitance of the circuit. For the design of the simple straight-line wavelength capacitor the following expressions are used:

$$C = A = a\theta^2 \tag{8}$$

In polar coordinates the area

$$A = {}^1/_2 \int r^2 \, d\theta \tag{9}$$

Differentiating both expressions:

$$\frac{dA}{d\theta} = \frac{r^2}{2} = 2a\theta$$

$$r = \sqrt{4a\theta} \tag{10}$$

which is the polar equation of the bounding curve to give the desired characteristic.

Plate Form, Frequency. In another type of capacitor, of much more importance than those mentioned above, the variation of capacitor setting is directly proportional to the frequency for which the total circuit is tuning. The importance of this type follows from certain considerations in radio communication, which require the spacing of broadcasting stations from each other by equal increments in frequency. It is this condition which makes highly desirable a capacitor so designed that equal increments in capacitor setting advance by equal increments the frequency to which the associated circuit is tuned. Such a capacitor will tune for the various broadcasting stations at equally spaced points in the capacitor dial.

In making this special form of variable capacitor the shapes of either rotor or stator plates may be adapted to perform the required area-setting variation. It is usually more convenient to use ordinary semicircular stator plates and form the rotor plates to the required shape. On this basis Forbes has shown that the radius vector to the edge of the rotor plate must satisfy the relation:

$$r = \sqrt{\frac{4D^2}{nkK^2\left[\dfrac{D}{K\sqrt{C_0}} - \theta\right]^3} + r_1^2} \tag{11}$$

in which $D = 1/(2\pi\sqrt{L})$; L = inductance of the circuit in henries; n = number of dielectric spaces; $k = 10^{-11}/(36\pi d)$; d = length of air gap between plates; $K = (f_{0°} - f_{180°})/\pi$ = cycles per radian of capacitor scale; $f_{0°}$ = frequency of circuit with capacitor set at 0 deg; $f_{180°}$ = frequency of circuit with capacitor set at 180 deg; C_0 = total capacitance of circuit when capacitor is set at 0 deg—this includes stray circuit capacitance as well as that of the zero setting of the capacitor in farads; θ = angle of rotation of the plates, radians; and r_1 = radius of the cut-out of stator plates to accommodate the rotor shaft. All dimensions in centimeters. The capacitance of such a capacitor, for any angular position θ of the rotor, is

$$C_\theta = \left[\frac{D}{\dfrac{D}{\sqrt{C_0}} - K\theta}\right]^2 + \left[\frac{nkr_1^2}{2}\theta\right] - [C_0] \tag{12}$$

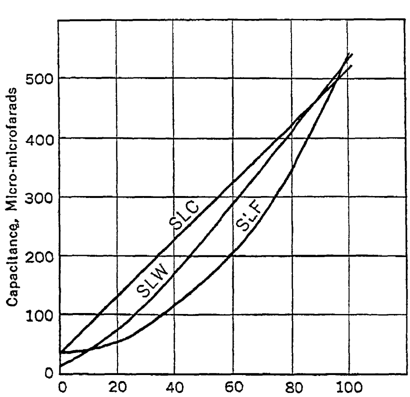

FIG. 4. Capacitance Calibrations for Three Typical Forms of Variable Air Capacitors, Straight-line Capacitance, Straight-line Wave Length, and Straight-line Frequency

Typical variations of capacitance with setting are shown in Fig. 4, which represents the construction practice of one manufacturer of variable capacitors. The curves shown indicate the value of capacitance obtained for various settings of the three general types of capacitors, straight-line capacitance (SLC), straight-line wavelength (SLW), and straight-line frequency (SLF).

Plate Form, Special Designs. Special considerations must be given to the design of variable air condensers when two or more units are connected together for operation on a common shaft. This grouping of sections into "gangs" sometimes places five condensers on a single control, and these may perform important functions in as many individual circuits. An illustration of this construction occurs in a radio receiver in which there are two identical units for tuning signal frequency circuits, one unit with specially shaped plates to tune the oscillator circuit and two smaller units to tune the short-wave circuits. In order to integrate the actions of all these condensers in the above superheterodyne radio receiver, where the single control is particularly desirable, various methods of design have been developed. E. D. Koepping has described the general principles involved, D. F. McNamee has presented a graphical solution of the design problem, and H. Schwartzmann has shown an analytical solution of the problem (see Bibliography, p. 3-73).

PLATE SPACING OF AIR CAPACITORS. Between two oppositely charged parallel plates of infinite extent the field is uniform. It is known, however, that the field between two finite plates is not uniform, tending to greater voltage gradients at the edges. Stress at a point in a dielectric is determined by the gradient at that point, and stresses above certain critical values lead to the formation of corona and sparkover. This may be pictured as follows, with plate spacing = S and thickness as T. For large values of S/T, the radius of the plate edge is small and a high gradient exists. As the plate thickness is increased, keeping plate center-to-center spacing and applied voltage constant, the radius of edge curvature is increased. This decreases the edge gradient. Inside the capacitor, however, the gradient increases because of the reduced spacing. It has been suggested by Ekstrand that the best value of S/T may be between 2 and 3. Investigation seems to corroborate Ekstrand figures by fixing the optimum S/T at 2.77.

Plate Dimensions and Voltages of Capacitors at Various Frequencies

T in.	S in.	S/T	Sparkover Voltage			Maximum Gradient		
			kv @ 60 cy.	kv @ 700 kc	kv @ 1500 kc	kv/in. @ 60 cy.	kv/in. @ 700 kc	kv/in. @ 1500 kc
0.128	0.218	1.705	14	13.5	13.7	89.1	85.8	87.1
0.04	0.192	4.8	8.4	7.59	6.82	80.2	72.5	75.1
0.064	0.719	11.24	24	14.28	11.7	82.0	48.8	40.0

It has become a habit to consider breakdown as coincidental with sparkover. Actually, breakdown has occurred at the first sign of corona, and corona may become evident at a considerably lower voltage than sparkover. When a conductor is raised beyond a certain critical potential, the air adjacent to it becomes ionized, forming corona. The ionized air,

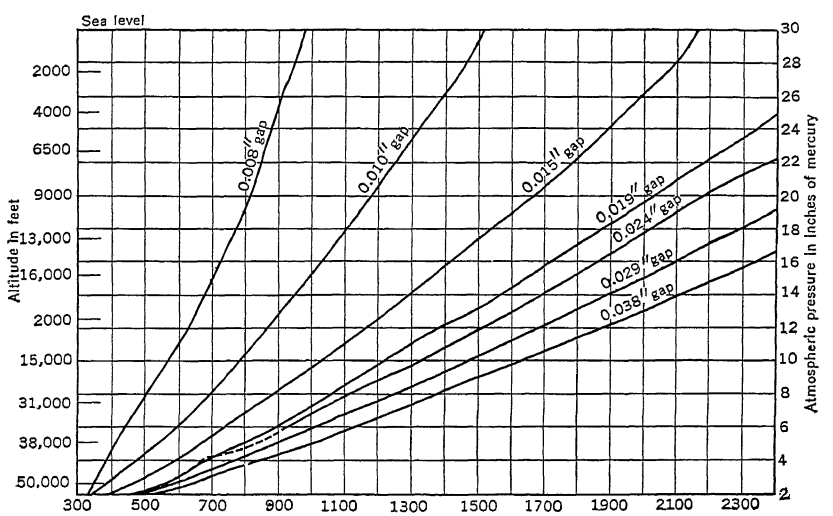

FIG. 5. Breakdown Voltage vs Altitude (Atmospheric Pressure)

being itself a conductor, can be considered to increase the dielectric losses. If the gradient is further increased, the conditions become unstable and sparkover occurs.

Not only are capacitors used in transmitters and electronic heating devices subjected to high voltages, but they also must carry considerable amounts of power. The power input to a capacitor is measured by the energy stored in it multiplied by the number of charges and discharges per second.

Transmitter capacitors used in aircraft electronic equipment must have their plates spaced properly to withstand voltages encountered at maximum flying altitudes. The curves of Fig. 5 indicate breakdown voltage for various plate spacings at various altitudes.

19. IMPREGNATED-PAPER CAPACITORS

Impregnated-paper capacitors are the most efficient of all types because of their flexibility in size, shape, and rating. They cover an extremely wide range in size from the small toothpick varieties found in hearing aids to large welded case blocks. Flexibility in voltage ratings is second only to size values with a range from 1 volt to 200,000 volts. Capacitance values are common in a range from $100\mu\mu f$ to $200\mu f$ in a single container.

Electronic equipment designers are primarily concerned with d-c application of impregnated-paper capacitors.

D-c service includes such applications as rectifier filters, energy storage, arc suppression, and by-passing for electron-tube and circuit elements. D-c ratings provide for small a-c components where their heating effects are negligible. Experience indicates that the a-c

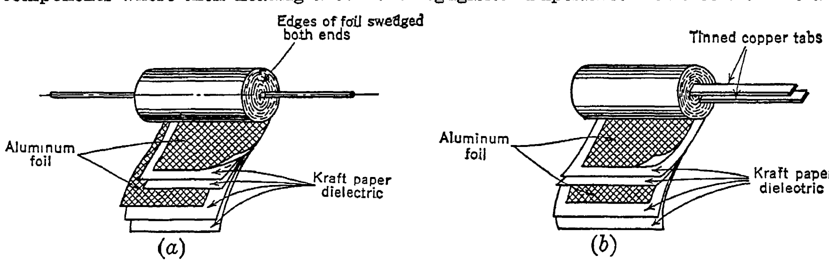

FIG. 6. Inductive and Non-inductive Capacitor Windings

components should not exceed 20 per cent of the d-c value at a frequency of 60 cycles, or 15 per cent for 120 cycles, or 1 per cent for 10,000 cycles, and for higher frequencies the allowable magnitude is determined strictly on thermal evaluation of the high frequency component.

Other special electronic applications require rating of the capacitor on an a-c rather than a d-c basis, such as tuned filters and pulse networks.

A-c versus D-c Ratings. It is possible to rate capacitors designed for a-c service in terms of d-c voltages, but it is not practical to rate d-c capacitors in terms of a-c voltage ratings because of the difference in design considerations in the d-c rated capacitors in comparison to those rated for alternating current.

Some of these design considerations are:

1. D-c voltage ratings depend essentially on dielectric stress.

2. A-c voltage ratings depend not only on dielectric stress but also on the operating frequency and power factor. Frequency and power factor determine the internal heating, which must be kept within limits determined by the radiating surface of the container. For small a-c capacitors, the ratings are determined from dielectric breakdown voltage considerations. In the larger a-c voltage ratings, the prime design consideration is heating.

In general, the following tabulation represents the nearest standard d-c rating corresponding to the several standard a-c voltage ratings:

A-c Volts	D-c Volts
110	200
220	400
330	600
440	1000
550	1500
660	2000

Chlorinated diphenyl impregnated capacitors designed for a-c service cannot be used on direct current unless the impregnant has been chemically treated with inhibitors or stabilizers to prevent deterioration of the impregnant from the combined influence of the d-c field and high temperature.

Construction of Winding. Impregnated-paper capacitors are made in a roll construction, consisting of two metallic foils separated by two or more sheets of impregnated kraft tissue. In the roll construction the resultant capacitance is twice that obtained with a parallel-plate construction since both sides of the foils are active. The capacitor winding may be round or flat, depending upon mechanical considerations of housing.

A further consideration in roll construction is whether the foils are of the "buried" type with tabs for contact members or of the extended foil construction. See Fig. 6(*a*) and (*b*). The extended foil construction gives the lowest value of self-inductance since all the turns are bonded together, the construction approaching that of a stacked parallel-plate capacitor. The "buried" foil winding approaches the "extended" foil if the tabs are inserted at the center of the winding within one turn of each other. Figure 7 shows a comparison of the impedance for "extended" vs. "buried" foil constructions for a frequency range of 60–5000 cycles.

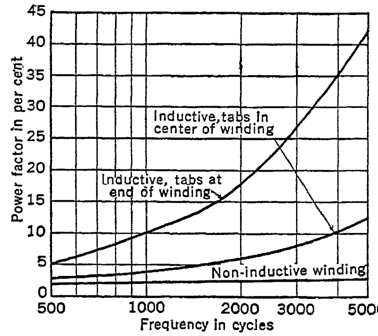

FIG. 7. Comparative Power Factors for Inductive and Non-inductive Windings

Impregnation of Winding. The impregnants most commonly used with kraft paper are microcrystalline hydrocarbon waxes, chlorinated waxes and oils, castor oil, mineral oil, and plastic compounds. These various impregnants offer a wide range of characteristics with temperature. Figure 8 shows six of the more common wax and oil impregnants for a temperature range of −40 to 100 deg cent. These data were taken for average production capacitors and do not represent minimum requirements. Minimum requirements are shown in the accompanying Table 1.

Voltage Rating of D-c Capacitors with Temperature and Service Conditions. All capacitors are affected by temperature, voltage stress, and time.

Table 1. Minimum Impregnant Requirements

	Castor Oil	Mineral Oil	Chlorinated Diphenyl	Halowax
Megohms times microfarads:				
At 25° C	500	2000	1500	2000
At high test temperature *	5	20	15	100
Insulation resistance in megohms:				
At 25° C	1500	6000	4500	6000
At high test temperature	150	600	450	1000
Capacitance change in per cent at low ambient test temperature from value at 25° C †	−30	−15	−30	−10

* 85° C for all impregnants except Halowax, which is measured at 65° C.
† Lowest temperature −40° C except for Halowax, which is −20° C.

It has been standard practice to rate d-c capacitors at a 40 deg cent ambient temperature on the basis that such a rating would provide sufficient factor of safety to withstand a life test of 1000 hours at twice the rated voltage at this temperature, which is equivalent to approximately 1 year of normal service conditions.

Design trends for electronic equipment toward smaller and smaller physical volume have resulted in ambient temperatures considerably in excess of the 40 deg cent value considered standard before World War II.

It has not been generally understood that increasing the ambient temperature above 40 deg cent required voltage derating for an equivalent life expectancy at the higher temperatures, and that the derating factors are a function of capacitor size. Capacitor size can best be evaluated for d-c ratings in terms of energy content in watt-seconds.

$$\text{Watt-second} = \tfrac{1}{2} CE^2$$

where C = capacitance in microfarads and E = d-c voltage in kilovolts.

This was a problem given joint industry and government appraisal during the war, and the findings resulted in a table of derating factors as a function of temperature and capaci-

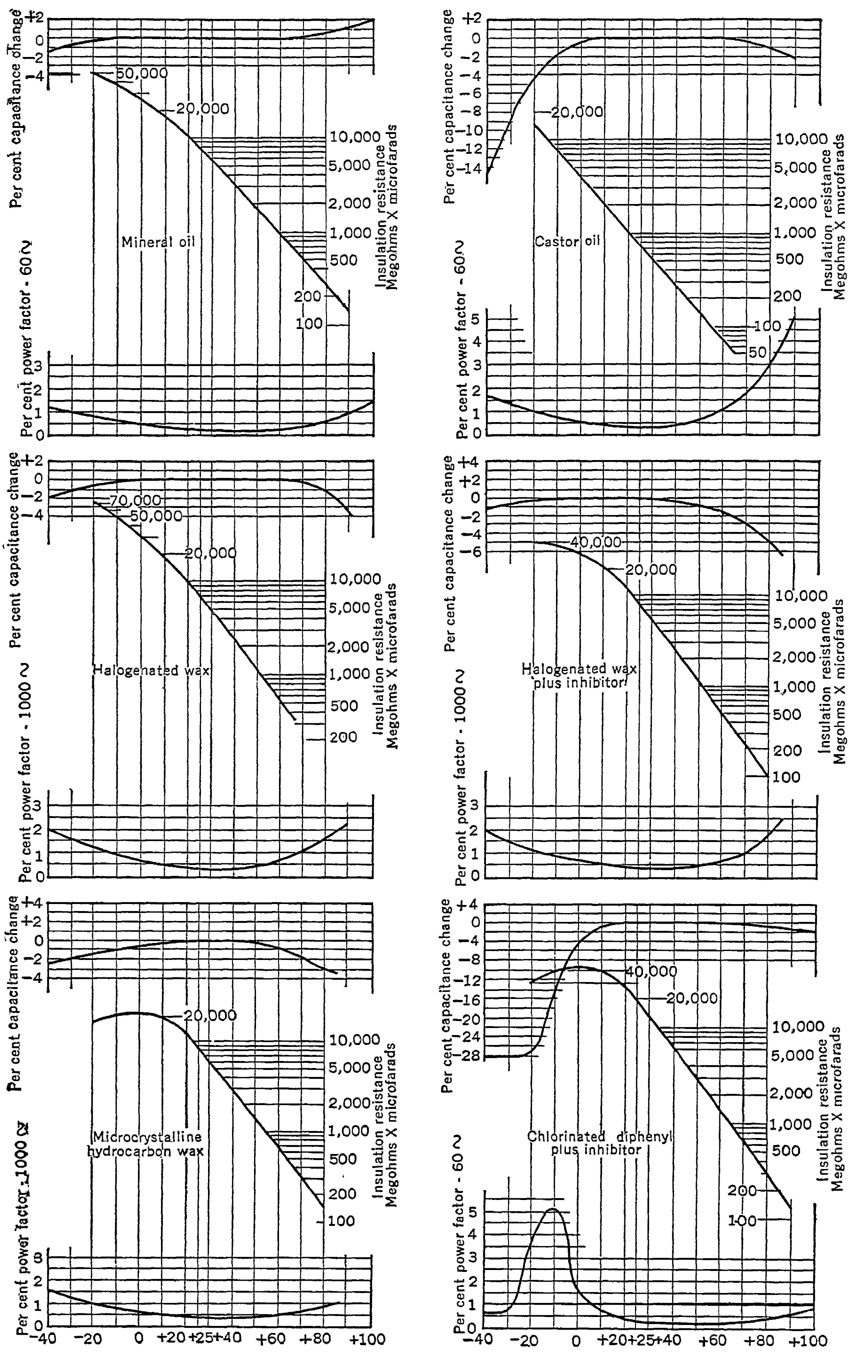

FIG. 8. Typical Electrical vs Temperature Characteristics of Paper-dielectric Capacitors with Various Impregnations (Courtesy of Solar Mfg. Corp.)

tor size. These data are shown in Fig. 9 and are extracted from data obtained in Proposed Joint Army-Navy Specification JAN-C-25 dated January 22, 1945, and published in *Communications* for August 1947.

These data show that a capacitor in the 0.5 watt-second class and rated for a given voltage at 40 deg cent must be voltage-derated to 95 per cent of its 40 deg cent rating at 85 deg cent or 60 per cent at 105 deg cent. Generally speaking, the life expectancy of a

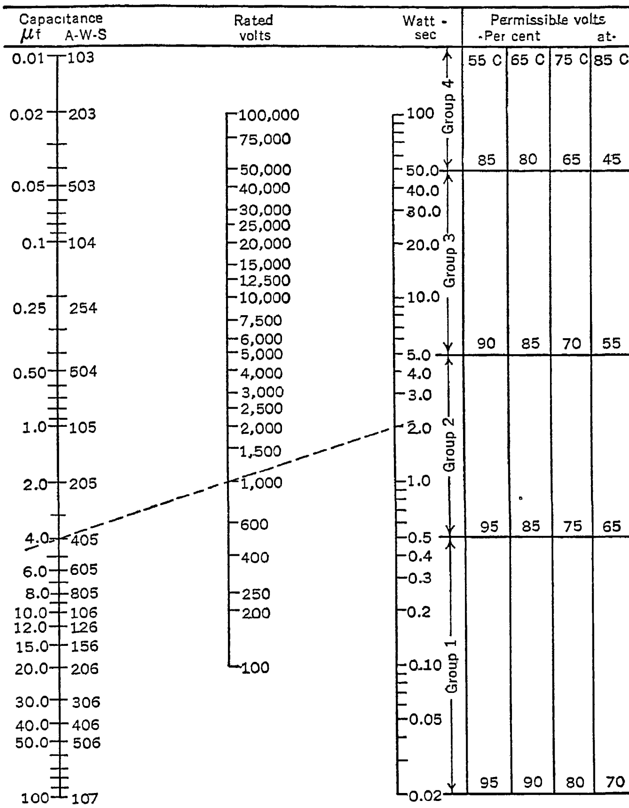

FIG. 9. Ratings of D-c Capacitors

capacitor without derating is halved for each 10 deg cent rise in temperature. For d-c voltage considerations, at a fixed temperature of 40 deg cent, the life expectancy is inversely proportional to the fifth power of the voltage.

D-c voltage ratings are not fixed values, but for a given insulation thickness they may be made variable depending upon the duty cycle and circuit conditions. A capacitor rated at 1000 volts d-c at 40 deg cent for continuous duty in a power-supply filter could be used in a photoflash circuit at a much higher voltage, such as 2000 volts d-c, and still have acceptable performance because of the lighter duty cycle. Life expectancy might increase to 100,000 flashes of the photoflash equipment.

This indicates that considerable flexibility may be used in rating capacitors provided that all the design requirements, operating conditions, and duty cycle are known. To illustrate, a 10-μf capacitor winding using three sheets of 0.0004 kraft tissue and impregnated in mineral oil would be normally rated at 1000 volts d-c at 40 deg cent continuous duty, at 1200 volts for an intermittent duty cycle of about 50 per cent, at 1500 volts intermittent duty for welder applications, and 2000 volts under a photoflash duty cycle. The d-c rating would have to be reduced to 600 volts for long-time (15 years) life expectancy.

Factors that affect capacitor ratings:

1. Microfarad value and tolerance.
2. Duty cycle, continuous or intermittent.

3. Ambient temperature range.
4. Ripple voltage, magnitude, and frequency.
5. Abnormal circuit voltages, such as no load voltage and peak charging voltage.
6. Discharge current, and nature of discharge, whether oscillatory, and, if so, whether critically damped.

It is well to remember that these factors that govern ratings are based on hermetically sealed capacitors which have been carefully dried, impregnated, and sealed. They do not apply to other constructions where life is limited by the vagaries introduced by moisture absorption.

METALLIZED PAPER CAPACITORS. The latest addition to the family of impregnated-paper capacitors is the MP type, in which the capacitor electrodes are deposited on the paper dielectric in very thin films, having a thickness range between 25 and 100 millimicrons. The thin film contributes the property of "self-healing" to capacitors, permitting the use of a single sheet of dielectric, which is not possible with conventional impregnated kraft paper designs. The combination of the extremely thin metallic film electrode and a single sheet of dielectric affords extremely compact designs for voltage ratings below 200 volts d-c or for 150 volts a-c.

Voltage ratings exceeding 200 volts employ a multiple-layer or interleaved paper dielectric of conventional construction. The volume saving is not as great as for the single-layer construction but is still considerable.

A new concept in capacitor rating is involved with MP capacitors, namely sparking voltage; this is defined as the lowest applied voltage that will cause continuous "self-healing" action to take place.

Table 2. D-c Voltage Ratings

D-c Working Voltage 25° C	1 Minute Flash Test 25° C	Sparking Voltage 25° C
200	300	400
400	600	900
600	900	1350

MP capacitors designed so that the maximum surge voltage encountered in service at the highest operating temperature does not exceed the sparking voltage are usable in all kinds of circuits without fear of their causing spurious noise. In the event of a transient voltage which would cause failure of a conventional capacitor type, there will be only a momentary arc discharge followed by the self-healing mechanism.

Insulation Resistance. The minimum insulation resistance of single-layer lacquered metallized paper capacitors will exceed 500 megohm microfarads or 2000 megohms at 25 deg cent. Interleaved unlacquered metallized paper capacitors will have a minimum insulation resistance of 1000 megohm microfarads or 6000 megohms at 25 deg cent, which compares favorably with conventional capacitor designs. The change in insulation resistance with temperature in metallized paper capacitors is similar to that of conventional mineral oil impregnated kraft paper designs, or there is approximately a 50 per cent decrease in insulation resistance for every 10 deg cent rise above 25 deg cent.

20. MICA CAPACITORS

Mica capacitors are useful in electronic circuits because of their low a-c losses and their high electrical stability over a wide temperature range. These characteristics, along with the fact that they are constructed to very close capacitance tolerances, make them ideally suited for use in frequency-determining circuits.

The word "mica" is derived from the Latin "micare" meaning to sparkle. It is a group name for a number of aluminum silicate minerals which are characterized by the properties of high reflection and a basal cleavage so perfect that they may be split in laminae of the order of 0.0005 in. thick.

Of the eight distinct species of mica recognized by mineralogists, muscovite is the most important as far as mica capacitor manufacture is concerned. Muscovite is virtually unaffected by weathering, is not porous, is not decomposed by acids, and is negligibly affected by moisture. It will withstand relatively high voltage gradients. Voltage tests made with spherical electrodes show that films $^1/_{1000}$ in. thick frequently withstand 5000 volts d-c with no puncture. Muscovite, because of its extremely low power factor, in addition to its other desirable properties described previously, is an ideal dielectric for use in capacitor manufacture.

Both micas and foils or silvered electrode patterns must be precision outlined. Micas

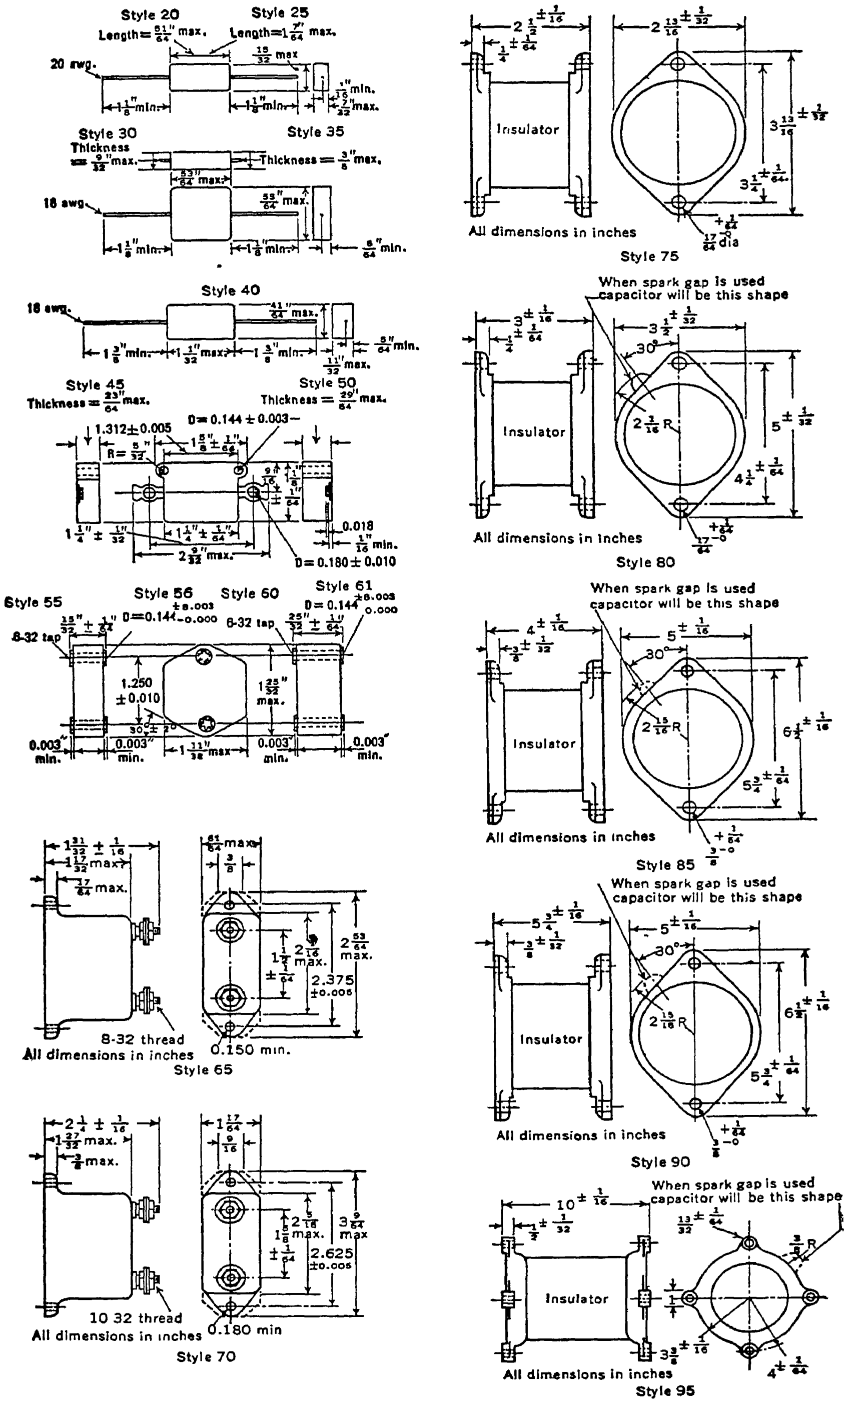

Fig. 10. Standard Outline Dimensions

are usually cut to within plus or minus 0.001 in. of specified lengths and widths and foils almost as accurately.

Sealing binders as well as metal clamps provide permanent positioning of the mica stack. This accuracy and permanency provide the stability of characteristics with respect to aging, frequency, and temperature which recommend mica capacitors for use in frequency-determining circuits or circuits that control reactance and phase and in precision measuring equipment.

Table 3. Capacitance Range for the Several Case Types

Case Type	From	To
20	5 μμf	1,000 μμf
25	5	1,500
30	470	10,000
35	3,300	10,000
40	100	10,000
45	17	10,000
50	2,000	27,000
55 and 56	22	30,000
60 and 61	100	47,000
65	47	100,000
70	47	100,000
75	47	100,000
80	47	100,000
85	47	100,000
90	100	100,000
95	100	10,000

Note: Capacitance values for 1000 μμf or less are measured at or referred to 500 kc/sec. Capacitance values greater than 1000 μμf are measured at or referred to 1000 kc/sec.

Standard commercial tolerance for molded-case types 20 to 61 is ±10 per cent and for potted types ±5 per cent; other tolerances are available as shown in Fig. 10.

Table 4. D-c Voltage or Peak Working Voltage Ratings for the Several Case Types

Style	Voltage Range
20, 25, 30, 35	300 and 500 volts
40	300, 500, 1000
45, 50, 55, 56, 60, 61	600, 1200, 2500
65	250, 500, 1000, 1500, 2000, 3000
70	500, 1000, 1500, 2000, 3000, 5000
75	1000, 1500, 2000, 3000, 4000, 6000
80	1500, 2000, 3000, 4000, 5000, 6000, 8000, 10,000
90	3000, 4000, 5000, 6000, 8000, 10,000, 12,000, 15,000, 20,000
95	15,000, 20,000, 25,000, 30,000, 35,000

Mica dielectric capacitors because of their low losses and high Q are useful at high frequencies and for high current circuits.

The mechanical forms of mica dielectric capacitors vary from small phenolic molded cases for receiver applications to large ceramic insulated housings required by high-current, high-voltage-transmitting circuits.

The mica capacitor is the only one of the many capacitor types that has obtained general industry standardization for case styles and electrical ratings.

Figure 10(*a*) shows outline dimensions for molded-case types, Styles 20, 25, 30, 35, 40, 45, 50, 55, 56, 60, and 61; Figs. 10(*b*) and (*c*) show outline dimensions for the potted-case types, Styles 65, 70, 75, 80, 85, 90, and 95.

Table 5. Classification

Designation	Temperature Coefficient Not more than	Capacitance Drift Not more than
Class A..........	±1000 ppm	±(5% + 1 μμf)
Class B..........	± 500 ppm	±(3% + 1 μμf)
Class C..........	± 200 ppm	±(0.5% + 0.5 μμf)
Class I..........	{+ 150 / − 50 ppm}	±(0.3% + 0.2 μμf)
Class D..........	± 100 ppm	±(0.3% + 0.1 μμf)
Class J..........	{+ 100 / − 50 ppm}	±(0.2% + 0.2 μμf)
Class E..........	{+ 100 / − 20 ppm}	±(0.1% + 0.1 μμf)
Class G..........	{0 / − 50 ppm}	±(0.1% + 0.1 μμf)

Note: Characters D, J, E, and G require individual tests of each capacitor and should be considered for use only where extreme stability and accuracy are required.

Capacitance. Capacitance values for mica capacitors are expressed in micro-microfarads.

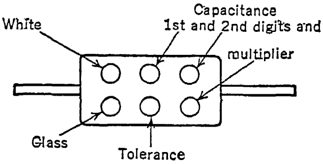

FIG. 11. RMA Capacitor Color Code (Proposed)

Color Marking of Molded Types. A convenient system of six-color marking is being used to identify molded mica case types. Two RMA color codes are in use, one as a standard and the other proposed, but industry standardization is expected to make the old system, which does not provide for identification of the class designation, obsolete.

Figure 11 shows the arrangement of the two rows of colors, and the significance of each color is shown in Table 6.

Radio-frequency Current Ratings. The potted-case type of mica capacitor is intended primarily for use in frequency-determining circuits or those requiring the capacitor to handle appreciable amounts of r-f current. Typical curves illustrating the current-carrying capacity for a frequency range of 0.1 to 30 megacycles of mica dielectric capacitors housed in potted ceramic cases are shown by Fig. 12.

Table 6

Color	Numerical Significance	Decimal Multiplier	Capacitance Tolerance	Class Designation
Black.....	0	1	20%	A
Brown....	1	10		B
Red.......	2	100	2%	C
Orange....	3	1,000	3%	D
Yellow....	4	10,000		E
Green.....	5		5%	
Blue......	6			
Violet.....	7			
Gray......	8			I
White.....	9			J
Gold......		0.1		
Silver.....		0.01	10%	

It is interesting to note the increasing current loading with frequency for the 0.0001-$\mu\mu f$ capacitor in comparison with the decreasing current rating with increasing frequency for capacitance values greater than 0.001 $\mu\mu f$, which is due to the inductance introduced in the series-paralleling of the mica sections which constitute the capacitor stack for the larger capacitance values.

The current-carrying capacity of mica dielectric capacitors can be materially increased by immersing the foil-mica stack in silicon oil and removing the heat generated by means of cooling coils.

Manufacturers' published ratings are based on an ambient temperature of 40 deg cent, and the current ratings must be derated for higher ambient temperatures as shown in Table 7.

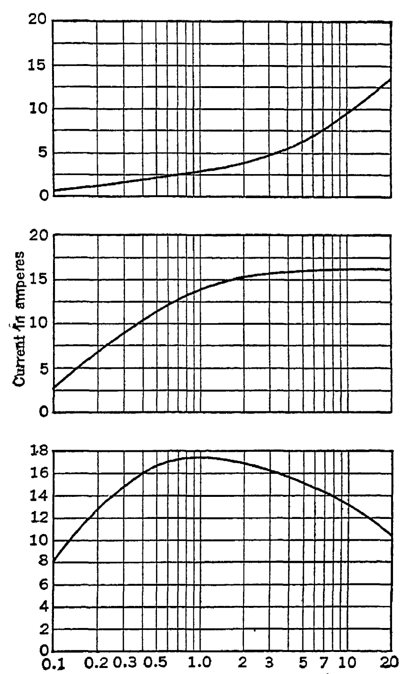

FIG. 12. Current-carrying Capacity for 10 Deg Cent Temperature Rise (Courtesy of Solar Mfg. Corp.)

Table 7. Current Deratings with Temperature

Characteristic	Temperature Range	Current Derating Factor
B, C	41 to 50 deg cent	0.95
B, C	51 to 60	0.85
B, C	61 to 70	0.70
D, E, G	40 to 70	0.50

21. CERAMIC DIELECTRIC CAPACITORS

Ceramic capacitors are neither new nor the result of any accidental discovery. They are the direct result of long research in the early 1900's when German scientists noted the unusual characteristics of titanate ceramic materials.

Europe has never had a domestic source of mica and was, therefore, faced with a serious shortage before World War I. This shortage focused attention and accelerated research into the possibilities of developing a suitable substitute. This problem in ceramic research took German scientists many years to solve. In the early 1930's, a ceramic titanate material was finally developed that was controllable in production quantities and, at the same time, would retain stable characteristics. These ceramic dielectric units were quickly used in substantial quantities by European radio and electronic industries.

The ceramic dielectric because of its negative temperature coefficient was used in temperature-compensating capacitors in oscillator circuits. As more experience was gained and the basic characteristics became more clearly understood, other forms of ceramic capacitors were used, including higher capacitances, such as by-pass and coupling types for transmitting and other high-voltage and high-current capacitors.

The electronics industry in the United States was slow to recognize the possibilities of ceramic capacitors and to utilize the general existing knowledge of European ceramic dielectric materials because of the abundant supplies of mica which were readily available. A second retarding factor was the general feeling that ceramic dielectrics in the titanate group would be far too costly for our mass-production methods.

Centralab, a division of Globe Union, Inc., in the early 1930's, initiated a research program to investigate the availability of raw materials and the possibility of producing ceramic capacitors similar to the European types. Abundant domestic supplies of raw materials were located which exhibited characteristics superior to those of the European materials.

The first group of capacitors was offered in capacitance value up to 1000 $\mu\mu$f and in controlled temperature coefficient varying from a positive change of 100 ppm to a negative change of 750 ppm. The dielectric constant of these materials varied from 50 in the zero temperature coefficient group to a maximum of 95 in the group having a negative temperature coefficient of 750 ppm.

The use of ceramic capacitors was greatly accelerated during World War II because of the increased demand for substitutes for mica capacitors, which were in short supply owing to a shortage of high-quality mica.

The fact that ceramic capacitors possess low losses at ultra-high frequencies makes them ideally suited for application where other types of dielectrics are not satisfactory. They are available in both tubular and disk constructions. The disk constructions employ a "feed-through" terminal arrangement which reduces lead inductance to the absolute minimum.

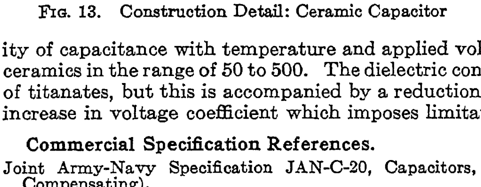

FIG. 13. Construction Detail: Ceramic Capacitor

A typical construction for the tubular ceramic capacitors is shown in Fig. 13. In this construction, the capacitance is controlled by the dielectric constant of the ceramic, by the length, diameter, and wall thickness of the ceramic tube, and by the silvered area of the electrodes. Stability of capacitance with temperature and applied voltage is obtained with the use of low-K ceramics in the range of 50 to 500. The dielectric constant may be increased through the use of titanates, but this is accompanied by a reduction in capacitance stability and a marked increase in voltage coefficient which imposes limitations on the use of the high-K bodies.

22. ELECTROLYTIC CAPACITORS

Electrolytic capacitors employ solid dielectric media on which an oxide film, produced electrochemically, is the dielectric in the presence of a d-c polarizing voltage and an ionic conducting medium.

Investigations have shown that the oxides of tantalum and aluminum exhibit desirable characteristics. Tantalum possesses an oxide with high dielectric constant and low leakage, but economic factors have limited its use. Its principal limitations are voltage rating and mechanical construction resulting from the use of sulfuric acid as the electrolyte. Aluminum is the metal used in all other electrolytic capacitors because of its low price and excellent film-forming characteristics.

An oxide film can be formed on aluminum by electrolytic means by immersing a ribbon of aluminum foil in an aqueous solution of boric acid and sodium borate and passing an electric current through the solution with the aluminum forming the positive pole or anode. Electrolysis of the solution causes oxygen to be generated at the positive pole, oxidizing the surface of the aluminum. The film thickness is a function of the d-c formation voltage.

The extremely thin oxide film formed on the aluminum anode offers a very high resistance to further passage of current if the applied voltage is not increased above the film formation voltage. A cell of this nature inserted in a container containing an aqueous electrolyte takes the form of the so-called wet electrolytic capacitor. The aluminum oxide film acts as the dielectric, the electrolyte as the cathode, and the container as the contact medium for the cathode.

The electrolytic capacitor has a very high capacitance per unit volume as compared to other types of capacitors, such as the impregnated-paper or mica dielectric types.

The primary reason why an electrolytic capacitor gives a high capacitance per unit volume is the extreme thinness of the dielectric or oxide film. The thickness of the oxide film covering the aluminum electrode is approximately 2×10^{-5} in., and the dielectric constant K of the oxide layer produced is high (approximately 10) as compared with 2.5 for a mineral oil impregnated paper capacitor.

There are two types of electrolytic capacitors, depending upon the physical characteristics of the electrolytes: the *wet type*, which uses an aqueous electrolyte; and the *dry type*, which uses a viscous or paste electrolyte.

ANODE FOIL TREATMENTS. The anode foil employed in electrolytic capacitors may assume several forms, depending upon design considerations:

1. *Plain foil*, where the oxide film is electrochemically formed on the surface of the aluminum foil without any previous treatment of the foil surface.
2. *Etched foil*, where the surface of the aluminum foil is first treated chemically or electrochemically to erode the surface, thereby increasing the superficial area prior to the film-forming procedures.
3. *Sprayed gauze*, where an inert carrier such as chemically pure cotton gauze is mechanically coated with aluminum by means of metal spraying.

The etched foil electrode is the most common one in both wet and dry types of electrolytic capacitors, although the sprayed gauze construction is becoming more common in the dry electrolytic capacitor types.

The hydrochloric acid etched anode foil construction is used in place of plain foil because it gives effective surface areas much greater than those obtained from plain foil and thereby cuts the physical size.

CATHODE OR COLLECTOR FOIL TREATMENTS. Filming of the cathode foil is a very interesting phenomenon which has been observed in very high gain foils in circuits of high ripple currents and which must be carefully considered in the use of electrolytic capacitors. The mechanism that causes cathode film formation can be explained by the fact that the cathode foil under high ripple current conditions is subject to a reversal of ripple current due to the charging of the capacitor on the conducting part of the cycle and the discharging of the capacitor into the load on the non-conducting part of the cycle even though the cathode never becomes positive with respect to the anode polarizing potential, as illustrated by Fig. 14. As can be seen from the diagram, on one part of the cycle the capacitor is charging and during the other half-cycle the capacitor is discharging through the load. The result is that the cathode becomes anodized to the value of the ripple voltage impressed across the capacitor. The value of this potential is a function of the power-supply regulation, the capacitor impedance, and the magnitude of the load current. When the capacitance of the cathode is reduced by formation, it produces in effect a low instead of a high capacitance in series with the anode capacitance and reduces the capacitance of the capacitor, depending upon the degree of cathode film formation.

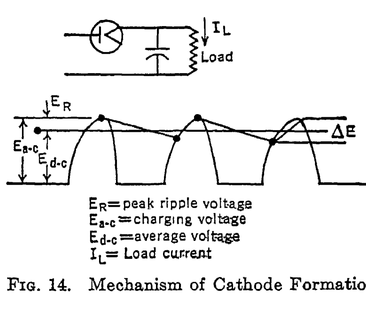

FIG. 14. Mechanism of Cathode Formation

Etched Cathodes. Most commercial designs employ etched cathode foil for low-voltage sections (less than 25 working volts d-c) and for other ratings where ripple current is high. Etched cathode foil is used for the following reasons:

1. An etched cathode foil increases the effective cathode surface area, which reduces the ripple current density to such a value that the cathode film does not build up to a value exceeding the initial thickness of the cathode film.
2. The increased cathode surface will afford a much higher cathode capacitance, and, the higher the value of the cathode capacitance, the smaller will be the reduction in initial

anode capacitance because of the series connection of the cathode and anode capacitance. For example, a 100-μf 15 working volt d-c electrolytic capacitor with a plain foil cathode has a cathode capacitance of approximately 120 μf, which would cut the total capacity of the unit to 54.5 μf. However, if an etched cathode foil was used, the cathode capacitance would be approximately 1200 μf, and the resultant total capacitance of the capacitor would be 93 μf.

Table 8 gives the maximum root mean square ripple currents recommended in RMA Standards Proposal 160A for various capacitance and voltage ratings.

Table 8. Maximum rms Ripple Current in Milliamperes at 120 Cycles

Micro-farads	15 v	25 v	50 v	150 v	250 v	300 v	350 v	400 v	450 v
10					80	90	145	150	150
20				90	160	180	180	180	180
30				135	180	200	200	200	200
40				190	190	200	200	200	200
50				200	200	200	200	200	200
60			135	200	200	200	200	200	200
70			150	200	200	200	200	200	200
80			200	200	200	200	200	200	200
90			200	200	200	200	200	200	
100		200	200	200	200	200	200

300		400	400	400					
400		500	500						
500	500	600	625						
600	550	650	700						
700	580	700	750						
800	625	750	900						
900	700	850							
1000	700	850							
1500	850	1000							
2000	1000								

It is very important that electrolytic capacitors should not be subjected to ripple currents in excess of the values listed in Table 8; otherwise, the capacitors will overheat and the life will be appreciably reduced.

CHARACTERISTICS OF ELECTROLYTIC CAPACITORS. A knowledge of the basic characteristics of electrolytic capacitors is essential for their correct use. These are:

Table 9. Commercial Capacitance Tolerances

D-c Working Voltage	Capacitance Tolerance
0– 50	−10; +250%
51–350	−10; +100%
351–450	−10; +50%

Capacitance. The capacitance of a dry electrolytic capacitor is determined by the surface area of the anode and the dielectric thickness by the formation voltage. With etched foil construction, the increase in superficial area or gain varies inversely with the formation voltage. There is a problem of capacitance control with formation voltage, since for lower voltages capacitance per unit area varies considerably. See Table 9.

Leakage Current. The leakage-current characteristic of a dry electrolytic capacitor represents the amount of direct current flowing through the capacitor with its rated polarizing voltage applied, and does not include the momentary charging current. This leakage current is an indication of the quality of the anode film. Commercial specifications for permissible leakage current may be determined by the formula:

$$I = KC + 0.3$$

where I is the d-c leakage in milliamperes, K is the constant as shown in Table 10, and C is the rated capacitance in microfarads. The leakage current is determined after application of rated d-c working voltage.

Table 10. Leakage-current Constant

D-c Rated Voltage	K
3 to 100	0.01
101 to 250	0.02
251 to 350	0.025
351 to 450	0.04

D-c Working Voltage. The d-c working voltage is the maximum d-c voltage the capacitor will stand under continuous operation within its normal temperature range.

Peak Working Voltage. The peak working voltage represents the d-c voltage plus the peak a-c ripple voltage; it refers to a continuous operating condition and should not be confused with surge voltage.

Surge Voltage. The surge voltage is a short-time d-c voltage rating that exceeds the peak working voltage and approaches the film formation voltage. This voltage is limited by the internal heating of the capacitor caused by the rapid increase in leakage current as shown by Fig. 17. Usage has established surge-voltage ratings for various d-c working voltages which are listed in Table 11 for a 1000-ohm circuit regulation resistance.

Power Factor. For all practical purposes, the power factor of an electrolytic capacitor is the ratio between equivalent series resistance and the capacitance reactance at a given frequency. It is expressed in percentage and indicates the energy consumed by the capacitor.

Equivalent Series Resistance. Equivalent series resistance is a more useful characteristic in mathematical equations relating to electrolytic capacitors. The equivalent series resistance represents the total losses. r_s = watts/i^2, where r_s = equivalent series resistance and i = leakage current. The total losses in an electrolytic capacitor consist of: (1) dielectric loss of oxide film, (2) electrolyte resistance, and (3) contact resistance. The combined effect of these losses is expressed as the equivalent series resistance value necessary to produce an i^2r loss of the same magnitude.

Table 11. Single-voltage Ratings.

D-c Rated Voltage	D-c Surge Voltage
3	4
10	12
15	20
25	40
50	75
150	185
250	300
300	350
350	400
400	450
450	500

A convenient figure of merit for evaluating losses in electrolytic capacitors is the P factor, which is expressed as the product of the rated capacitance in microfarads and equivalent series resistance in ohms, as measured on a polarized capacitance bridge at a frequency of 120 cycles per second. Commercial capacitors have P factors which do not exceed the values shown in Table 12 for the several standard d-c voltage ratings. When the high- and low-voltage sections are combined into a single capacitor winding, the electrolyte for the high-voltage section determines the P factor for the low-voltage section and raises the P factor over what would be obtained with a low-voltage electrolyte. This makes it necessary to double the P factor (Table 12) for the low-voltage section in combination with sections having d-c ratings exceeding 150 volts.

Table 12. *P* **Factors**

Temperature Effects. Capacitance, series resistance, power factor, and impedance of electrolytic capacitors are all somewhat affected by temperature. Figure 15 shows capacitance and power factor vs. temperature for typical commercial electrolytic capacitors when operated over a temperature range of −20 to 85 deg cent.

Aircraft and other special industrial applications require dry electrolytic capacitors which will maintain constancy of characteristics for temperatures as low as −40 deg cent. Special electrolytes are available which meet these requirements; see Fig. 16.

Dry electrolytic capacitors are not recommended for use in ambient temperatures exceeding 85 deg cent because of rapid drying out of the electrolyte.

Leakage current increases with temperature, as shown by curve Fig. 17 for a high-voltage filter capacitor and low-voltage by-pass section combined in a single winding.

Dry electrolytic capacitors intended for operation at ambient temperatures of 85 deg cent require the electrolyte to be heat-stabilized to prevent the leakage current from increasing to the point where the capacitor overheats and fails. The dotted curve of Fig. 18 shows the reduction in leakage current at rated d-c voltage for various temperatures in comparison with the leakage current for these same temperatures before heat stabilizing.

Early failure of dry electrolytic capacitors in electronic equipment is often due to failure to allow for excessive temperature in the electrolytic capacitor specifications.

R-f Impedance. Multiple-section concentrically wound dry electrolytic capacitors employ a common cathode which gives rise to coupling in the cathode circuit because of the common current paths as shown by Fig. 19. In circuits where common coupling causes circuit unstability, a swedged cathode is employed. This construction effectively cuts the common r-f impedance to a negligible value by the extension of the cathode foil with the turns swedged together, which, in effect, gives a non-inductive cathode construction since each cathode or ground terminal is directly under its corresponding anode terminal. This construction is similar as far as the cathode is concerned to the non-inductive winding shown in Fig. 6 for impregnated-paper capacitors.

Gas Pressure. Electrolytic capacitors should be supplied with a liberal space for gas expansion. This extra space is to accommodate any sudden generation of gas which may

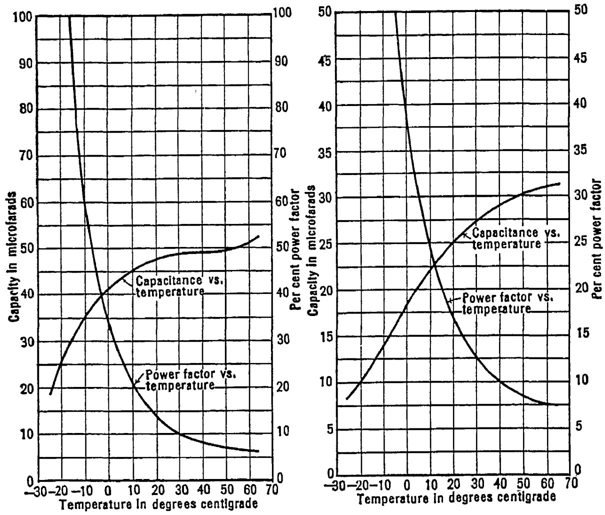

FIG. 15. Capacitance and % Power Factor vs Temperature of Electrolytic Capacitor (Courtesy Solar Mfg. Corp.)

be liberated as the result of improper uses of the capacitor. In addition, most electrolytics are supplied with built-in vents which prevent capacitors from exploding when they are improperly used, as being accidentally connected across alternating current.

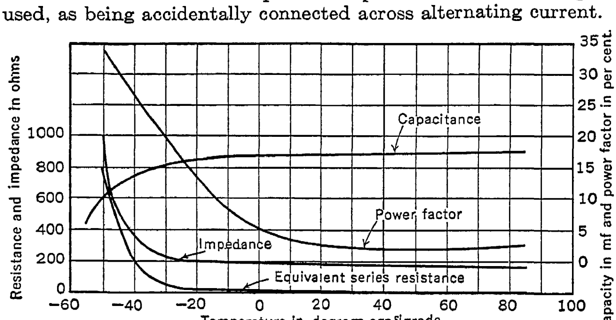

FIG. 16. Variation of Characteristics of Low-temperature Electrolytic Capacitor with Temperature (16 μf—350 WVDC—Courtesy of Solar Mfg. Corp.)

Polarity. *Polarized* types of dry electrolytic capacitors are designed for use in d-c or intermittent d-c circuits produced by rectifying alternating current. D-c polarized capacitors should not be subjected to reversed polarity, as the heavy current passing through the capacitor under this condition will raise its internal temperature and seriously damage it.

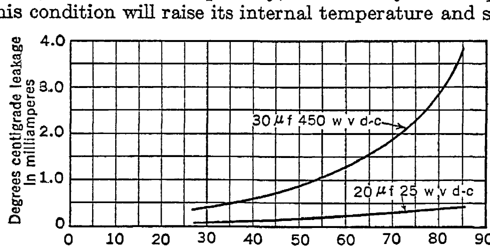

FIG. 17. D-c Leakage vs Temperature—Dry Electrolytic Capacitors

Non-polarized Types. This term applies to dry electrolytic capacitors constructed with two formed electrodes so that they function equally well with direct current impressed on either electrode irrespective of polarity. This does not mean that they can be used on alternating current continuously. Non-polarized capacitors are for applications where the d-c voltage supply might become reversed and remain so indefinitely. A non-polarized capacitor is equivalent to two polarized capacitors connected in series opposition.

A-c Motor-starting Capacitors. Non-polarized dry electrolytic capacitors may be used for intermittent duty in a-c circuits such as for motor starting, and they are known as motor-starting capacitors. They are ideal for intermittent duty when used within the manufacturers' limits for operating voltage, temperature, and duty cycle.

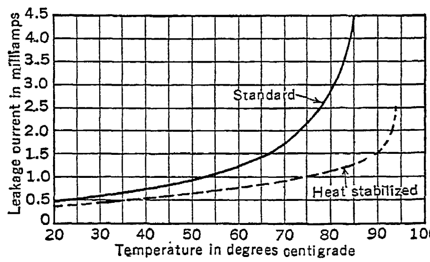

FIG. 18. Effect of Heat Stabilization of Electrolyte (30 μf—450 WVDC—Courtesy of Solar Mfg. Corp.)

Since the duty cycle is based on internal heating of the capacitor, it is possible to vary the number of application periods of voltage with the period of duration of voltage so that the product is a constant. The manufacturers' guarantee is usually twenty 0.5-sec starts per hour.

The normal maximum operating temperature of these capacitors is 65 deg cent. They may be successfully operated up to 85 deg cent provided that the duty cycle and maximum voltage conditions are adjusted accordingly. However, it must be noted that operating at higher than normal temperatures decreases the life considerably as it dries out the electrolyte at an accelerated rate. Operation of capacitors at low temperatures cannot harm capacitors because any change in characteristics is only temporary at subzero temperatures. The increase in power factor represents an increased resistance loss when the capacitor is in operation, and this creates sufficient heat to warm up the capacitor and quickly return it to normal operating conditions.

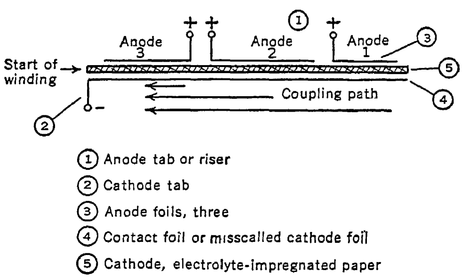

FIG. 19. Schematic Diagram of Three Section Dry Electrolytic Capacitor Winding

Commercial Specification Reference. Where more specific information and data are required for testing methods and procedures and for specific capacitor ratings, the following are suggested:

SECTION 4

ELECTRON TUBES

ELECTRON TUBES

THERMIONIC VACUUM TUBES

By A. P. Kauzmann

As dealt with in articles 1–6, vacuum tubes in operation are characterized by a source of electron emission; the conduction through a vacuous space, which may or may not contain sufficient gas to affect the conduction, of a current between the source of emission and one or more other electrodes by means of the emitted electrons; and the varying of this current by means of variations in electrode potential to produce an electrical response in an associated circuit. Thus, phototubes and cathode-ray tubes, though strictly vacuum tubes, are excluded (see Section 15). Grid-controlled gas-discharge tubes (see articles 13–21) and mercury-pool-type rectifiers (see article 21) are treated later in the section because their special properties and applications require special treatment.

1. PRINCIPLES OF OPERATION

HIGH-VACUUM TUBES. The simplest form of *high-vacuum tube* is the *diode*, consisting of a *thermionic cathode* and an *anode.* The cathode is heated to a temperature, depending on its nature, at which electrons are emitted from its surface into the surrounding vacuous space. When the anode is placed at a potential positive with respect to the cathode some of these emitted electrons are caused to flow to the anode under the influence of the electrostatic field, thus constituting a current flowing from cathode to anode in the external circuit, since the electrons are negatively charged. Those electrons which are not drawn to the anode return to the cathode.

Because of the mutual repulsion between the like charges of the electrons, only a definite number of them may be accommodated in the space between cathode and anode at any given anode potential, and therefore the current flowing is definitely limited. This limiting effect is called *space charge*, and the current is said to be *space-charge limited.* As the anode potential is increased the current increases until the total emission of the cathode is drawn to the anode, beyond which point the current is said to be *temperature limited.*

The relation between current and potential under conditions of space-charge limitation may be represented approximately by the equation

$$i_b = K_1 e_b^{3/2}$$

where K_1 is a constant depending on the physical dimensions of the tube.

Since the electron flow to the anode depends on the electrostatic field in the neighborhood of the cathode, the current may be controlled in part by the potential of another electrode in a position to influence this field. In the simple *triode* this additional electrode consists of a *grid*-like structure placed between cathode and anode. Because of its proximity to the cathode, the grid has more control of the field near the cathode than the anode has, but because of its open structure most of the electrons pass through to the anode. When the grid is operated at a negative potential with respect to the cathode, none of the electrons are taken by the grid.

The relation between anode current and grid and anode potentials is usually represented by the equation

$$i_b = K_2(e_b + \mu e_c)^{\eta} \tag{1}$$

where K_2 is a constant depending primarily on the cathode and grid dimensions, μ is the *amplification factor* of the tube (determined by the grid structure and grid-anode spacing), and η is usually between 1.5 and 2.5.

Other electrodes, usually grids, may be added to the structure, but the fundamental principles involved remain the same. For applications of high-vacuum tubes see Sections 7, 16, 17, 19, 20, and 21.

GAS-FILLED TUBES. In a *gas-filled diode*, the space contains sufficient gas at a low pressure to cause an appreciable fraction of the electrons passing between cathode and anode to collide with the gas molecules and thereby ionize them. The dislodged electrons pass on to the anode as additional anode current, while the positively charged ions are drawn to the cathode, but at a much lower velocity, owing to their greater mass, than the electrons possess. Because of this low velocity a given *positive-ion current* produces a much higher space-charge density than the same electron current. Therefore, the net space-charge density produced by the two currents (the algebraic sum of the positive and negative space charges) may approach zero, though the electron current is by far the larger.

Since the limitation of current in a high-vacuum diode is due to the negative space charge and this space charge is reduced by the positive ions, it follows that the presence of the gas increases the current which may flow at a given anode potential. Under normal conditions, the discharge is unstable at potentials much in excess of the ionizing potential of the gas, the current increasing until limited by the cathode emission. For this reason, the current is usually limited by an external resistance in series with the anode.

The relation between applied voltage and current may be expressed by the equation

$$i_b = \frac{e_{bb} - E_b}{r} \tag{2}$$

where E_b is the practically constant "anode drop" of the tube and r is the load resistance.

2. CLASSIFICATIONS

Vacuum tubes in general are classified according to many different structural and electrical characteristics.

Cathodes are *directly heated* if the actual emitter is also the resistance element which supplies the heat, and *indirectly heated* if the heat is supplied by conduction or radiation from a resistance element. The directly heated cathode is more efficient than the indirectly heated, but for many applications may not be heated by alternating current. The cathode *material* may be *tungsten, thoriated tungsten,* or *oxide-coated metal.* Tungsten is the least efficient and is generally used only in high-voltage tubes. Thoriated tungsten is much more efficient than tungsten and is used in many medium-voltage tubes (500 to 2000 volts anode potential) and some low-voltage tubes; at high voltages the emission life may be short. Neither of these materials is used for indirectly heated cathodes. Oxide-coated cathodes are the most efficient but (except in gas-filled tubes) are commonly used only in low-voltage tubes because of troubles from grid emission.

Anodes are *radiation cooled,* or *air cooled,* if no other cooling means is provided, or *water cooled* if provided with means for circulating water about or through the anode. Only high-voltage high-power (more than 6000 volts, 2500 watts rating) tubes are water cooled, except for special high-frequency tubes.

Rectifiers are *high vacuum* or *gas filled.* For high-power high-voltage applications, gas-filled tubes are usual, though high-vacuum tubes are used above 20,000 volts. For radio receivers both are used, gas-filled tubes predominating in other low-voltage applications.

Triodes are classified according to voltage and power rating, amplification factor, and special features such as designs for high-frequency oscillators, freedom from mechanical disturbance, etc. There are so many triodes of varying characteristics that almost any requirement can be met.

Multigrid tubes have been developed largely for specialized radio purposes, but the *screen-grid tubes,* including *suppressor-grid pentodes,* have wide application. In the screen-grid tube, the grid is screened or shielded from the anode, thus greatly reducing the feedback capacitance between plate and grid. For high-frequency voltage amplification, these tubes are used almost exclusively.

3. DEFINITIONS

Vacuum Tube. (Electron Tube.) A vacuum tube is a device consisting of an evacuated enclosure containing a number of electrodes between two or more of which conduction of electricity through the vacuum or contained gas may take place.

NOTE: The term is used in a more restricted sense to mean a device of this nature designed for such use as amplifier, rectifier, modulator, or oscillator.

Gas Tube. A gas tube is a vacuum tube in which the pressure of the contained gas or vapor is such as to affect substantially the electrical characteristics of the tube.

Mercury-vapor Tube. A mercury-vapor tube is a gas tube in which the active contained gas is mercury vapor.

High-vacuum Tube. A high-vacuum tube is a vacuum tube evacuated to such a degree that its electrical characteristics are essentially unaffected by gaseous ionization.

Thermionic Tube. A thermionic tube is a vacuum tube in which one of the electrodes is heated for the purpose of causing electron or ion emission.

Phototube. (Photoelectric Tube.) A phototube is a vacuum tube in which one of the electrodes is irradiated for the purpose of causing electron emission

Cathode-ray Tube. A cathode-ray tube is a vacuum tube in which the electron stream is directed along a confined path to produce non-electrical effects on the object upon which the electrons impinge.

NOTE: This classification includes cathode-ray oscillograph tubes, similar devices for television reception, electron microscopes, etc.

Cathode-ray Oscillograph Tube. A cathode-ray oscillograph tube is a cathode-ray tube in which the movement of an electron beam, deflected by means of applied electric and/or magnetic fields, indicates the instantaneous values of the actuating voltages and/or currents.

Diode. A diode is a two-electrode vacuum tube containing an anode and a cathode.

Triode. A triode is a three-electrode vacuum tube containing an anode, a cathode, and a control electrode.

Tetrode. A tetrode is a four-electrode vacuum tube containing an anode, a cathode, a control electrode, and one additional electrode ordinarily in the nature of a grid.

Pentode. A pentode is a five-electrode vacuum tube containing an anode, a cathode, a control electrode, and two additional electrodes ordinarily in the nature of grids.

Hexode. A hexode is a six-electrode vacuum tube containing an anode, a cathode, a control electrode, and three additional electrodes ordinarily in the nature of grids.

Heptode. A heptode is a seven-electrode vacuum tube containing an anode, a cathode, a control electrode, and four additional electrodes ordinarily in the nature of grids.

Octode. An octode is an eight-electrode vacuum tube containing an anode, a cathode, a control electrode, and five additional electrodes ordinarily in the nature of grids.

Multiple-unit Tube. A multiple-unit tube is a vacuum tube containing within one envelope two or more groups of electrodes associated with independent electron streams.

NOTE: A multiple-unit tube may be so indicated, as, for example; duodiode, duotriode, diode-pentode, duodiode-triode, duodiode-pentode, and triode-pentode.

Cathode. A cathode is an electrode which is the primary source of an electron stream.

Filament. A filament is a cathode of a thermionic tube, usually in the form of a wire or ribbon, to which heat may be supplied by passing current through it.

Indirectly Heated Cathode. (Equipotential Cathode, Unipotential Cathode.) An indirectly heated cathode is a cathode of a thermionic tube to which heat may be supplied by an independent heater element.

Heater. A heater is an electric heating element for supplying heat to an indirectly heated cathode.

Control Electrode. A control electrode is an electrode on which a voltage is impressed to vary the current flowing between two or more other electrodes.

Grid. A grid is an electrode having one or more openings through which electrons or ions may pass.

Space-charge Grid. A space-charge grid is a grid which is placed adjacent to the cathode and positively biased so as to reduce the limiting effect of space charge on the current through the tube.

Control Grid. A control grid is a grid, ordinarily placed between the cathode and the anode, for use as a control electrode.

Screen Grid. A screen grid is a grid placed between a control grid and an anode, and usually maintained at a fixed positive potential, for the purpose of reducing the electrostatic influence of the anode in the space between the screen grid and the cathode.

Suppressor Grid. A suppressor grid is a grid which is interposed between two electrodes (usually the screen grid and plate), both positive with respect to the cathode, in order to prevent the passing of secondary electrons from one to the other.

Anode. An anode is an electrode to which a principal electron stream flows.

Plate. Plate is a common name for the principal anode in a vacuum tube.

Electron Emission. Electron emission is the liberation of electrons from an electrode into the surrounding space. Quantitatively, it is the rate at which electrons are emitted from an electrode.

Thermionic Emission. Thermionic emission is electron or ion emission due directly to the temperature of the emitter.

Secondary Emission. Secondary emission is electron emission due directly to the impact of electrons or ions.

Grid Emission. Grid emission is electron or ion emission from a grid.

Emission Characteristic. An emission characteristic is a relation, usually shown by a graph, between the emission and a factor controlling the emission (as temperature, voltage, or current of the filament or heater).

Cathode Current. Cathode current is the total current passing to or from the cathode through the vacuous space.

NOTE: This term should be carefully distinguished from heater current and filament current.

Filament Current. Filament current is the current supplied to a filament to heat it.

Filament Voltage. Filament voltage is the voltage between the terminals of a filament.

Heater Current. Heater current is the current flowing through a heater.

Heater Voltage. Heater voltage is the voltage between the terminals of a heater.

Grid Current. Grid current is the current passing from or to a grid through the vacuous space.

Grid Voltage. Grid voltage is the voltage between a grid and a specified point of the cathode.

Grid Bias. Grid bias is the direct component of grid voltage.

Grid Driving Power. Grid driving power is the integral of the product of the instantaneous values of the alternating components of the grid current and voltage over a complete cycle.

Anode Current. (Plate Current.) Anode current is the current passing to or from an anode through the vacuous space.

Anode Voltage. (Plate Voltage.) Anode voltage is the voltage between an anode and a specified point of the cathode.

Peak (or Crest) Forward Anode Voltage. Peak (or crest) forward anode voltage is the maximum instantaneous anode voltage in the direction in which the tube is designed to pass current.

Peak (or Crest) Inverse Anode Voltage. The peak (or crest) inverse anode voltage is the maximum instantaneous anode voltage in the direction opposite to that in which the tube is designed to pass current.

Tube Voltage Drop. Tube voltage drop in a gas- or vapor-filled tube is the anode voltage during the conducting period.

Anode Dissipation. Anode dissipation is the power dissipated in the form of heat by an anode as a result of electron and/or ion bombardment.

Gas Current. A gas current is a current flowing to an electrode and composed of positive ions which have been produced as a result of gas ionization by an electron current flowing between other electrodes.

Leakage Current. A leakage current is a current which flows between two or more electrodes by any other path than across the vacuous space.

Electrode Conductance. (Variational.) Electrode conductance is the ratio of the in-phase component of the electrode alternating current to the electrode alternating voltage, all other electrode voltages being maintained constant.

NOTE: As most precisely used, the term refers to infinitesimal amplitudes.

Electrode Resistance. (Variational.) Electrode resistance is the reciprocal of the electrode conductance.

Electrode Admittance. Electrode admittance is the ratio of the alternating component of the electrode current to the alternating component of the electrode voltage, all other electrode voltages being maintained constant.

NOTE: As most precisely used, the term refers to infinitesimal amplitudes.

Electrode Impedance. Electrode impedance is the reciprocal of the electrode admittance.

Transadmittance. Transadmittance between two electrodes is the ratio of the alternating component of the current of one electrode to the alternating component of the voltage of the other electrode, all other electrode voltages being maintained constant.

NOTE: As most precisely used, the term refers to infinitesimal amplitudes.

Transconductance. Transconductance between two electrodes is the ratio of the in-phase component of the alternating current of one electrode to the alternating voltage of the other electrode, all other electrode voltages being maintained constant.

NOTE: As most precisely used, the term refers to infinitesimal amplitudes.

Control-grid—Plate Transconductance. (Transconductance, Mutual Conductance.) Control-grid—plate transconductance is the name for the plate-current to control-grid voltage transconductance.

Conversion Transconductance. Conversion transconductance is the ratio of the magnitude of a single beat-frequency component $(f_1 + f_2)$ or $(f_1 - f_2)$, of the output electrode current to the magnitude of the control electrode voltage of frequency f_1 under the conditions that all direct electrode voltages and the magnitude of the electrode alternating voltage f_2 remain constant.

NOTE: As most precisely used, the term refers to an infinitesimal magnitude of the voltage of frequency f_1.

Mu Factor. The mu factor is the ratio of the change in one electrode voltage to the change in another electrode voltage, under the conditions that a specified current remains unchanged and that all other electrode voltages are maintained constant. It is a measure of the relative effect of the voltages of two electrodes on the current in the circuit of any specified electrode.

NOTE: As most precisely used, the term refers to infinitesimal changes.

Amplification Factor. The amplification factor is the ratio of the change in plate voltage to a change in control-electrode voltage, under the conditions that the plate current remains unchanged and that all other electrode voltages are maintained constant. It is a measure of the effectiveness of the control-electrode voltage relative to that of the plate voltage on the plate current. The sense is usually taken as positive when the voltages are changed in opposite directions.

NOTE: As most precisely used, the term refers to infinitesimal changes. *See also* Mu Factor.

Electrode Characteristic. An electrode characteristic is a relation, usually shown by a graph, between an electrode voltage and current, other electrode voltages being maintained constant.

Transfer Characteristic. A transfer characteristic is a relation, usually shown by a graph, between one electrode voltage and another electrode current.

Interelectrode Capacitance. Interelectrode capacitance is the direct capacitance between two electrodes.

Electrode Capacitance. Electrode capacitance is the capacitance of one electrode to all other electrodes connected together.

Input Capacitance. The input capacitance of a vacuum tube is the sum of the direct capacitances between the control grid and cathode and such other electrodes as are operated at the alternating potential of the cathode.

Output Capacitance. The output capacitance of a vacuum tube is the sum of the direct capacitances between the output electrode (usually the plate) and the cathode and such other electrodes as are operated at the alternating potential of the cathode.

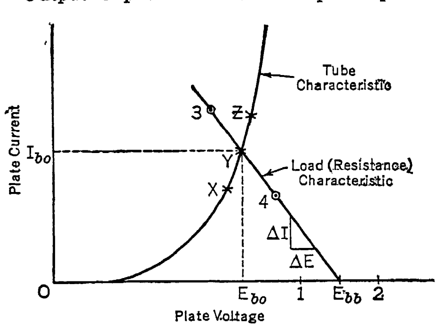

FIG. 1. Tube and Load Characteristics

QUIESCENT POINT AND OPERATING RANGE. The *quiescent point* is the point on the plate characteristic that represents operating conditions with no signal applied to the grid. With a load in the plate circuit, it may be determined as follows. For a load resistance of r ohms the slope of the load characteristic line is $1/r = -\Delta I/\Delta E$, drawn from the point E_{bb} (Fig. 1) corresponding to the plate supply voltage. The intersection y of the two characteristic curves is the quiescent operating point, giving a plate voltage of E_{bo} and a plate current of I_{bo}.

The plate supply voltage E_{bb} is divided into the voltage drop across the tube, E_{bo}, and the voltage drop across the load, $E_{bb} - E_{bo}$.

When the plate supply voltage is varied over the range 1 to 2, the load resistance line will shift parallel to the position shown and over the *operating range* 1 to 2. The intersections of the load line with the tube characteristic determine the corresponding variation in E_{bo} and I_{bo}.

When the plate supply voltage is constant but the tube characteristic is changed, for example by changing the grid voltage, the intersection of the characteristics for the changed values of grid voltage with the load line determines the change in I_{bo} and E_{bo}.

In Fig. 1 a voltage in the grid circuit changes the characteristic curve so that it intersects the load line at points 3 or 4. The projections of these points on the two axes show the change in I_{bo} and E_{bo}.

The tube characteristic, unlike the load characteristic, cannot be shifted parallel to the initial position to represent other operating conditions, since it usually changes shape. The tube characteristics should be known for a few voltages throughout the range of operation. Intermediate values may be interpolated.

A-C EQUIVALENT CIRCUIT. In the circuit of Fig. 2 the a-c voltage E_g in the grid circuit produces an a-c plate current I_p and an a-c plate voltage E_p. For small a-c voltages

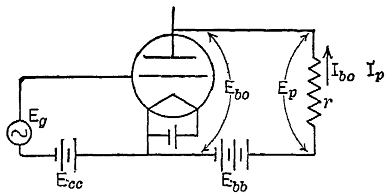

FIG. 2. Triode with Resistance Load

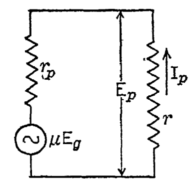

FIG. 3. Equivalent A-c Circuit of Tube with Resistance Load

the tube is equivalent to a generator with an internally generated voltage μE_g and internal resistance r_p. Figure 3 is the *a-c equivalent* of the circuit in Fig. 2.

From Fig. 3 the *a-c plate current* is

$$I_p = \frac{\mu E_g}{r_p + r} \tag{3}$$

The *a-c plate voltage* is

$$E_p = I_p r = \mu E_g \frac{r}{r_p + r} \tag{4}$$

The *voltage amplification* is

$$A = \frac{E_p}{E_g} = \frac{\mu r}{r_p + r} \tag{5}$$

The *power output* of the tube is

$$P_o = E_p \cdot I_p = \frac{(\mu E_g)^2 r}{(r_p + r)^2} \tag{6}$$

Figure 4 illustrates an a-c equivalent of the circuit of Fig. 2 in which the tube is represented as a *generator of constant current* $I = g_m E_g$.

The *a-c plate voltage* is

$$E_p = I \frac{r_p r}{r_p + r} = (g_m E_g) \frac{r_p r}{r_p + r} \tag{7}$$

The *a-c plate current* is

$$I_p = \frac{E_p}{r} = g_m E_g \left(\frac{r_p}{r_p + r}\right) \tag{8}$$

The constant-current form of representation is convenient for calculation when the load consists of a number of parallel elements or when the plate resistance of the tube is high and $r_p/(r_p + r)$ approaches unity.

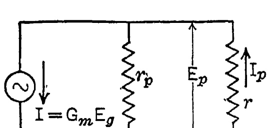

FIG. 4. Equivalent A-c Circuit of Tube with Resistance Load.

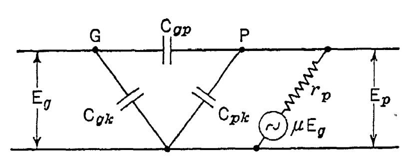

FIG. 5. Equivalent Circuit of Triode

When the tube is amplifying a-c voltages at frequencies at which the *capacitances of tube electrodes, socket, and wiring are not negligible* the equivalent a-c circuit is as shown in Fig. 5.

The capacitances marked C_{gp}, C_{gk}, C_{pk} represent the grid-plate, grid-cathode, and plate-cathode capacitances (see Section 5, Article 25). Any socket and wiring capacitances can be added in parallel. In screen-grid and other multielectrode tubes where the additional electrodes are grounded the circuit reduces to an equivalent-triode network similar to Fig. 3.

BALLAST TUBES AND VOLTAGE REGULATORS. A *ballast tube* is used as a series resistance to limit the load current. It is designed for a definite current and voltage drop. Over the useful portion of its characteristic a large change in voltage accompanies a small change in current. As a result of this characteristic a large part of any line-voltage change is absorbed by the ballast tube and a relatively small change occurs at the load.

In reading data for the characteristic curves, it may be necessary to allow a few minutes after each change in voltage for the tube to reach its temperature equilibrium condition.

The performance may be determined graphically by a method similar to that described for determining the quiescent operating point by plotting the line for a resistance load with the experimentally determined current-voltage characteristic of the ballast tube.

A *voltage-regulator tube* is operated in parallel with the load. Its characteristic shows a large change in current for a small change in voltage near the operating point. When connected in parallel with the load with a suitable resistance effective in the supply voltage source any change in the supply voltage will cause a change in the current in the voltage-regulator tube such that the voltage across the regulator tube and load remains practically constant.

The voltage-regulator tube is designed for a definite voltage and is operated between specified minimum and maximum current limits. A certain *starting voltage* somewhat higher than the operating voltage is required.

The operating characteristics are most conveniently obtained in a normal operating circuit.

4. METHODS OF MEASURING TUBE CURRENTS AND PARAMETERS

The characteristic relations between the direct voltages and currents of the electrodes of a tube may be obtained in a *static-characteristic measuring circuit* arranged as in Fig. 6.

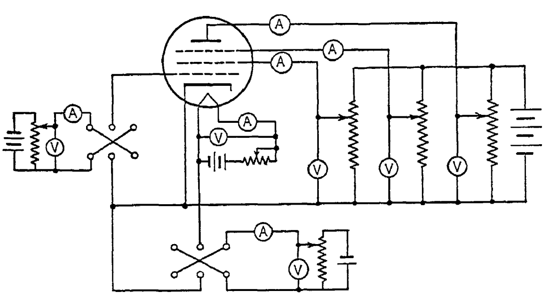

FIG. 6. Circuit for Measuring Static Characteristics

The voltages applied to the different electrodes as illustrated are measured from a *unipotential cathode.* If the tube has a *filamentary cathode* it is understood that, when operating with *direct-current filament supply* such as when measuring static characteristics, the electrode voltages are measured from the negative filament terminal. With *alternating-current* operation of a filamentary cathode, the center of the filament is used as the datum of potential and the electrode voltages are corrected for one-half of the filament voltage. Ordinarily only the control-grid bias voltage is made more negative by approximately one-half of the peak alternating voltage on the filament.

FILAMENT OR HEATER CHARACTERISTIC. The *filament* or *heater current* is obtained for several values of filament or heater voltage ranging from values producing temperatures too low to give appreciable electron emission to values producing the maximum safe operating temperature. The other electrodes should be at zero voltage.

The curves are plotted with filament or heater voltage as abscissas and filament or heater current and power as ordinates.

CATHODE HEATING TIME. The *cathode heating time* is defined for purposes of measurement as the interval from the time of application of filament or heater voltage to the time at which the rate of increase of plate current is a maximum.

If the primary winding of a transformer is connected in the plate circuit and a meter is connected to the secondary winding, then the instant at which the rate of increase of plate current is a maximum is indicated by a maximum reading on the meter.

The voltage at the terminals of the filament or heater should remain constant at the rated or specified value.

Because of the very slow rate of change of plate current in the usual tube, the characteristics of the transformer or meter do not greatly influence the result. A step-down transformer and a current meter which is sufficiently damped though not too sluggish are suitable.

EMISSION CHARACTERISTIC. The *emission characteristic* shows the emission current plotted as a function of the cathode heating power.

The readings are obtained with all electrodes, except the cathode, connected together as the anode and with sufficient positive voltage applied to the electrodes to draw the entire emission current from the cathode. Since the emission current at normal filament power may be so great as to damage the tube, readings are taken at lower filament powers

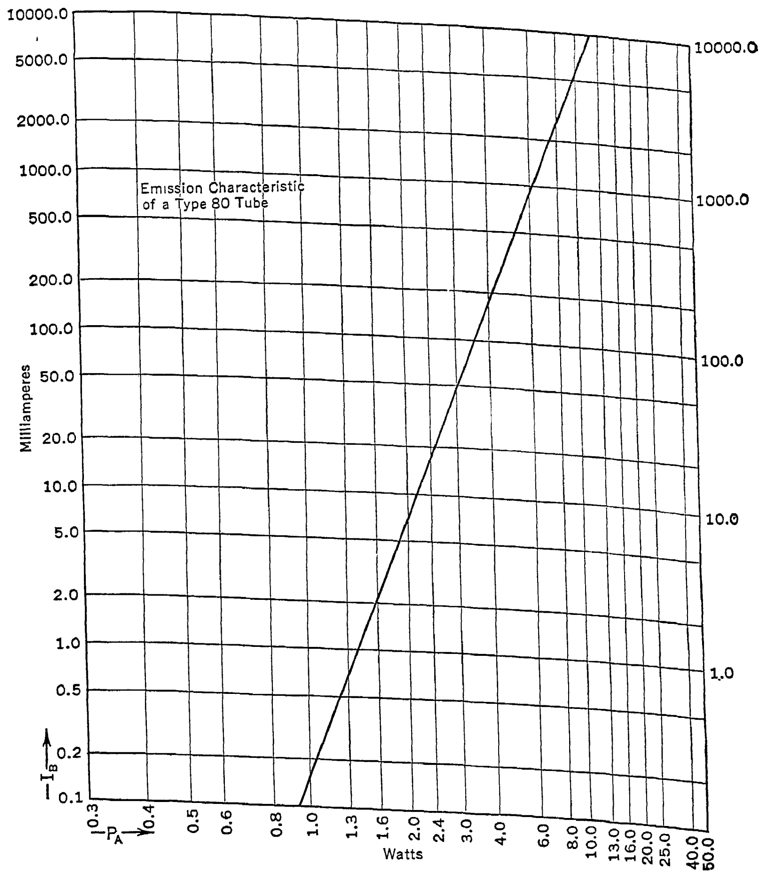

FIG. 7. Emission Characteristic

only, and normal emission current is obtained by *extrapolation.* A suitable procedure is as follows, the values applying to ordinary receiving tubes. Readings of cathode heating power are taken with emission currents of 0.1, 0.2, 0.5, 1.0, 2.0, and 5.0 ma, with 45 volts positive applied to the anode. The results are plotted in *Davisson coordinates* (see Fig. 7), which are a special system of curvilinear coordinates. If the emission follows *Richardson's temperature law* and the cathode cooling follows the *Stefan-Boltzmann law* of radiation, the characteristic will be a straight line when plotted in these coordinates. The observed points may be extended or extrapolated to obtain the emission at normal filament power.

The emission characteristic for a type-80 tube plotted according to the above procedure is shown in Fig. 7.

If the curve of the experimental data plotted in Davisson coordinates is *not a straight line* this may be due to one or more of the following conditions:

1. Departure from the Stefan-Boltzmann cooling (bends downward).
2. Anode voltage too low to draw off all the electrons (bends downward).

3. Effect of cooling due to heat of evaporation of electrons (bends downward). The cooling due to electron evaporation amounts to approximately ϕI_s watts, where I_s represents the emission current in amperes and ϕ represents the work function of the cathode in volts. This effect may be considerable in transmitting tubes where the currents are high and in tungsten-filament tubes where the work function is large.

4. Poor vacuum (gas ionization effects) (bends upward).

5. Heating of the anode by the emission current (bends upward).

6. Progressive change in activity of the cathode.

Reliable analytical data cannot be obtained by this method when these extraneous effects are appreciable.

ELECTRON EMISSION. Normal *electron emission* is determined with the filament voltage adjusted to the normal rated value.

All electrodes in the tube, except the cathode and heater, are connected together, and a sufficiently positive voltage with respect to the cathode is applied to them to obtain practically the full electron emission.

For *power-type tubes* this test is not advisable on account of possible damage to the tube. The method of extrapolation described under Emission Characteristic should be used.

For *receiving-type tubes* a check on the emissive condition of the cathode can usually be made safely if the time of application of the voltage is not permitted to exceed that required for rapid reading of the emission current meter. An anode voltage of about 45 volts is used.

Since this test usually results in the liberation of gas and abnormal heating of the electrodes, it should be postponed until after the completion of other tests, or a sufficient time should elapse between this and other tests for clean-up and return to normal temperature conditions.

For tubes with extremely low cathode heating power, such as the oxide-coated low-filament-current types 1R5, 1S4, 1T4, etc., this test is neither reliable nor safe for the tube. In *checking the emission* of tubes of this type a low filament voltage is applied and gradually increased until a specified emission (less than normal for the particular type of tube, usually 3 to 5 ma) is obtained. The filament voltage required to obtain the specified emission is an indirect measure of the cathode or filament activity. This is an arbitrary method suitable for comparing tubes of the same type.

In general a *safe method for reading emission* under all different conditions consists in using a rotating contactor to apply the voltage for only a small fraction of the time. An oscillograph is used to read the emission current which flows during the small interval of time that the voltage is applied.

GRID CHARACTERISTIC. A *grid characteristic curve* shows the current in a grid electrode as a function of the voltage on this electrode. The voltage on all the remaining electrodes is held constant. A *family of curves* is obtained by using a different value of voltage on one of the remaining electrodes for each curve.

The grid characteristic used most frequently is that of the control grid with the plate voltage as the parameter for the several curves.

In reading data for the curves the current should not be allowed to flow long enough to cause abnormal heating of the grid. The readings should be taken near enough together to show any irregularities due to secondary emission or gas.

IONIZATION, LEAKAGE, AND STRAY EMISSION CURRENTS. In vacuum tubes the normally small currents due to *ionization*, *leakage*, and *electron emission* from electrodes other than the cathode, although usually negligible in the plate and other current-carrying electrodes, may have an appreciable effect in the control-grid circuit of the tube.

The total current flowing to the negatively biased control grid may be divided into components as follows:

1. Electrons from the cathode which reach the grid by virtue of *contact potential and initial velocities*.
2. Electrons from other electrodes to the control grid.
3. *Ionization current.*
4. *Leakage current.*
5. *Electron emission* from the control grid.

Figure 8 illustrates the contributions of the various sources enumerated with the exception of 2, which is generally negligible.

The several components may be separated and measured by the following methods.

The *leakage current* is measured with a direct voltage applied between any two electrodes and without any connections on the other electrodes. The tube should be operated with normal voltages and currents until all parts have reached full operating temperature. The filament voltage is then disconnected and the leakage currents read while the insulation is at normal operating temperature. The tube should be complete with its base but without socket or holder. The test voltage should be specified. Normal maximum operating voltage is preferable.

If any of the electrodes remain hot enough to emit electrons an error will be introduced into the leakage readings.

The *grid emission* can be measured by noting the current at a bias sufficiently negative (point A in the figure) to stop the plate current, since at this point (A) the ionization current (3), being proportional to the plate current, is negligible.

The grid emission is found by subtracting the leakage current from the grid current at the point A. If the leakage current is negligible the test gives the grid emission directly.

A *direct measurement of grid emission* can be made (when leakage current is negligible) by connecting the test voltage between the grid and plate without any connection to the cathode. The positive voltage on the plate draws the electrons emitted by the grid. The cathode should be at its normal operating temperature. The tube should be operated with normal operating voltages for a time preceding this test, and then quickly switched to the emission test circuit and grid emission noted while the electrodes are still approximately at their normal temperatures.

The *ionization current* (3) is the difference between the total grid current and the sum of the leakage (4) and emission (5) currents in the range of grid bias over which this difference is proportional to the plate current. Departure from this proportionality indicates the start of electron current (1) to the grid.

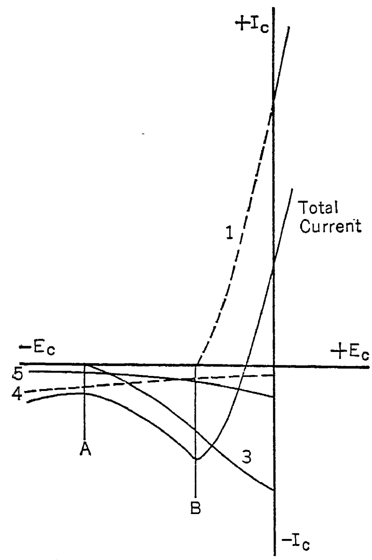

FIG. 8. Stray Electron Currents

PLATE CHARACTERISTIC. The *plate characteristic* gives the plate current as a function of the plate voltage, the voltages on the other electrodes being held constant. A family of curves may be obtained by using a series of voltages on one of the other electrodes. A series of control-grid voltages is ordinarily used for the different curves. For examples see Figs. 21, 24, and 27.

The data for the curves are read in the static characteristic test circuit. For the range of currents and voltages beyond the normal average values, it is sometimes necessary to employ a method which is rapid enough to avoid heating of the electrodes. When a well-regulated voltage source is available the voltages may be set to the desired values and a switch closed only long enough for rapidly reading the current on a suitably damped meter.

GRID-PLATE CHARACTERISTIC. The *grid-plate characteristic* or *transfer characteristic* gives the plate current vs. grid voltage for the condition of constant voltage on the remaining electrodes. Such a transfer characteristic may be taken for any of the grids of a multigrid tube. The curves generally used show the control-grid voltage as abscissa and plate current as ordinate, several curves being plotted each for a different plate voltage. See for examples Figs. 22, 25, and 29.

The data for the curves are obtained in the static-characteristic test circuit, the same precautions being observed as in reading data for plate characteristics.

CONDUCTANCE. The *conductance* of an electrode may be obtained from the characteristic curve showing the electrode current vs. the electrode voltage. The slope of this curve at any point gives the electrode conductance at the voltages represented by the point. The accuracy of the measurement as determined in this way from the static characteristics may be made as good as desired by reading small current and voltage increments with sufficient accuracy.

The *electrode resistance* is the reciprocal of the conductance. For example, the *plate resistance* is the reciprocal of the plate conductance, the *grid resistance* is the reciprocal of the grid conductance, etc.

When many readings are to be made, a method of *direct measurement* is most convenient. One means might be to read the alternating current produced by a small alternating voltage in the circuit. In general a *Wheatstone bridge circuit* is preferred as shown in Fig. 9.

In this circuit a small alternating voltage (about 0.5 volt, 1000 cps) is applied to terminals 1–3 of the bridge. The electrodes being measured are connected to terminals 1–2, and the bridge is balanced with r_2 for minimum sound in the telephone receivers. The *conductance* of the electrode j is given by

$$g_j = \frac{r_2}{r_1 r_3} \tag{9}$$

If the receivers are preceded by an amplifier the alternating input voltage may be kept small enough so that the measurements are independent of the magnitude of this voltage.

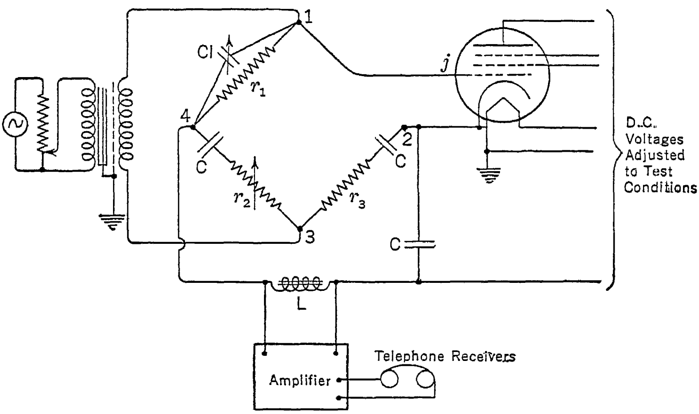

FIG. 9. Conductance Measurement Circuit

This also reduces any harmonics produced by non-linearity of the characteristic. The *stray capacitances* of the wiring and parts of the bridge should be kept low or balanced by a suitable arrangement of parts. A variable capacitance C_1 connected across r_1 can be used to balance different *tube capacitances.*

The *voltage drop in the bridge* circuit should be taken into account in determining the electrode voltage of the tube. The inductance L provides a low d-c resistance path across the amplifier. The blocking condensers C keep the direct current in a path of constant resistance which simplifies the correction.

TRANSCONDUCTANCE. The *transconductance* is a measure of the change in current in one electrode produced by a voltage on another electrode. In a tube having several electrodes the transconductance may be measured between any two electrode circuits,

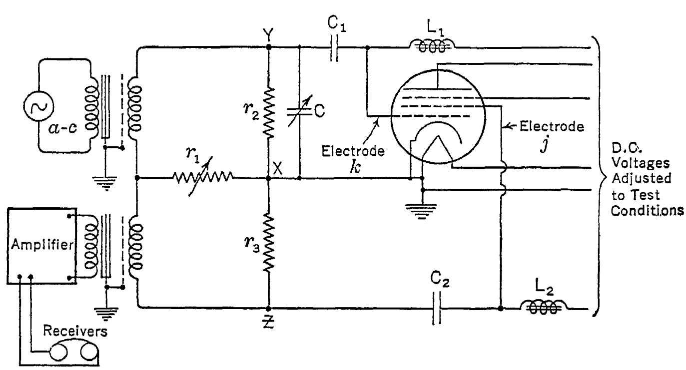

FIG. 10. Transconductance Measurement Circuit

the cathode being common to both circuits. For example, the grid-plate transconductance, or *mutual conductance,* may be determined from the curves for the grid-plate transfer characteristic since this shows the plate current vs. grid voltage. The slope of this curve at a certain point gives the transconductance at the voltages represented by the point.

The transconductance may be *measured directly* by means of the circuit of Fig. 10. An alternating voltage as small as convenient is applied in this circuit, and the resistor r_1 is adjusted for minimum sound in the receivers. The stray capacitances due to the wiring and the tube may be balanced by means of the condenser C connected either between points X–Y or X–Z as determined by trial. The direct voltages are supplied to the electrodes through the choke coils L_1 and L_2. The reactance of the choke coils at the frequency of the applied alternating voltage should be large with respect to r_2 and r_3. If the resistances of the choke coils cause an appreciable drop in direct voltage the electrode voltages should be corrected accordingly.

At balance the *transconductance* is given by

$$g_{jk} = \frac{r_1}{r_2 r_3} \tag{10}$$

This relation assumes that the *electrode conductance* is negligible. If the conductance of electrode j is $1/r_j$ and that of k is $1/r_k$ the transconductance is given by

$$g_{jk} = \frac{r_1}{r_2 r_3} \frac{(r_k + r_2)}{r_k} \cdot \frac{(r_j + r_3)}{r_j} \tag{11}$$

The following circuit constants will cover a range of transconductance from 1 micromho to 10,000 micromhos.

$r_1 = 10 \times 0.1$ ohm		$r_2 = 1000$ ohms
$10 \times 1.$ ohm		
$10 \times 10.$ ohms		$r_3 = 100$ ohms
$10 \times 100.$ ohms		

With L_1 equal to 50 henrys and L_2 equal to 10 henrys and a 1000 cps alternating voltage the error in using the simplified equation will be less than 2 per cent if r_j and r_k are greater than 10,000 ohms and 100,000 ohms, respectively.

MU FACTOR. The *mu factor* is the ratio of the voltages in two electrode circuits required to maintain constant current in the circuit of any specified electrode. It may be determined from the static characteristic curves or measured by a balance method. For example, the *amplification factor* is a special case in which the control-grid voltage and plate voltage are changed in such a way as to maintain constant plate current.

In the circuit of Fig. 11 the electrode in which the current is to be held constant is connected to point A. The other two electrodes entering directly in the measurement

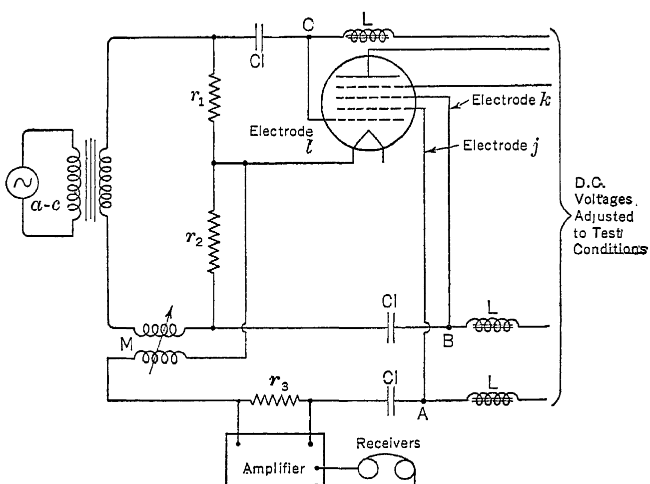

FIG. 11. Mu Factor Measurement Circuit

are connected to points B and C. When r_1 and r_2 and M are adjusted for minimum sound in the telephone receivers, the *mu factor* is given by

$$\mu_{jkl} = \frac{r_2}{r_1}$$

The direct voltages to the electrodes under test may be supplied through choke coils L having a reactance at the frequency of the alternating voltage which is high with respect to the resistances r_1, r_2, and r_3. The resistances of the chokes should be low enough to cause negligible loss in direct voltage or the true electrode voltage determined by subtracting the loss. If the *electrode conductances* are not negligible in comparison with r_1, r_2, and r_3 a correction should be made for this.

INTERELECTRODE CAPACITANCE. The *capacitance between the electrodes* of a tube may be measured in various ways. It is preferable to read the *direct capacitance* between any two electrodes rather than the *total capacitance* between an electrode and all other electrodes. The readings are normally made with the tube *cold* and no direct voltages applied. When the tube is *heated* the capacitance changes a small amount owing to the presence of space charge, but the change is ordinarily negligible. The tube should be complete with base, though the socket capacitance is not included in the measurement. For most reliable results, readings should not be taken with any electrodes disconnected, and the tube should be mounted in a specified way with respect to any shields. For *indirectly heated types* the filament and cathode should be tied together.

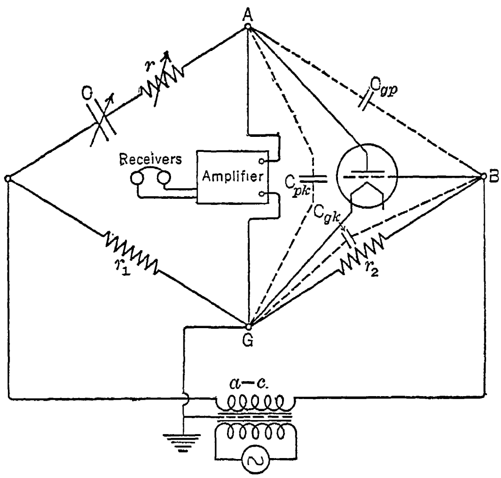

FIG. 12. Electrode Capacitance Measurement Circuit

A *bridge method* for the measurement of *direct interelectrode capacitance* in a *triode* is shown in Fig. 12. The capacitance to be measured is connected to the terminals *A–B*. The figure shows the grid-plate capacitance C_{gp} connected for measurement. The effect of the grid-cathode capacitance C_{gk} in the circuit across r_2 is ordinarily negligible owing to the low resistance of r_2. The plate-cathode capacitance C_{pk} is across the amplifier and telephone receivers, which does not affect the balance. The standard capacitance C and resistance r are adjusted for minimum sound in the receivers. When the bridge is balanced the capacitance is

$$C_x \equiv C_{gp} = \frac{r_1 C}{r_2} \tag{12}$$

An error in the reading may result if appreciable *leakage resistance* exists across C_x.

5. VACUUM-TUBE OPERATION

ELECTRON TRANSIT TIMES AND INERTIA EFFECT. Since the single electron has a mass of 9.035×10^{-28} gram there will be a force acting on the electron in the presence of an electric field which is proportional to the product of the field strength and the electron unit of charge. This force will accelerate the electron, giving it finite velocities. If the electron has started from rest and attains final velocities much smaller than the speed of light, the velocity in practical units may be expressed as

$$v = 5.95 \times 10^7 \sqrt{V} \quad \text{cm per sec}$$

where V is in volts. It is common practice to express the velocity of an electron in terms of the voltage in the above expression instead of the usual centimeters per second.

If, however, the velocity of the electron has been accelerated to velocities not negligible compared to the speed of light, c, which is 3×10^{10} cm per sec, the mass of the electron, m, will increase in the ratio

$$\frac{m}{m_e} = 1.96 \times 10^{-6}V + [(1.96 \times 10^{-6}V)^2 + 1]^{1/2} \tag{13}$$

where m_e is the mass of the electron at rest. At 100,000 volts the increase in mass is about 22 per cent, whereas at 1000 volts the increase is only about 0.2 per cent. At very high voltages, therefore, the velocity of an electron will be less than the above expression by the square root of m_e/m, the resulting velocity being

$$v = 5.95 \times 10^7 \sqrt{V \frac{m_e}{m}} \quad \text{cm per sec} \tag{14}$$

The transit time of an electron becomes of importance at very high frequencies and as would be expected depends upon the electron velocity expressed at some convenient point and the distance it has traveled. The constant K in the following expressions is a factor taking into account the geometry of the electric field and the effect of space charge, if present, on the electric field. For all the cases where the electron has been assumed to start with zero velocity the transit time, τ, is

$$\tau = \frac{KD}{5.95 \times 10^7} \times \frac{1}{\sqrt{V}} \quad \text{sec} \tag{15}$$

where D, in centimeters, is the distance traveled from rest to the point of voltage V, in volts. The dimensionless constant K has the following values: $K = 1$ for a field-free space; $K = 2$ for field between parallel planes without space charge; $K = 3$ for field between parallel planes with space charge.

For concentric cylinders the values of K are given in Fig. 13. The A and B curves are for the usual case where the higher voltage is on the outside cylinder (the cathode being

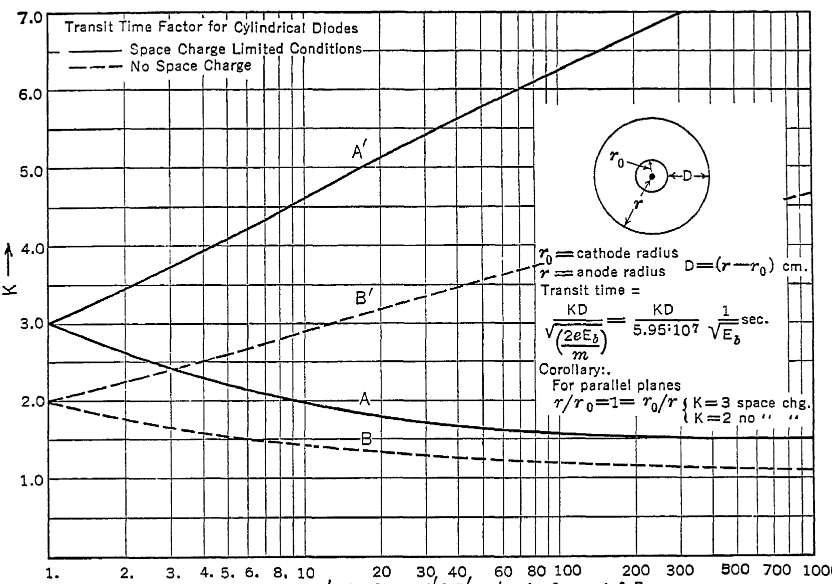

FIG. 13. Electron-transit Time for an Electron Starting with Zero Initial Velocity. Chart Includes Cylindrical and Parallel Plane Structures in an Electric Field with and without Space Charge. (Courtesy *RCA Review*.)

the inner one); the A' and B' curves are for the case where the positive voltage is on the inner cylinder.

In many cases one is interested in the transit time when the electron is not starting from rest, as, for example, for the electron transit from the control grid to the screen grid region of a pentode. For this case

$$\tau = \frac{KD}{5.95 \times 10^7} \times \frac{1}{\sqrt{V_1}} \frac{1}{\sqrt{V_2/V_1} + 1} \quad \text{sec} \tag{16}$$

where K and D are defined as before, V_1 and V_2 are the voltages of the two points between which the electron is passing, and $V_2 > V_1$.

THE INPUT ADMITTANCE OF VACUUM TUBES. The input admittance of negative-grid-controlled vacuum tubes may have deleterious effects especially at high frequencies. Its conductive component is, to a first order, proportional to the square of the input-signal frequency. Being a power-absorbing element it will thus broaden the frequency-response characteristic of the input circuit and lower the anticipated gain of the preceding stage. Furthermore, it also varies with the tube transconductance or tube gain. The reactive component of admittance is fortunately independent of frequency, but unfortunately it varies with the tube transconductance. For a triode or a pentode radio-frequency amplifier the effect is to increase the input capacitance of the tube in the order of 1 to 2 $\mu\mu$f as the tube gain is varied from cutoff to its maximum value. At low frequencies this small capacitance change is made negligible by padding the input circuit with a sufficiently large fixed capacitance, but at high frequencies this precaution is impractical. These admittance variations which change with the tube transconductance may be greatly reduced by the use of an unbypassed cathode resistor so positioned that it will be common to both the input and output circuits of the tube.

The input conductance, g_g, of a vacuum tube consists essentially of two components. One of these components, g_t, has its origin in the electron-transit time phenomena, and the other, g_L, has its origin in that portion of the cathode-lead inductance which is common to both the input and the output terminals of the vacuum tube. Quantitatively the transit-time loading, g_t, as determined by D. O. North is

$$g_t = \frac{4\pi^2 f^2 \tau_1^2 g_{1k}}{180}\left\{9 + 44\frac{\tau_2}{\tau_1} + 45\left(\frac{\tau_2}{\tau_1}\right)^2 - 2\frac{\tau_2}{\tau_1}\frac{17 + 35\,(\tau_2/\tau_1)}{1 + (v_p/v_g)} + \frac{20\,(\tau_2/\tau_1)^2}{[1 + (v_p/v_g)]^2}\right\} + \cdots \quad (17)$$

where g_t is the transit time input loading in mhos, g_{1k} is the signal-grid-to-cathode transconductance in mhos, f is the signal frequency in cycles per second, τ_1 is the transit time in seconds for an electron to move from the cathode to the plane of the signal grid, τ_2 is the transit time in seconds for an electron to move from the signal grid plane to the plate, and v_p and v_g are the electron d-c velocities at the plate and grid respectively. It should be noted that for a well-screened tetrode or pentode the transit time, τ_2, and the plate velocity, v_p, are with reference to the screen grid. Also it should be noted that the grid-to-cathode transconductance of a triode is the same as its grid-to-plate transconductance, whereas for a pentode or tetrode the grid-to-cathode transconductance has a value equal to the grid-to-plate transconductance multiplied by the ratio of cathode current to plate current. The last two terms in the brackets of the above expression are only of second order of magnitude in the conventional amplifier tubes since the ratio v_p/v_g is approximately equal to 10. Inspection of this expression further indicates that considerable loading may be contributed to the input circuit by electrons moving in the space between the control grid and plate (or screen grid). As a precaution in using the above relationship, the simplifying assumptions applied for its derivation are listed below.

1. The transit times, τ_1 and τ_2, are small compared to the period, $1/f$.
2. The electrodes are parallel planes.
3. The initial velocity of the emitted electrons is zero and the emission is ample, so that the three-halves power of voltage vs. current holds in the cathode-grid region.
4. The amplification factor of the signal grid is high, so that electrons on one side do not appreciably influence the field on the other side.
5. The grid is an equipotential plane surface.
6. The alternating voltage at the grid is very small with respect to the effective static grid potential.
7. The alternating voltage at the plate (or screen grid) is zero.
8. The potential between grid and plate (or screen grid) is substantially linear and free of space charge.

That part of the input conductance, g_L, which stems from the cathode-lead inductance may be expressed to a first approximation, as shown by J. O. Strutt and Van der Ziel, by

$$g_L = 4\pi^2 f^2 L_k C_{gk} g_{1k} \quad (18)$$

where g_L is the input loading due to cathode-lead inductance in mhos, f is the signal frequency in cycles per second, L_k is the cathode-lead inductance common to both input and output circuits in henrys, C_{gk} is the capacitance between the signal grid and the cathode in farads, and g_{1k} is the signal-grid-to-cathode transconductance in mhos.

Since both the aforementioned components of input loading are proportional to the signal frequency squared and to the tube transconductance, the two effects are therefore impractical to measure separately. It is also difficult to measure the cathode-lead inductance. If one estimates this inductance to be 5 to 10 millimicrohenrys for the glass miniature tubes and 10 to 15 millimicrohenrys for the single-ended metal or loctal tubes where the lower values are used for those tubes having two cathode leads, we find that from 10 per cent to about 35 per cent of the total input loading is contributed by the effect of cathode-lead inductance.

The screen-grid lead inductance, L_{g2}, in a pentode amplifier or tetrode amplifier introduces negative input loading, g_{L2}, which quantitatively is

$$g_{L2} = -4\pi^2 f^2 L_{g2} C_{g1g2} g_{12} \tag{19}$$

where f is the frequency in cycles per second, L_{g2} is the screen-grid lead inductance in henrys, C_{g1g2} is the capacitance between the signal grid and the screen grid in farads, and

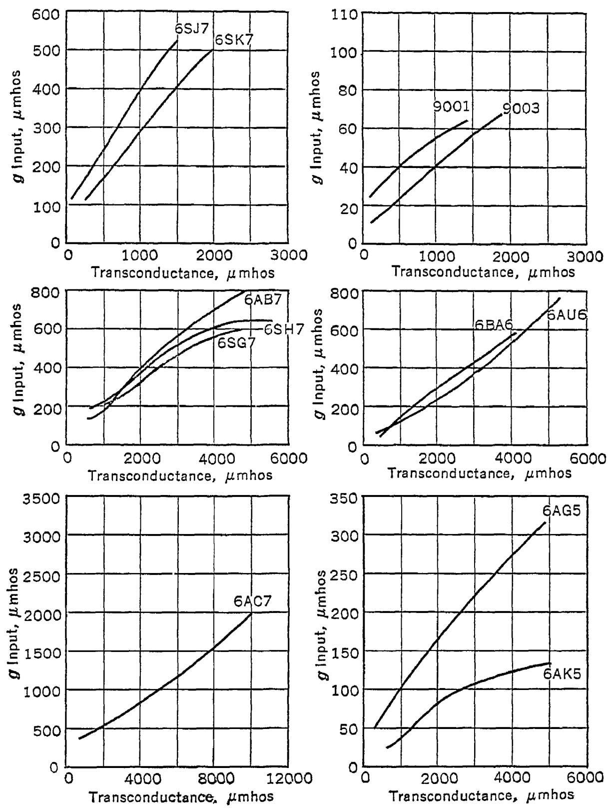

FIG. 14. Input-loading Conductance vs. Grid-plate Transconductance for a Group of R-f Pentode Amplifying Tubes at 100 Mc.

g_{12} is the transconductance from signal to screen grid. This negative loading is small in magnitude compared to the positive loading introduced by the cathode-lead inductance, and for the typical pentode amplifier ($g_{12} \approx 0.2g_{1k}$, $C_{g1g2} < C_{gk}$, and $L_{g2} \approx L_k$) it will reduce the total loading by only a few per cent. If, however, additional inductance is placed in series with the screen lead it should be possible to neutralize the positive input loading completely, with the distinct disadvantage that instability or even parasitic oscillations may be produced in the amplifier stage.

If the static tube voltages are held constant so that the electron-transit times do not vary and the frequency only is varied, we may write the total input loading, g_g, as

$$g_g = g_t + g_L = Kf^2 \tag{20}$$

where, if the g terms are expressed in micromhos and the frequency f in megacycles, the constant K will be in the unit micromhos per megacycle squared. This proportionality factor K is listed in Table 1 for several tube types with the static operating voltages, currents, and signal-grid-to-plate transconductances to which it applies. At frequencies below 25 Mc a conduction term negligible at higher frequencies should be added. This is due to dielectric losses and is proportional to frequency. For single-ended metal tubes this added conduction loss, g_H, is approximately equal to

$$g_H = 0.03f$$

when f is in megacycles and g_H is in micromhos. For the glass miniature and acorn tubes this loss is too small to be measured accurately.

It should be noted that in Table 1 the five entries at the bottom of the list are for mixer or converter use. Those applications where the signal is injected on an outer grid and the local oscillator is injected on the inner grid produce negative loading. In the case of the 6L7, the signal being placed on the grid adjacent to the cathode, positive input loading is produced as in the amplifier applications discussed.

If the grid-plate transconductance is varied from minimum bias to cutoff bias the input loading will vary in proportion to this transconductance and a complicated function of the electron transit times. In Fig. 14 are given in graphical form some measured values of input loading. These data were observed at 100 Mc with the static voltages of Table 1 applied. The grid-plate transconductances were varied by changing the signal-grid bias. To compute the input loading at any frequency, f in megacycles, multiply the loading at 100 Mc by the ratio $(f/100)^2$.

* This is the capacitance between grid and cathode with all voltages applied and grid biased to plate-current cutoff.

† This is the increase in input capacitance as the grid bias is varied from cutoff to the plate current indicated in this table.

‡ Self-excited.

§ Separately excited.

The reactive component of input admittance is essentially capacitative since the reactances due to the lead inductances to the several tube elements are small up to frequencies of the order of 100 Mc. This input capacitance consists, in the typical grid-controlled amplifiers, of the static paralleling capacitances between the signal grid and all grounded elements plus a variable capacitance which is independent of frequency but changes with tube cathode current and therefore varies with the tube gain.

The variable component of input capacitance may be broken down into two components. One known as the Miller effect is due to the grid-plate or feedback capacitance, C_{gp}. With a pure resistance output load in the plate circuit or one tuned to resonance with the signal-input frequency the added input capacitance is

$$C_{\text{input}} = (1 + A)C_{gp} \tag{21}$$

where A is the voltage gain of the stage. In a triode this component may be of the order of 10 to 100 times as large as the other input capacitance components. Since the grid-plate capacitance of a pentode r-f amplifier tube is of the order of 0.001 that of a triode, this Miller effect can be made negligibly small with a properly designed pentode amplifier.

A second source of input-capacitance variation is due to the space charge in the cathode-grid region. Theory predicts that the capacitance between grid and cathode, C_{gk}, should increase by 33 $^1/_3$ per cent when space-charge-limited current flows as compared to no current flow. Measurements show that there is an increase with current flow but not an abrupt one, the difference being due in all probability to the theory's assumptions of simple geometry and zero initial velocity of emitted electrons not being fulfilled. In Fig. 15 are shown graphically the results of measurements of input-capacitance increases

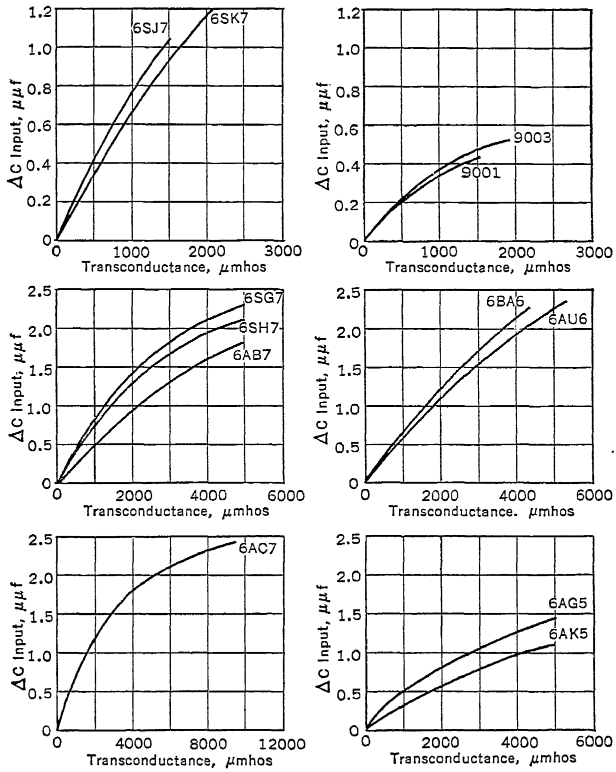

FIG. 15. Increase in Input Capacitance vs. Grid-plate Transconductance for a Group of R-f Pentode Amplifying Tubes

against grid-plate transconductance for a group of typical r-f amplifier pentodes. These measurements were made with the plate grounded to radio frequencies at 100 Mc. Static voltages are as indicated in the previous chart, where the maximum input-capacitance change has also been entered. The transconductance was varied by changing the grid bias.

COMPENSATING FOR INPUT-ADMITTANCE CHANGES. The undesirable changes of input admittance as the gain of an amplifier tube is varied may be made reasonably constant by the introduction of negative feedback through the use of a small unby-passed cathode resistance, r_k. For the input capacitance to have the same value at full transconductance as it has at cutoff, the value of r_k in ohms is given by

$$r_k = \frac{\Delta C_{\text{Input}}}{C_{gk}} \frac{1}{g_{gk}} \tag{22}$$

when C_{gk} is the capacitance at cutoff between grid and cathode, ΔC_{Input} is the increase in input capacitance from cutoff to maximum transconductance, and g_{gk} in mhos is the grid-to-cathode maximum transconductance if the cathode resistance were by-passed with a large capacitor. Both fixed and maximum variational capacitance values are given in Table 1. Note that this compensation holds for any frequency.

For the input conductance to have the same value at cutoff as it has at full gain, the value of the unbypassed cathode resistor, r_k, in ohms is given by

$$r_k = \frac{10^6}{2g_{gk}}\left[-1 + \sqrt{1 + \frac{Kg_{gk}}{\pi^2 C_{gk}^2}}\right] \tag{23}$$

where g_{gk} in micromhos is grid-cathode transconductance, C_{gk} in micromicrofarads is grid-cathode capacitance, and K in micromhos per megacycle squared is the frequency coefficient of input loading. This compensation is also independent of frequency.

Generally r_k will not have the same value for both capacitance and conductance compensation, but practically they are of the same order of magnitude so that correcting for one will usually improve the other. In Fig. 16 are shown graphically the effects on two tube types of adding several different values of r_k.

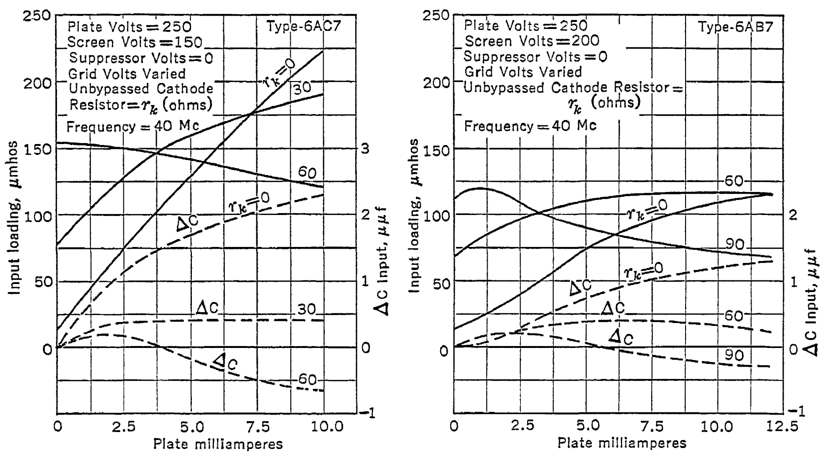

FIG. 16. Input-capacitance Change and Input Loading vs. Plate Current for the 6AB7 and 6AC7 Tubes. (Courtesy *RCA Review*.)

It should be noted that the unbypassed cathode resistance, because it produces degenerative amplification, reduces the gain to $1/(1 + g_{gk}r_k)$ of its value when r_k is by-passed.

NOISE GENERATED IN VACUUM TUBES. The vacuum tube is a noise generator having several possible sources. One important type, known as the "shot effect," stems from the fact that the electron current consists of discrete particles which leave the cathode in a random fashion, producing fluctuation currents uniformly distributed over all frequencies. The "flicker effect" is a low-frequency phenomenon caused by small emitting areas of the cathode constantly changing their emission characteristics. This effect is small compared to the shot effect. In tubes having more than one collector element, such as the screen and plate of a pentode, the random division of current produces uniform noise currents over the whole frequency spectrum of a tube's output or plate current. Other sources are positive-ion-emission currents, positive-ion currents produced as the result of gas ionization, and secondary-electron emission. In the low-frequency region may also be found microphonics due to the motion of the tube elements, and hum resulting from the use of an a-c power source for heating the cathode. Associated with the input loading and therefore present only at high frequencies is another noise source which may add appreciable noise above, say, 30 Mc.

The thermal agitation or shot effect for a temperature-limited current, I, of a diode produces a mean-square fluctuation current $\overline{i^2}$, measured in a frequency band width Δf, as given by the equation

$$\overline{i^2} = 3.18 \times 10^{-19} I \,\Delta f \tag{24}$$

where i and I are expressed in amperes and Δf is in cycles per second. It is often more convenient to express the tube-noise generators in terms of an equivalent resistance which at room temperature produces the same noise as the hot-cathode vacuum tube. The mean-square thermal agitated fluctuation current for any short-circuited pure resistance is

$$\overline{i^2} = \frac{4KT\,\Delta f}{r} \tag{25}$$

where r is the ohmic value of the resistance; K is Boltzmann's constant, 1.372×10^{-23} joule per degree; T is the temperature of the resistance in degrees Kelvin; and i is in amperes. Similarly the mean-square fluctuation voltage, $\overline{e^2}$, across the open-circuit terminals of a pure resistance is

$$\overline{e^2} = 4KTr\,\Delta f$$

where e is now given in volts. If room temperature is assumed to be 290 deg K (81 deg Fahr) the above expressions become

$$\overline{i^2} = \frac{1.59 \times 10^{-20}\,\Delta f}{r} \tag{26}$$

$$\overline{e^2} = 1.59 \times 10^{-20} r\,\Delta f \tag{27}$$

By direct substitution the equivalent-noise resistance of the diode with temperature-limited current flowing is

$$r_{\text{eq}} = \frac{1}{20I} \tag{28}$$

Such a diode is conveniently used as a noise-signal source generator.

With the diode current limited by space charge, and provided that I is small compared to the total available emission current, the fluctuation noise currents are reduced so that the equivalent noise resistance for the diode becomes

$$r_{\text{eq}} = \frac{1}{30I} \tag{29}$$

In triodes and pentodes, shot-effect noise is present as in the diodes and may be represented by a noise-equivalent resistance whose thermal-agitation noise at room temperature is equal to the tube noise referred to the control grid of the tube. In pentodes the random current distributions between the screen grid and anode produce noise usually several times greater than the thermal noise. In the following expressions for equivalent-noise resistances, for the pentode, the first term in the parenthesis is due to shot effect and the second term is due to screen current fluctuation:

For triode amplifiers,

$$r_{\text{eq}} = \frac{2.5}{g_m} \tag{30}$$

For pentode amplifiers,

$$r_{\text{eq}} = \frac{I_b}{I_b + I_{c2}}\left(\frac{2.5}{g_m} + \frac{20I_{c2}}{g_m^2}\right) \tag{31}$$

For triode mixers,

$$r_{\text{eq}} = \frac{4}{g_c} \tag{32}$$

For pentode mixers,

$$r_{\text{eq}} = \frac{I_b}{I_b + I_{c2}}\left(\frac{4}{g_c} + \frac{20I_{c2}}{g_c^2}\right) \tag{33}$$

For multigrid converters (with inner-grid or outer-grid injection),

$$r_{\text{eq}} = 20I_b\,\frac{(I_0 - I_b)}{I_0 g_c^2} \tag{34}$$

The following approximate relationships for triode and pentode mixers, when both the oscillator and signal frequencies are injected in the grid adjacent to the cathode, are useful when the data required for eqs. (32) and (33) are not available. The values "as amplifier" refer to conditions at the peak of the assumed oscillator cycle which is usually very close to zero grid-bias.

g_c (as converter) $= g_m/4$ (as amplifier)
I_b (as converter) $= I_b/4$ (as amplifier)
I_{c2} (as converter) $= I_{c2}/4$ (as amplifier)
r_{eq} (as pentode converter) $= 4r_{eq}$ (as amplifier)
r_{eq} (as triode converter) $= 6.5r_{eq}$ (as amplifier)

Conversion from noise-equivalent resistance to noise-equivalent rms voltage is effected by use of eq. (27):

$$\sqrt{\overline{e^2}} = 1.3 \times 10^{-10}\sqrt{r_{eq}\,\Delta f} \tag{27a}$$

Conversion from noise-equivalent resistance to noise-equivalent rms current is effected by use of eq. (26):

$$\sqrt{\overline{i^2}} = 1.3 \times 10^{-10}\sqrt{\frac{\Delta f}{r_{eq}}} \tag{26a}$$

The symbols in the above equations have conventional significance whose definitions are:

r_{eq}, noise-equivalent resistance, ohms.
g_m, grid-plate transconductance, mhos.
g_c, conversion transconductance (frequency converters and mixers), mhos.
I_b, average plate current, amperes.
I_{c2}, average screen-grid current, amperes.
I_0, average cathode current, amperes.
$\sqrt{\overline{e^2}}$, noise-equivalent rms voltage for band width Δf, volts.
$\sqrt{\overline{i^2}}$, noise-equivalent rms current for band width Δf, amperes.
Δf, effective band width, cycles.

In Table 2 is a listing of representative receiving-tube types showing equivalent-noise values. Several, covering a large range of equivalent-noise resistance values, show measured values all in good agreement with values computed from the above relationships.

Positive-ion noise produced by collision ionization results from residual gas in a vacuum tube. This very undesirable fluctuation noise may be investigated in order to determine the magnitude of grid current (positive-ion current) which may be tolerated from analysis of the following equation for the equivalent-noise resistance, $r_{\text{eq (gas)}}$:

$$r_{\text{eq (gas)}} = \left(20r^2 + A\,\frac{I_0}{g_m{}^3}\right) I_{ig} \quad \text{ohms} \tag{35}$$

where r = grid-circuit resonance impedance, ohms.
I_0 = cathode current, amperes.
I_{ig} = positive-ion current to grid, amperes.
g_m = grid-plate transconductance, mhos.
A = coefficient of the order of 40,000.

The term $20r^2I_{ig}$ represents shot-effect voltage fluctuations produced by the gas current flowing in the grid circuit. It may be increased several fold by induction effects associated with the ion transit time, even at frequencies of a few megacycles. The second term is the noise generator term within the tube. If, for an example, we assume r as 10^5 ohms, g_m as 2000×10^{-6} mho, I_0 as 10^{-2} amp, and a grid current of 10^{-6} amp, the resulting $r_{\text{eq (gas)}}$ is 250,000 ohms. To reduce this equivalent-noise resistance to a value negligible compared to the noise produced by the grid circuit resistance, here assumed to be 100,000 ohms, calls for a reduction of the gas current some 100 fold or to 10^{-2} microampere. Equation (35) is applicable to triodes or pentodes.

There is a source of current fluctuations associated with the component of tube input-conductance produced by electron transit time effects, a source which becomes important when the input frequency is high enough to make the transit-time input conductance relatively large. The random variations in space current will induce current fluctuations in the control-grid circuit, giving rise to grid-voltage fluctuations proportional to the total input impedance (tube and circuit). These induced mean-square grid-current fluctuations may be expressed thus:

$$\overline{i_g{}^2} \approx \frac{20}{3}\left(1 - \frac{\pi}{4}\right) 4KT_kg_g\,\Delta f = 1.43(4KT_kg_g\,\Delta f)$$

Inserting the value for Boltzmann's constant K, and assuming the cathode temperature, T_k, to be 1000 deg K, the above expression simplifies to

$$\overline{i_g{}^2} = 7.5 \times 10^{-20} g_g\,\Delta f \quad \text{amperes} \tag{36}$$

The noise-equivalent rms voltage for the band width Δf appearing at the tube control-grid may be deduced from the above expression; it is

$$\sqrt{\overline{e_g{}^2}} = 2.75 \times 10^{-10}\,\frac{\sqrt{g_g\,\Delta f}}{g + g_g} \quad \text{volts} \tag{37}$$

when g_g in mhos is that portion of the tube input conductance traceable to electronic loading alone; g in mhos is the grid-circuit resonance conductance; and Δf in cycles is the effective band width of the amplifier. As an example, assume the input circuit resonance impedance to be 20,000 ohms so that its reciprocal g is 50×10^{-6} mho; let g_g be 200×10^{-6}

Table 2. Tube-noise Values

* For effective band width of 5,000 cycles.
† At peak of oscillator cycle.
‡ Hexode section only. Triode section takes its current from a separate part of the cathode.
§ Conversion transconductance value.

mho and assume the effective band width to be 5000 cycles. The rms noise voltage appearing at the signal grid is then 1.1×10^{-6} volt, certainly not negligible for a high-gain amplifier!

DISTORTION INTRODUCED BY R-f AMPLIFIER TUBES. Owing to the inherent curvature of the plate-current vs. signal-grid-voltage characteristic of all r-f amplifier tubes, there are present in the tube output three types of distortion when the input signal has the form of an amplitude-modulated carrier. By means of a Taylor expansion series (see also Section 5, articles 16–24), the plate current about any given operating point may be written

$$i_b = I_{b0} + e_g \frac{\partial i_b}{\partial e_c} + \frac{e_g^2}{2!}\frac{\partial^2 i_b}{\partial e_c^2} + \frac{e_g^3}{3!}\frac{\partial^3 i_b}{\partial e_c^3} + \cdots \tag{38}$$

In this expression $\partial i_b/\partial e_c$ is the slope or transconductance, g_{m0}, of the plate-voltage vs. grid-bias curve, and $\partial^2 i_b/\partial e_c^2$ and $\partial^3 i_b/\partial^3 e_c$ are the second and third derivatives respectively of this same curve. The quantity e_g is the alternating part of the grid voltage or the signal input voltage. If an amplitude-modulated carrier signal voltage of the form

$$e_g = E_1(1 + m_1 \sin pt) \sin \omega_1 t$$

is inserted in the above series, we may neglect all the terms having harmonic frequencies of ω_1: if it is assumed that there is a tuned circuit in the output of the tube which band-passes only those frequencies and the sideband frequencies associated with the carrier frequency ω_1. Two types of distortion become apparent from this operation. The modulation factor, m_1, is changed, and the modulation-frequency component has amplitude distortion which is indicated by the presence of harmonic terms of p, the modulation frequency.

The modulation factor is thereby changed by the ratio

$$\frac{\Delta m}{m_1} = \left[\frac{1}{4}\left(1 - \frac{3}{8} m_1^2\right) \frac{\partial^3 i_b/\partial e_c^3}{g_{m0}}\right] E_1^2 \tag{39}$$

The amplitudes of the second and third harmonics producing amplitude distortion of the modulating frequency are expressible as: (*a*) Second harmonic distortion (ratio of the amplitude of sin $2pt$ to the amplitude of sin pt).

$$\text{Ratio of 2nd harmonic to fundamental} = \left[\frac{3}{16} m_1 \frac{\partial^3 i_b/\partial e_c^3}{g_{m0}}\right] E_1^2 \tag{40}$$

(*b*) Third harmonic distortion (ratio of the amplitude of sin $3pt$ to the amplitude of sin pt).

$$\text{Ratio of 3rd harmonic to fundamental} = \left[\frac{1}{32} m_1^2 \frac{\partial^3 i_b/\partial e_c^3}{g_{m0}}\right] E_1^2 \tag{41}$$

A third type of distortion occurs when a second, and usually an unwanted, signal modulates the desired signal. This is known as "cross modulation."

If there is substituted in the above series, for e_g, $e_g = E_1(1 + m_1 \sin pt) \sin \omega_1 t + E_2(1 + m_2 \sin qt) \sin \omega_2 t$ where the subscripts 1 apply to the desired signal and the subscripts 2 apply to the undesired signal, then the cross-modulation ratio is

$$\text{Cross-modulation ratio} = \left[\frac{1}{2}\frac{m_2}{m_1}\frac{\partial^3 i_b/\partial e_c^3}{g_{m0}}\right] E_2^2 \tag{42}$$

Inspection of the three different distortion types indicates that all are proportional to the square of the signal voltage amplitude and that all also are proportional to the third derivative of plate current to grid voltage and inversely proportional to the transconductance. It should also be noted that, since this analysis discards all higher derivatives than the third, reasonably small signal voltages are implied.

It is rather tedious to obtain sufficient points for an i_b vs. e_1 curve to determine the third derivatives accurately by graphical means. A more practical method is to use a conventional g_m bridge having a calibrated and variable signal grid voltage. The procedure is to apply a small signal, of the order of 0.01 to 0.1 volt, to the signal grid, with which a balance is established which gives a transconductance reading equal to g_{m0}. The bridge is then set off-balance by a predetermined small amount, say 1 to 5 per cent, and the input signal is increased until the bridge is again in balance. The required change in g_{m0} balance may be either positive or negative, depending on the curve shape. It can be shown by application of the Taylor's series that

$$\frac{\Delta g_m}{g_{m0}} \approx \left[\frac{1}{8}\frac{\partial^3 i_b/\partial e_c^3}{g_{m0}}\right] E_0^2 \tag{43}$$

where E_0 is the peak value of the large signal applied to the grid. Substitution of the above into the previous distortion equations results in the following expressions:

$$\text{Per cent change in modulation} = 2\left(1 - \frac{3}{8}m_1^2\right)\frac{\Delta g_m}{g_{m0}} \times 100$$

$$\text{Per cent 2nd harmonic distortion} = \frac{3}{2}m_1\frac{\Delta g_m}{g_{m0}} \times 100$$

$$\text{Per cent 3rd harmonic distortion} = \frac{1}{4}m_1^2\frac{\Delta g_m}{g_{m0}} \times 100$$

$$\text{Per cent cross modulation} = 4\frac{m_2}{m_1}\frac{\Delta g_m}{g_{m0}} \times 100$$

If it is assumed that $m_1 = 1$, that $m_2/m_1 = 1$, and that the transconductance is changed 1 per cent, the above may be expressed to show the relative magnitudes of the various distortions, giving

Modulation change = 1.25%
2nd harmonic distortion = 1.5%
3rd harmonic distortion = 0.25%
Cross modulation = 4%

In Fig. 17 are plotted the signal voltage necessary to change the g_m by 3 per cent vs. the

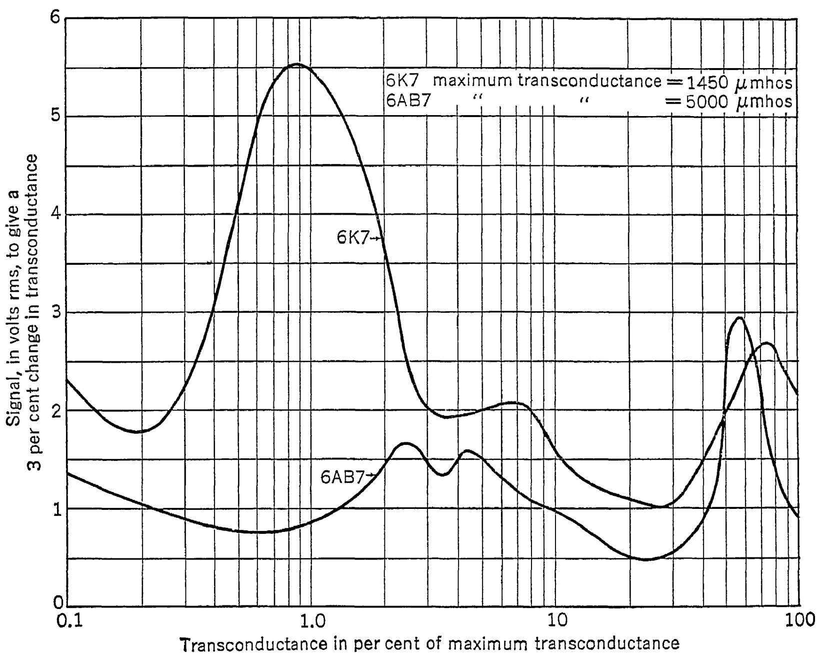

FIG. 17. Comparison of Signal Voltages Applied to the Remote and Semi-remote Cutoff Tube Types 6K7 and 6AB7 Respectively to Produce the Same Amount of Distortion

transconductance in terms of the maximum transconductance. For modulation factors of unity, this corresponds to saying that the signal voltages indicated will produce

Modulation change = 3.75%
2nd harmonic distortion = 4.5%
3rd harmonic distortion = 0.75%
Cross modulation = 12%

The one curve is for a "remote cutoff" tube, 6K7, which requires approximately 45 volts bias to reduce its maximum transconductance of 1500 μmhos to about 10^{-3} this value.

The second curve is for a "semi-remote cutoff" tube, 6AB7, which requires about 22 volts bias to reduce its maximum transconductance from 5000 to 10^{-3} this value. It is apparent that the 6K7 can handle a much larger signal than the 6AB7. The 6AB7 tube is limited to lower signal values because of its higher transconductance value, and if it were designed to have a similar cutoff as the 6K7 it would draw exceedingly large plate currents when the bias was set low for maximum gain. There is thus a practical limitation governing the maximum transconductance and maximum signal-handling capacity that can be designed into a tube.

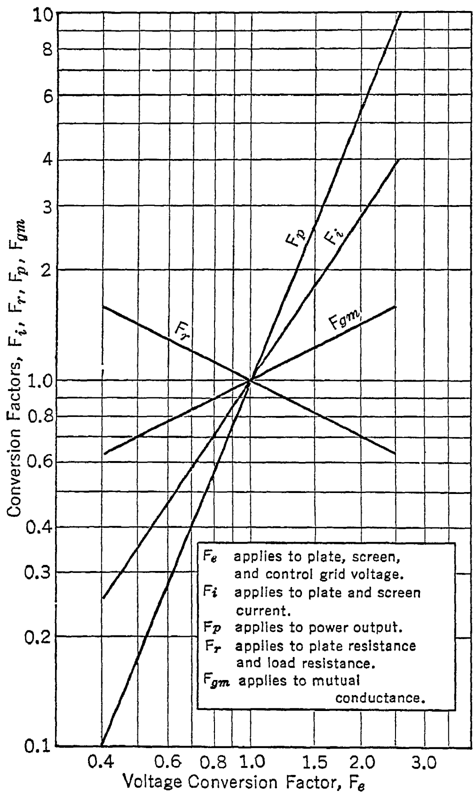

FIG. 18. Conversion Factor for Triode and Pentode

CHANGING OPERATING CONDITIONS. Operating Voltages. It is sometimes necessary to change the operating potentials of an amplifier or a power output triode or pentode tube from the published typical operating conditions. By means of the conversion factor chart, Fig. 18, it is possible to determine the new voltages, currents, transconductance, plate and load resistances, and power output. The curves are based on the fact that, if all applied voltages (except heater voltage) are changed by a factor n, the resulting currents will all be changed by $n^{3/2}$, the g_m by $n^{1/2}$, and the plate resistance by $n^{5/2}$. The accuracy of the chart is reasonably good for small changes, but for large voltage changes exceeding 2.5 to 1 the chart is unsuitable. As an example, assume a pentode with the following typical ratings:

Plate voltage	250 volts
Screen voltage	250 volts
Grid bias	−18 volts
Plate current	32 ma
Screen current	5.5 ma
Plate resistance	70,000 ohms
Transconductance	2,300 μmhos
Load resistance	7,600 ohms
Power output	3.4 watts

It is desired to determine the operation characteristics for a plate voltage of 100 volts. All voltages will have to be changed in the ratio of 100 to 250 (e.g., F_e, the voltage conversion factor, is 0.4). From the chart the new to the old ratios are picked off so that F_i is 0.25, F_p is 0.1, F_{gm} is 0.63, and F_r is 1.6. The new conditions will then be

Plate voltage		100 volts
Screen voltage	250 × 0.4	= 100 volts
Grid bias	−18 × 0.4	= −7.2 volts
Plate current	32 × 0.25	= 8 ma
Screen current	5.5 × 0.25	= 1.4 ma
Plate resistance	70,000 × 1.6	= 112,000 ohm
Transconductance	2,300 × 0.63	= 1,450 μmhos
Load resistance	7,600 × 1.6	= 12,000 ohms
Power output	3.4 × 0.1	= 0.34 watt

It should be noted that this chart cannot be used if only one voltage is varied.

Changes in Heater or Filament Voltage. Changing the heater or filament voltage of a tube will increase or decrease the temperature, current, and power input of the emitting cathode. The curves of Fig. 19 show these relationships, which were based on taking average values of radiation coefficients and resistivity of tungsten, molybdenum, tantalum, and nickel covering temperature ranges of 1000 to 2800 deg. K. With a maximum filament voltage variation of ±25 per cent, engineering accuracy holds for vacuum and gas-filled tubes, the greatest deviation between observed and predicted currents and power input being only 4 per cent.

As an example assume that a 6.3 volt 0.3 amp heater is running with a cathode temperature of 1050 deg K and a heater temperature of 1400 deg K and that the heater voltage is decreased to 5.5 volts or 87.3 per cent of nominal. From Fig. 19 we find that the resulting power input is 80 per cent of 1.89 watts, or 1.51 watts. The new filament current is reduced to 92 per cent of 0.3 amp, or 0.276 amp, and the cathode and heater temperature are reduced to 95.8 per cent, or 1005 and 1340 deg K, respectively.

Maximum Allowable Grid Resistance. Common practice is to apply the d-c bias to the negative control grid of an amplifier through a series grid resistor. It is desirable to make this resistor as high valued as possible since it shunts the signal source and therefore absorbs power and may have detrimental results on the frequency response and loading of the signal source. Its limiting value is usually of the order of 0.1 to 10 megohms and is established by the radio-tube manufacturer on the basis of life tests and maximum expected grid current. Grid current flowing through the grid resistor decreases the grid bias by the IR drop through the resistor and may cause the tube to "run away" since the resulting increase in plate current will produce excessive plate dissipation. By the addition of a cathode self-bias resistor, or the use of a series dropping resistor in the screen lead of a pentode, or the use of a d-c load resistor in the plate lead of a triode, there results some d-c degeneration, thereby making it possible to increase the value of the grid resistor above that indicated as a maximum. Also, if the tube is operated at a reduced value of transconductance, the maximum allowable grid resistance value may be increased.

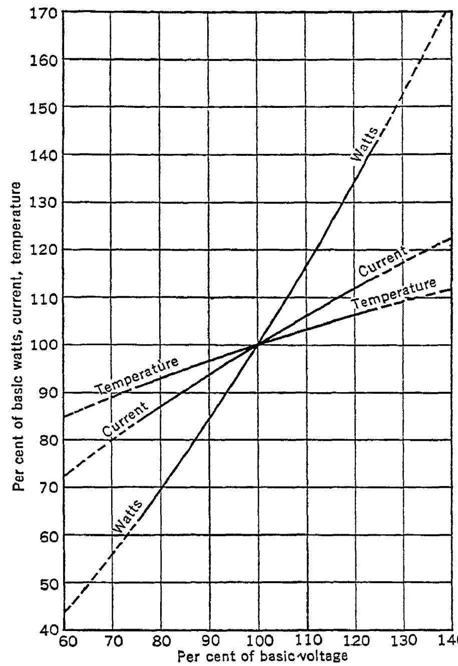

FIG. 19. Chart Giving Wattage, Current, and Temperature of a Filament, Heater, or Cathode at Operating Voltages up to 25 Per Cent above or below Basic Voltage, with Sufficient Accuracy for Most Engineering Purposes. Accuracy drops in dotted regions.

From the following equation it is possible to determine the maximum allowable value of grid resistance, r_{g1}, for any new set of operating conditions differing from those published.

$$r_{g_1} = \frac{\Delta I_k}{\Delta I_{g_1}}\left[\frac{1}{g_k}\left(1 + \frac{r}{r_p + r}\right) + r_k\left(1 + \frac{1}{\mu}\right)\right] \tag{44}$$

where, for a triode,

$\Delta I_k/\Delta I_{g_1}$ is the ratio of plate current change per unit change in grid current;
g_k is the grid-plate transconductance in mhos;
r is the d-c plate load resistance;
r_p is the internal tube plate resistance;
r_k is the cathode self-bias resistance in ohms;
μ is the triode mu;

and where, for a pentode,

$\Delta I_k/\Delta I_{g_1}$ is the ratio of cathode current change per unit change in grid current;
g_k is the signal-grid-to-cathode transconductance in mhos (this may be determined by multiplying the signal-grid-to-plate transconductance by the factor $(I_p + I_{c_2})/I_p$);
r is the screen dropping resistance;
r_p is the internal tube screen resistance;
r_k is the cathode self-bias resistance, in ohms;
μ is the triode connected amplification factor, i.e., the mu from control grid to screen grid of the pentode.

fication Chart. (Courtesy RCA.)

All the above factors can usually be obtained from published tube characteristics or are measurable for a given tube type with the exception of the ratio $\Delta I_k/\Delta I_{g_1}$. This ratio indicates that for any given amount of grid current flow there is a definite increase in cathode current flow. If it were possible to manufacture vacuum tubes so that with a negative grid absolutely no grid current flowed, the series-grid resistance could be infinite in value. However, for practical tubes, grid currents of the order of a microampere may exist due to residual gas ionization, thermal and photoelectric emission, and leakage currents. This ratio, $\Delta I_k/\Delta I_{g_1}$, for a given tube may be determined from the published maximum allowable grid resistance by substituting it in the above equation, and once determined it may be used to determine a new value of maximum resistance for a new operating condition.

Example. A pentode with fixed bias and fixed screen voltage has indicated a maximum allowable grid resistance of 0.2 megohm. What is the maximum grid resistance with full self-bias and a series dropping resistance from a 300-volt supply? What is the maximum grid resistance if the bias is increased so that the cathode current is reduced to one-tenth its maximum value?

For $r_{g1} = 0.2$ megohm,

$$\begin{aligned} E_{g1} &= -2\,1/2 \text{ volts} \\ E_{c2} &= 100 \text{ volts} \\ E_{c3} &= 0 \text{ volts} \\ E_b &= 250 \text{ volts} \\ g_{1-p} &= 5000\ \mu\text{mhos} \\ \mu_{12} &= 25 \\ r_2 &= 25{,}000 \text{ ohms (internal screen resistance)} \\ i_{c2} &= 2.5 \text{ ma} \\ i_p &= 10 \text{ ma} \end{aligned}$$

The cathode transconductance, g_{1k}, is determined by,

$$g_k = g_{1-p}\frac{(I_p + I_{c_2})}{I_p} = \frac{5000}{10^{-6}}\frac{(12.5)}{10} = 6250 \times 10^{-6} \text{ mho} \tag{45}$$

Then $r_1 = \dfrac{\Delta I_k}{\Delta I_{g_1}}\left(\dfrac{1}{g_k}\right)$, since there are no self-bias or screen dropping resistors used. Then

$$\frac{\Delta I_k}{\Delta I_{g_1}} = r_1 g_k = (0.2 \times 10^6)(6250 \times 10^{-6}) = 1250 \tag{46}$$

For the new conditions the self-bias and series dropping screen resistors are

$$r_k = 2.5/(12.5 \times 10^{-3} \text{ amp}) = 200 \text{ ohms}$$

$$r_{g_2} = (300 - 100)/(2.5 \times 10^{-3} \text{ amp}) = 160{,}000 \text{ ohms series dropping screen resistor}$$

The new maximum grid resistance is

$$\begin{aligned} r_{g_1} &= 1{,}250\left[\frac{10^6}{6250}\left(1 + \frac{160{,}000}{160{,}000 + 25{,}000}\right) + 200\left(1 + \frac{1}{25}\right)\right] \\ &= 632{,}000 \text{ ohms} \end{aligned} \tag{47}$$

At one-tenth normal cathode current the new bias is computed to be approximately -3.7 volts, assuming that the tube obeys the three-halves power of effective voltage law. The new values are then

$$\begin{aligned} r_k &= 3.7/(1.25 \times 10^{-3} \text{ amp}) = 2950 \text{ ohms} \\ r_{12} &= 160{,}000 \times 10 = 1.6 \text{ megohms series screen resistor} \\ r_{g_2} &= 25{,}000\ (10)^{1/3} = 53{,}000 \text{ internal screen resistance} \\ g_k &= 6250 \times 10^{-6}/10^{1/3} = 2910 \times 10^{-6} \text{ mho} \end{aligned}$$

From the above the new maximum grid resistance is

$$\begin{aligned} r_{g_1} &= 1250\left[\frac{10^6}{2910}\left(1 + \frac{1.6}{1.6 + 0.053}\right) + 2950\left(1 + \frac{1}{25}\right)\right] \\ &= 4.7 \text{ megohms} \end{aligned} \tag{48}$$

RECEIVING TUBE CLASSIFICATION CHART. Figure 20 classifies the commonly used receiving tubes according to their functions and their cathode voltages. It is arranged to permit quick determination by the tube user of the type designations of tubes applicable to specific design requirements. Types having similar characteristics and in the same cathode-voltage groups are bracketed.

6. TYPICAL VACUUM-TUBE CHARACTERISTIC CURVES

The following vacuum-tube characteristic curves were selected as representative of the *triode* (type 10), the *tetrode* (type 865), and the *suppressor-grid pentode* with normal (type 57) and with *remote-cut-off* control grid (type 58). The data were furnished by the RCA Radiotron Division, RCA Mfg. Co., Inc.

MAGNETRONS

By W. B. Hebenstreit

In this section only those magnetrons of circular cylinder geometry will be considered. A cylindrical anode is coaxial to an emitting cathode, and the elements are mounted in a vacuum envelope. A static magnetic field is parallel, or nearly parallel, to the axis of the cathode, and a d-c potential applied between the cathode and anode sets up a radial, static electric field. Under conditions of oscillation, the electrons also interact with an a-c field.

7. THE NON-OSCILLATING MAGNETRON

The simplest example is the non-oscillating solid anode magnetron. Under the influence of the electric field, the electron is impelled to move toward the anode. The magnetic field results in a force on the electron which is normal both to the direction of motion and to the direction of the magnetic field. Theoretically, there is a minimum critical voltage, V_c, called the cutoff voltage, for each value of the magnetic field, B, for which electrons will just reach the anode. The formula * for the cutoff voltage is

$$V_c = \frac{eB^2 r_a^2}{8m}(1 - \sigma^2)^2 \tag{1}$$

where e is the electronic charge, m is the electronic mass, r_a is the anode radius, and σ is the ratio of the cathode radius to the anode radius. In this formula it is assumed that the electrons have zero velocity at the cathode; in addition the relativistic effects, which become significant at high voltages, are neglected. Since V_c is proportional to B^2, the locus of eq. (1) for any given geometry is often referred to as the cutoff parabola.

8. THE OSCILLATING MAGNETRON

Principal current interest lies in the use of a magnetron as a self-excited oscillator. A convenient classification of oscillating magnetrons can be made by distinguishing among the several ways in which electrons interact with the a-c fields to sustain oscillations. For this purpose, three types of interactions can be identified.

Type I. The Negative Resistance Magnetron. If the anode of the magnetron is split into halves and one half is raised to a higher potential than the other, under certain conditions, most of the electrons will go to the plate of lower potential. In this event, a negative

* Unless otherwise indicated, mks units will be used in articles 7–9.

resistance exists between the two halves of the anode, and oscillations will be sustained in a tank circuit which is connected between them.

Type II. The Cyclotron Frequency Magnetron. In the neighborhood of cutoff (see eq. [1]), the solid anode magnetron will sustain oscillations if the terminals of an L-C tank circuit are connected between the cathode and anode. The wavelength of the oscillations which will be sustained is given by

$$\lambda B = \text{Constant} \tag{2}$$

The most commonly observed value of the constant is about 15,000 centimeter-gausses. The disadvantage of this type of magnetron is that the electronic efficiency is very low.

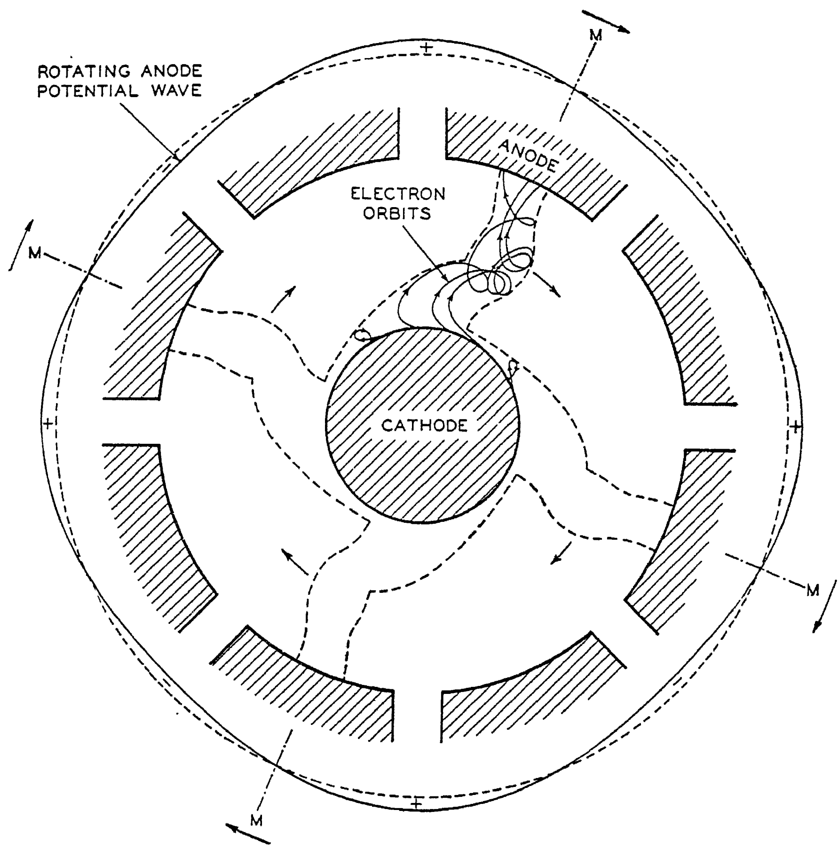

FIG. 1. Approximate Configuration of a Space-charge Cloud of an 8-segment Magnetron Operating in the π-mode

The electrons that initially absorb energy from the field are removed from the interaction space within approximately one cycle either by striking the anode or by being returned to the cathode. Those electrons that initially yield energy to the field stay in the interaction space for a longer time. However, after they have lost their energy they begin to reabsorb it again unless some method is provided for their removal. This is sometimes done either by tilting the magnetic field slightly with respect to the axis of the cathode or by installing electrodes at the ends of the interaction space which are made positive with respect to the cathode. In either method the electrons that have given energy to the r-f field are drawn off at the ends if the interaction space is short enough.

Type III. The Traveling Wave Magnetron. In this magnetron, the anode consists of a number of segments. In operation, an r-f standing wave pattern exists in the interaction space between the cathode and anode. In general, standing wave patterns may be thought of as being composed of two waves traveling in opposite directions. The standing wave pattern in the interaction space is composed of two traveling waves rotating in opposite directions around the interaction space.

Oscillations are sustained by interaction between one of the traveling-wave components and the electronic stream. The electronic stream assumes the shape of a spoked cloud which is centered on the axis of the tube as is indicated schematically in Fig. 1. The spokes wheel around the interaction space in synchronism with one of the components of the rotating wave in such a phase that the spokes are in a retarding tangential * electric field. That is to say that the electrons in the spokes are yielding energy to the r-f field. Those electrons that come from the cathode in such a phase as initially to absorb energy from the field are returned to the cathode after only one orbital loop. Figure 1 shows the computed paths of electrons emitted at several different phases. The paths are drawn as they would appear to an observer stationed in a system of coordinates which is centered at the axis of the tube and which is rotating with the same angular velocity as the rotating wave.

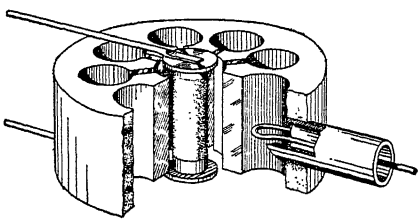

FIG. 2a. Schematic Representation of a Hole and Slot Magnetron

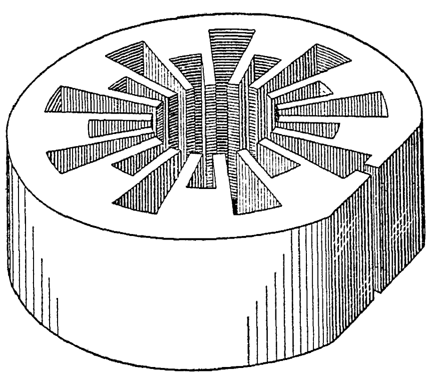

FIG. 2b. Schematic Representation of a Rising Sun Anode Block

This selective mechanism, that is, the mechanism by which the unfavorable electrons are rejected by being returned to the cathode in a relatively short time and the favorable electrons are grouped into spokes which stay in a retarding r-f field, results in very high electronic efficiencies. Electronic efficiencies of 60 per cent are not uncommon.

Associated with the segments of the anode is a system of resonators. The resonator system may assume any one of a variety of forms. One of the commonest forms is illustrated in Fig. 2a. This figure is a schematic representation of the hole-and-slot-type magnetron. Each hole and slot can be thought of as an L-C tank circuit with an associated resonant frequency.

In the rising sun structure, illustrated in Fig. 2b, resonators of one resonant frequency alternate with resonators of another frequency. In normal operation, the operating frequency of the ensemble is roughly midway between the resonant frequencies of the two sets.

From the standpoint of practical application, the traveling-wave magnetron is by far the most important type of magnetron oscillator. It will be the exclusive concern of article 9, and, unless explicitly stated, the term "magnetron" will mean a traveling-wave magnetron.

9. OPERATION OF THE TRAVELING-WAVE MAGNETRON

THE R-F PATTERNS OF THE MODES. In a magnetron of N segments there are N possible modes of oscillation. The different modes have periodicities of n, where n is any of the integers $0, 1, 2, \cdots N/2$ if N is even, and $0, 1, 2, \cdots, (N-1)/2$ if N is odd. A mode number, or designation, is numerically equal to n. Periodicity is here defined to mean the integral number of repeats of a field pattern in a single revolution around the anode at any given instant.

The tangential component of the r-f electric field is zero across the face of a segment. Therefore, the field distribution of a given mode will be the sum of an infinite series of harmonics. Each harmonic will have a periodicity of k. The only values of k possible are those for which

$$k = n - pN \tag{3}$$

where p is any integer—positive, negative, or zero. If the tube is of the rising-sun variety,

* The type III magnetron is also called the tangential resonance magnetron.

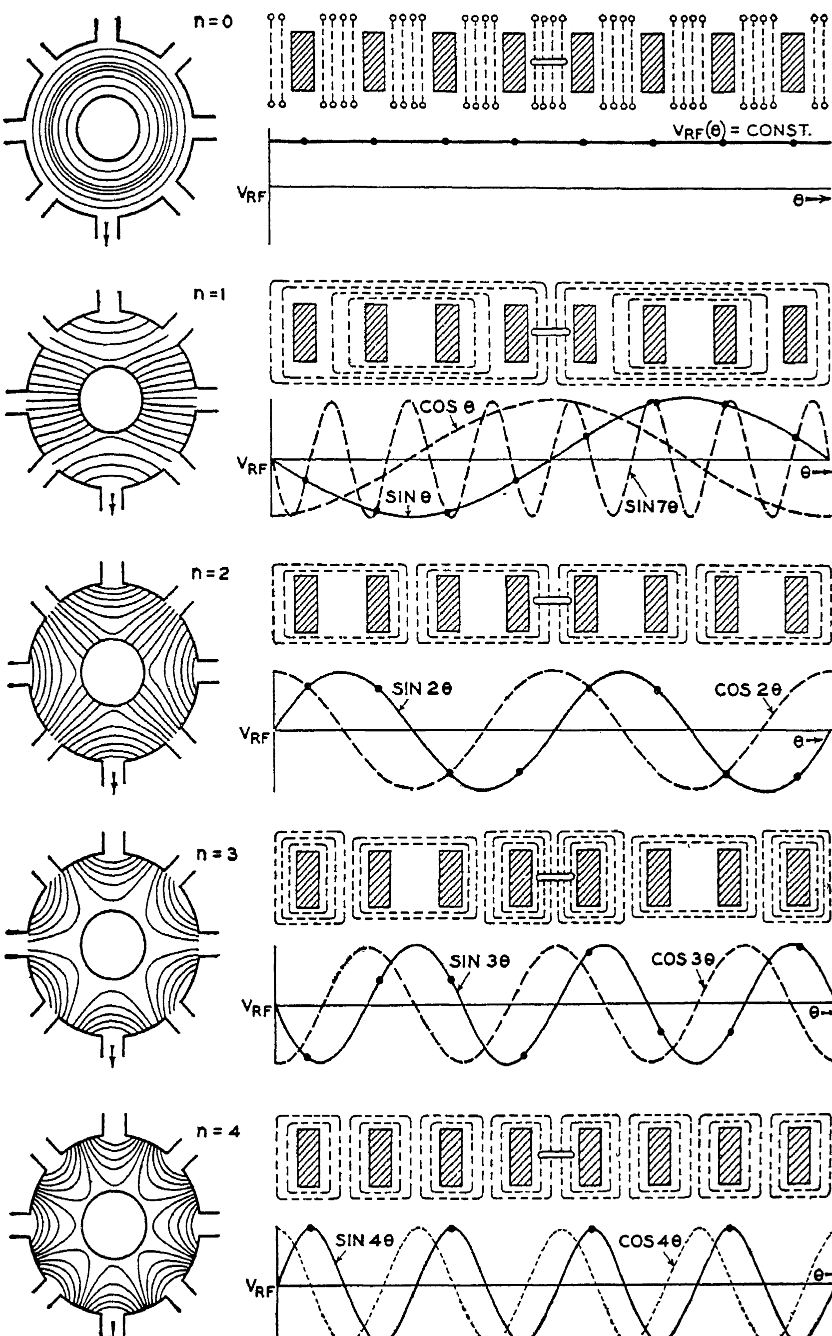

Fig. 3. Field and Potential Distributions of the Modes in an 8-segment Magnetron

where the resonators which connect the segments are alternately large and small, the allowed values of k will be given by

$$k = n - p\frac{N}{2} \tag{3a}$$

That is, there will be a set of harmonics associated with each of the two sets of resonators.

The mode for which $n = N/2$ is sometimes called the π mode for the reason that adjacent segments are 180°, or π radians, out of phase.

All the modes except the zero mode and the π mode occur in pairs, or doublets. The two members of a doublet have the same periodicity although they usually differ in frequency and the patterns are displaced with respect to one another in such a way that a current loop in the fundamental of one pattern occurs in the same position as a current node in the fundamental of the pattern of the other.

Some of these principles are illustrated in Fig. 3 for an eight-segment tube. For clarity only the electric flux lines of the fundamental component are shown in the interaction space. To illustrate the field configurations in the resonators, only the magnetic flux lines are shown. Below these are plotted the distributions in potential for the fundamental component. The reason for the existence of only one π-mode is illustrated in Fig. 3. The cos 4θ solution corresponds to zero potential on all the segments.

Although the frequencies of the several modes are usually different, all the harmonics of a given mode are at the same frequency. Thus, if $f_n(=\omega_n/2\pi)$ is the operating frequency of the nth mode, then the angular velocity of the pth harmonic of the rotating wave is ω_n/k, where k is given by eq. (3). This point is stressed for the reason that, in steady-state operation, the electronic stream interacts with only one harmonic of one mode at any instant.

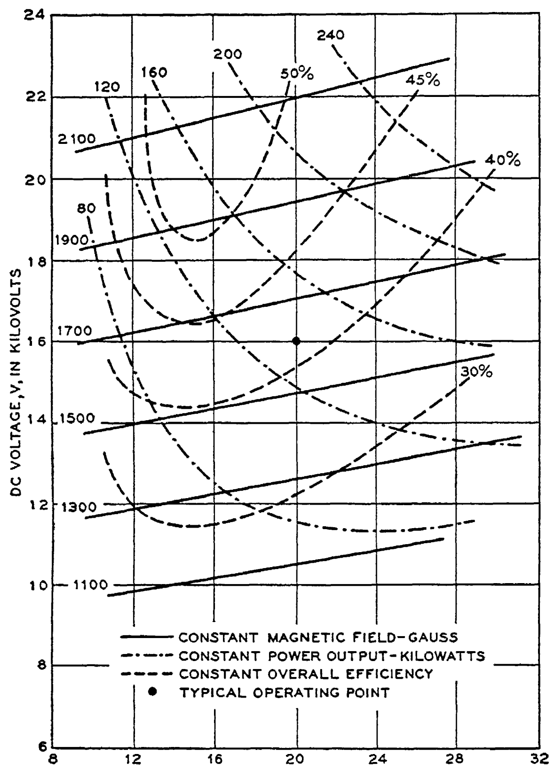

FIG. 4. Magnetron Input V-I Characteristic

INPUT CHARACTERISTICS. The d-c voltage for which an electron will just reach the anode for an infinitesimal r-f voltage on the anode of frequency f and periodicity k is given by

$$V_T = \frac{\pi f r_a^2 B}{k}\left[1 - \sigma^2 - \frac{2\pi f m}{keB}\right] \tag{4}$$

Equation (4) defines a threshold voltage. Empirically it is approximately equal to the operating voltage at low currents although changes in the r-f loading will cause changes in the input d-c voltage.

For any fixed loading the input voltage varies approximately linearly with input current for any fixed value of magnetic field, as is indicated in Fig. 4. Figure 4 shows voltage plotted as a function of current for various values of magnetic field. In addition to the constant magnetic field lines, contours of constant efficiency and constant power output are also shown. A method for obtaining the type of data required for such a V-I characteristic is described in Section 11, Microwave Measurements.

Although the performance chart in Fig. 4 is typical, it does not indicate the possible range of operating characteristics and parameters of magnetrons. Table 1 lists operating data for five magnetrons. The data for each tube are for some one point on its V-I characteristic. The most striking thing about the data is the large range of variation of the several parameters without any apparent correlation. It will be shown in the sequel, however, that the data do fit into a logical scheme.

Table 1

Example	Wavelength, centimeters	Voltage, volts	Current, amperes	Magnetic field, gausses	R-f Power Output, Watts
I	1	15,000	15.0	8,000	75,000
II	3	30,000	40.0	8,000	500,000
III	5	2,500	0.1	3,000	100
IV	10	50,000	200.1	2,500	4,000,000
V	50	2,000	1.0	800	1,000

SCALING. If, in the examples in Table 1, all the tubes were assumed to be working in an equivalent way (for example, all with the same electronic efficiency), then the data shown, together with the geometrical parameters, would correlate in accordance with the principles of scaling. The principles of scaling state that in the variation of the parameters, V, I, B, h, r_a, and λ, where h is the anode length, equivalent operation may be obtained by maintaining the following three parameters invariant:

$$V\left(\frac{\lambda}{r_a}\right)^2 \qquad I\left(\frac{\lambda}{r_a}\right)^2\left(\frac{\lambda}{h}\right) \qquad \lambda B \tag{5}$$

In addition, it is assumed that the ratio of cathode radius to anode radius and the number of segments also are maintained constant.

It would be instructive to consider an example of the type of scaling in which every linear dimension is scaled by the same factor, S. Let the unprimed quantities represent the tube from which it is desired to scale, and let the primed quantities represent the tube to be derived; then

$$\lambda' = S\lambda$$
$$r_a' = Sr_a$$
$$h' = Sh$$

From (5), since $(\lambda'/h') = (\lambda/h)$ and $(\lambda'/r_a') = (\lambda/r_a)$,

$$V' = V \qquad I' = I \qquad B' = \frac{B}{S}$$

Thus, the new tube will work at the same voltage and current but the new magnetic field will be $1/S$ times the original magnetic field. This type of scaling is most useful when the factor S does not differ greatly from unity. Ordinarily it cannot be applied if S is very large or very small. For example, suppose that $\lambda = 30$ cm and $\lambda' = 3$ cm. In this case, $S = 0.1$, and, since $I = I'$, the surface current density at the cathode will be up by a factor of 100 in the new tube. A current density of 10 amp per sq cm in the 30-cm tube is a quite moderate figure. A current density of 1000 amp per sq cm cannot be attained with present techniques. In order to scale over such wide ranges, it is usually necessary to extend the scaling laws to include N and σ. When these parameters are included, the quantities that must be kept invariant are

$$V\left(\frac{k\lambda}{r_a}\right)^2 \qquad I\left(\frac{k\lambda}{r_a}\right)^2\left(\frac{k\lambda}{h}\right)(1-\sigma^2)^2\left(\frac{1}{\sigma}+1\right) \qquad kB\lambda(1-\sigma^2) \tag{5a}$$

where k is used instead of N to emphasize the importance of the field periodicity. In π-mode operation k will be $N/2$.

Scaling in accordance with the invariants in (5) and at the same time maintaining the same N and σ gives fairly accurate results. Scaling in accordance with the invariants in (5a) will give good results in predicting currents, voltages, and magnetic fields. However, it is usually found that equivalence does not hold for large changes in N or in σ. In particular it is usually found that electronic efficiency decreases with increasing N and increasing σ.

MODE SEPARATION AND MODING. The frequencies of the several modes are separated by an amount which depends upon the type and degree of coupling among the several resonators. Such mode separation is advantageous for the reason that it allows

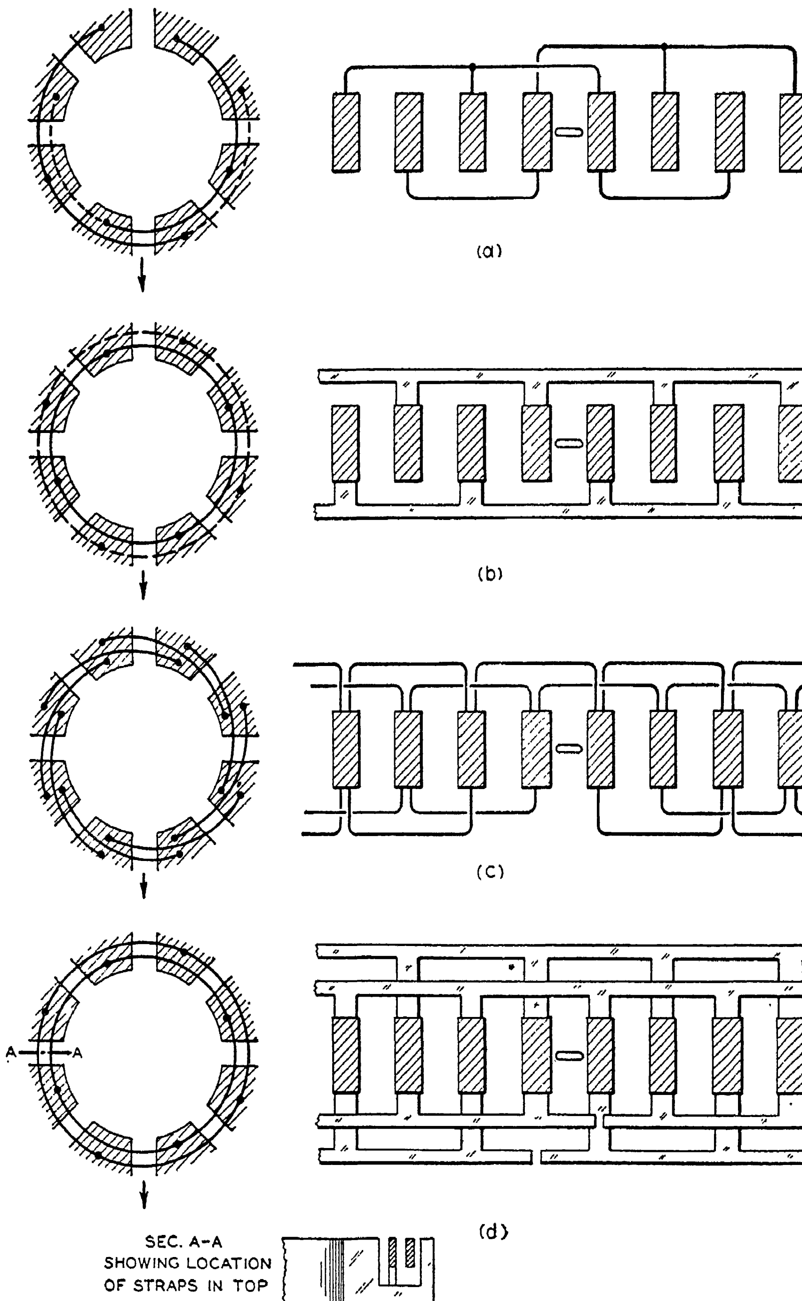

FIG. 5. Magnetron Anode Strapping Methods. (*a*) Early British, (*b*) single ring, (*c*) echelon, (*d*) double ring.

the desired mode of operation to be excited independently of the other modes. This appears to be one of the conditions necessary for high electronic efficiency.

From eq. (3) it might also seem desirable to separate the values of f/k in order that no two modes have the same threshold voltages. This has appeared to be true in some cases, but, in general, when taken alone, this condition is an unreliable index of the possibility of moding. The problem is complicated by several factors including, principally, such things as relative r-f loading of the modes, the noise levels at the start of oscillations, the transient behavior of the modulator and power supply, and the instability of the space charge of the magnetron at high current levels. A complete analysis of moding is beyond the scope of this article. However, a few general remarks can be made. In these remarks, it will be assumed that N is even and the π-mode operation is desired.

Two distinct types of moding have been observed. One, called the mode skip, occurs principally in the high-voltage pulse magnetrons. The magnetron fires in both the π mode and an unwanted mode. ("Unwanted mode" is to be considered as being defined here so as to include a non-oscillating state which sometimes occurs.) However, it fires in only one mode during any one pulse. It alternates between the two modes in more or less random fashion. This type of moding can usually be cured either by reducing the r-f loading on the magnetron, by reducing the rate of rise of the applied voltage pulse or by reducing the applied voltage, or by a combination of the three.

A mode shift, the other type of moding, is encountered chiefly in low-voltage c-w magnetrons. It consists of a shift from one mode to another. One of its principal causes is an inherent instability in the space charge at high current. In general, it can be cured by reducing the r-f loading or by reducing the operating current. In the pulsed case, a mode shift is usually observed to occur during a single pulse and is relatively unaffected by changes in the rate of rise of the applied pulse. If the cathode is well designed, the high current instability will occur at currents which are lower than those necessary for temperature limitation. Occasionally, however, mode shifts have been observed which involve instability due to temperature-limited operation.

METHODS OF MODE SEPARATION. The two most important devices for achieving frequency separation of the modes involve the use of straps and of the rising-sun structure.

Figure 5 shows several strapping methods schematically. One of the most widely used is the double ring strapping of Fig. 5*a*, in which there is a pair of concentric rings at each end of the anode. One ring of a pair is connected to one set of alternate segments. The other ring is connected to the other alternate set of segments. In π-mode operation, one strap or ring is everywhere at the same potential and the two rings at one end are 180° out of phase. Hence, the straps constitute mainly a capacitance loading of the resonators with a resultant increase in wavelength in the π mode over the unstrapped case. In the $n = 1$ mode, the potential distribution on a strap is almost sinusoidal and periodic in only one revolution around the anode. Moreover, the two rings in a set are at nearly the same potential. Thus, the principal effect of straps in the $n = 1$ mode is a shunt inductance so that the $n = 1$ mode wavelength will be less in the strapped case than it is in the unstrapped case. Modes in between the $n = 1$ and the π mode will be affected in a way intermediate between the two extremes first mentioned. That is, as n increases from 1 to $N/2$, the inductance effect of the straps decrease while the capacitive effect increases.

Figure 6 shows the mode spectra of three different types of 18 segment magnetrons. The spectrum in Fig. 6*a* is for an unstrapped symmetrical tube, that in Fig. 6*b* for a strapped symmetrical tube, while Fig. 6*c* shows the spectrum for a rising-sun tube.

At wavelengths shorter than 3 cm, the mechanical problem of making strapped magnetrons becomes very difficult. The rising-sun structure avoids this difficulty by providing mode separation without straps. It works on the principle that the normal mode frequencies of a system of resonators become separated by the introduction of asymmetries. The mode spectrum of the rising sun is composed of two branches. Each branch is associated with one of the two sets of resonators.

OUTPUT COUPLING. The r-f energy can be coupled to the load in several ways. Of these, two are of major interest: loop coupling and wave-guide coupling. The first type is indicated schematically in Fig. 2*a*; the second is shown schematically in Fig. 7. In Fig. 7, coupling is obtained through a slot in the back of one of the resonators. The quarter-wave low-impedance transformer section steps down the impedance of the wave guide, which is of the order of a few hundred ohms, to the low impedance required at the slot opening, which is, in some cases, as low as 1 or 2 ohms.

The choice between loop output or wave-guide output is usually made on the grounds of mechanical feasibility and convenience. At wavelengths greater than 10 cm, r-f transmission is ordinarily done in coaxial lines. The size of choke assemblies and window structures in wave guides makes them cumbersome and difficult to fabricate. For these rea-

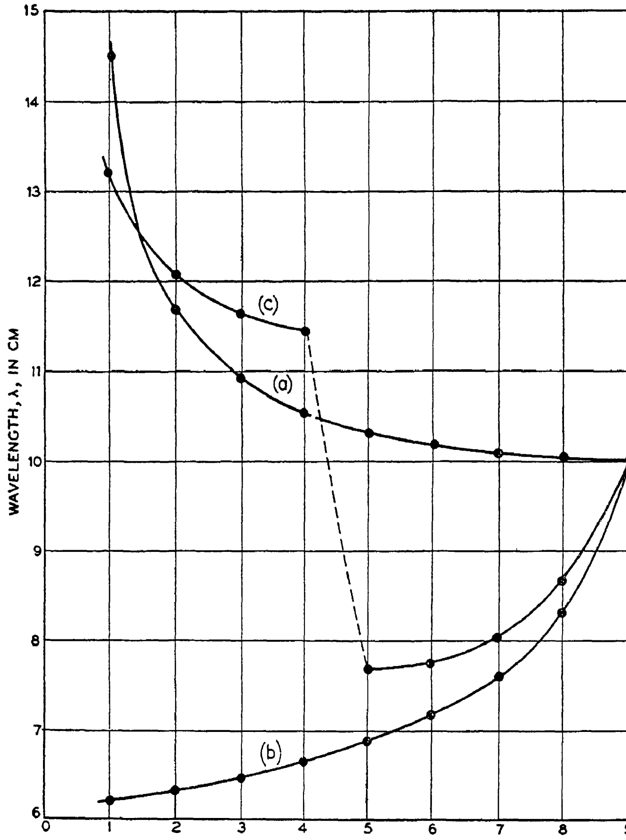

FIG. 6. Mode Spectra for Three Different Types of 18-segment Magnetrons Having the Same π-mode Wavelength. (*a*) Unstrapped symmetrical magnetron, (*b*) strapped symmetrical magnetron, (*c*) rising sun magnetron.

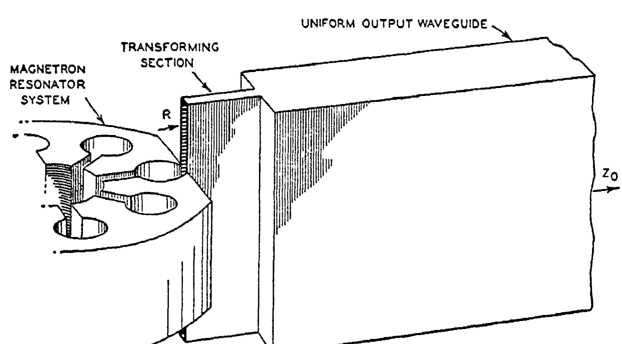

FIG. 7. Illustration of a Method of Wave Guide Output Coupling

sons, loop coupling outputs are usually found at the longer wavelengths. Below 10 cm, wave guides are usually used for transmission, and the physical size of wave-guide outputs is reduced to manageable proportions.

In common with any self-excited oscillator, the efficiency and frequency stability of a magnetron depends upon the amount of coupling between the magnetron and the load. In addition, for any given coupling, the efficiency and frequency stability will change as the amount of loading is changed. A quantitative measure of the variation of efficiency and frequency with loading is obtained from a Rieke diagram, an example of which is shown in Fig. 8. Contours of constant power output and contours of constant frequency are

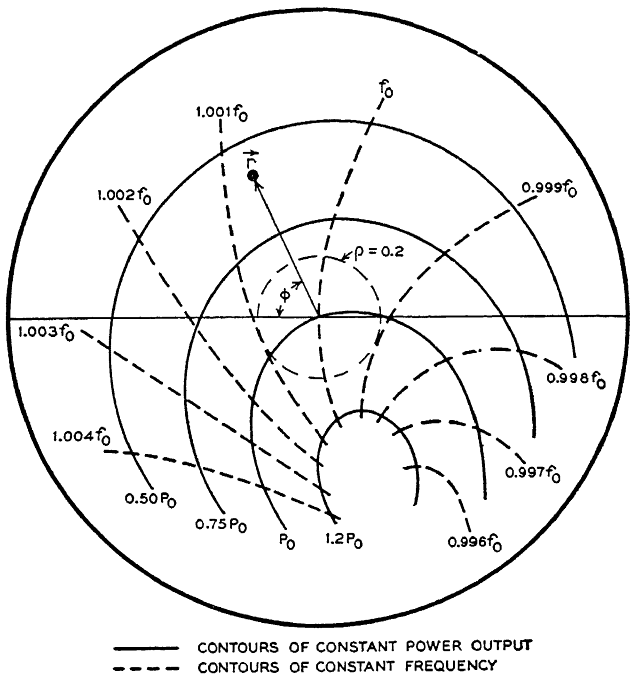

FIG. 8. Rieke Diagram

plotted on a polar diagram. Load impedances on a polar diagram may be specified by a characteristic impedance of the transmission line into which the magnetron is coupled, together with a reflection coefficient. The modulus of the reflection coefficient is proportional to the distance from the pole of the diagram while its argument is proportional to the angular displacement around the diagram. The load line characteristic impedance Z_0, the load impedance Z, and the voltage reflection coefficient r are related by

$$r = \frac{Z - Z_0}{Z + Z_0} = \rho e^{j\phi} \tag{6}$$

where ρ is the modulus and ϕ is the argument of r. The region on the Rieke diagram of high power and high frequency density is the region of heavy loading. The center of the diagram corresponds to a matched load; that is, the load impedance is equal to the transmission-line characteristic impedance. Ordinarily, the loading is maintained constant, at the match point, over the V-I characteristic, as in Fig. 4. On the other hand, the magnetic field and either the current or voltage is held constant over a Rieke diagram. A description of some of the techniques for obtaining the data for a Rieke diagram and a discussion of polar diagrams will be found in Section 11, Microwave Measurements.

A quantitative measure of the frequency stability with respect to perturbations in loading at the match point is the pulling figure. Pulling figure is defined as the greatest excursion of frequency observed as the modulus of the reflection coefficient is maintained constant at a value of 0.2 and its phase angle is varied through 360°. For the example shown, the pulling figure is about 0.2 per cent of the center frequency. For a magnetron operating at a wavelength of 3 cm this would represent a pulling figure of 20 Mc.

If the coupling from the magnetron to the transmission line is made tighter, the power output and the pulling figure at the match point will both increase. Nearly all magnetron output circuits are designed to provide some predetermined compromise of efficiency and pulling figure when the tube is operated into a matched line.

TUNING. The frequency of oscillation is determined almost entirely by the geometry of the cavities, that is, by the equivalent inductance and capacitance of the oscillator tank circuit. In order to tune the magnetron, it is necessary to change either the inductance or capacitance or both.

Figure 9 shows three tuning methods schematically. The inductive pin tuning method is depicted in (*a*). An array of copper pins is disposed so that they may be inserted and

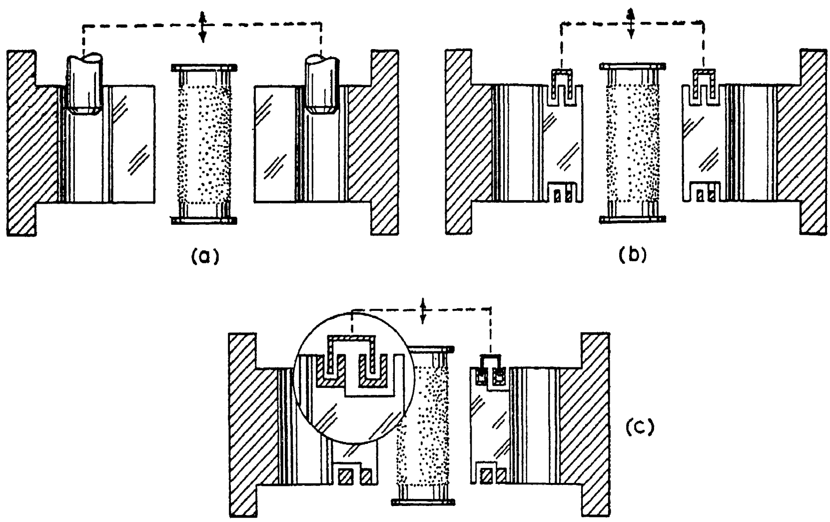

FIG. 9. Methods of Magnetron Tuning. (*a*) Inductive pin, (*b*) segment-to-segment capacitance, (*c*) strap-to-strap capacitance.

withdrawn from the inductive portion of the resonators. As the pins are inserted, the effective inductance is decreased and the frequency goes up. Capacitance variation schemes are shown in Figs. 9*b* and 9*c*. In (*b*), a movable conducting ring changes capacitance between the segments. In (*c*), the ring changes the capacitance of the straps. The schemes shown in (*a*) and (*c*) are capable of giving tuning ranges of about 20 per cent. The scheme shown in (*b*) is usually limited to a somewhat shorter tuning range for the reason that different modes tune at such widely varying rates with respect to tuner displacement that the π mode tunes but a relatively short distance before encountering interference from other modes.

KLYSTRONS

By A. L. Samuel

Electron tubes which make use of the principle of velocity modulation are now known as klystrons. The name klystron was originally a registered trademark. It is now applied to all tubes of the same general type without regard to the manufacturer. A klystron has been defined by the IRE as an electron tube in which the distinguishing features are the modulation or periodic variation of the longitudinal velocity of an electron stream without appreciable variation of its convection current and the subsequent conversion of this velocity modulation into convection-current modulation by the process of punching. All commercial tubes of the klystron type make use of cavity resonators, although such resonators are not, in principle, essential to their operation. Two types of klystrons are in general use: tubes of the first type bear no further designation: tubes of the second type are referred to as reflex klystrons or simply reflex tubes.

10. KLYSTRONS (EMPLOYING TRANSIT TIME BUNCHING)

A few typical klystrons are shown in Figs. 1 and 2. As already stated, it is customary, although not essential, to employ resonant cavities as the tuned circuits associated with the input and output portions of these amplifiers. These cavities take the place of conventional circuits and must be tuned to the operating frequency. They may be partly external to the tube proper, or they may form an integral part of the tube as supplied to the user. Cavities are used because they produce larger effective fields in the interaction gap regions than could be obtained by any other means.

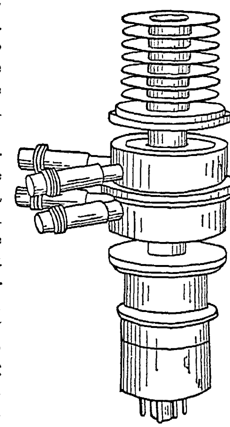

FIG. 1a. A Typical Klystron of the Integral Cavity Type Shown without Its Tuner. (The 3K30 oscillator amplifier.)

The basic principles of the klystron amplifier may be explained by referring to Fig. 3. This figure illustrates a tube which consists of (1) an electron gun, composed of a heater, a cathode, and auxiliary focusing electrodes; (2) an input region called the input gap, defined by two grids which in this case form a part of a cavity resonator; (3) a conversion region called the drift space which is relatively free of electric or electromagnetic fields; (4) an output region, called the output gap, again defined by two grids which form a part of a second cavity resonator; and (5) a collector electrode whose sole function is to collect the electron stream after it has traversed the working region of the tube. These five portions of the tube correspond directly to the five essential operations that must be performed in any electron tube. The separation of these operations makes it possible to consider them separately and to explain the operation of the device in very simple terms. These operations are, obviously, (1) the production of an electron stream, (2) the modulation or variation of some property of this stream in accordance with an input signal, (3) the conversion of the original modulation into a form in which it can be utilized, (4) the utilization of the stream to produce an output signal, and (5) the collection of the electron stream.

Referring to Fig. 3, the field in the input gap region of the tube varies the velocity of the electron stream in a cyclic manner, the variation in velocity being assumed to be small compared to the average velocity imparted to the stream by the d-c fields. Those electrons which arrive when the field is in an aiding direction are speeded up; those arriving a half cycle later are slowed down. The contributions in energy made by the field to some of the electrons of the stream is nearly balanced by the energy taken from those electrons which are slowed down. The modulating process, therefore, requires substantially no power, most of the input power being consumed by ohmic losses in the walls of the input cavity. All the electrons, except those intercepted by the grids, proceed through the next region of the tube, the so-called drift space, where the electron stream becomes bunched through the simple process of the faster electrons, that is, those that are speeded up by the field in the input gap, overtaking the group of slower electrons that precede them. This bunching process converts the original velocity modulation into a variation in the rate at which electrons pass any given point. The stream as it crosses the output gap appears superficially like the stream of electrons in the screen-grid plate region of the conventional space-

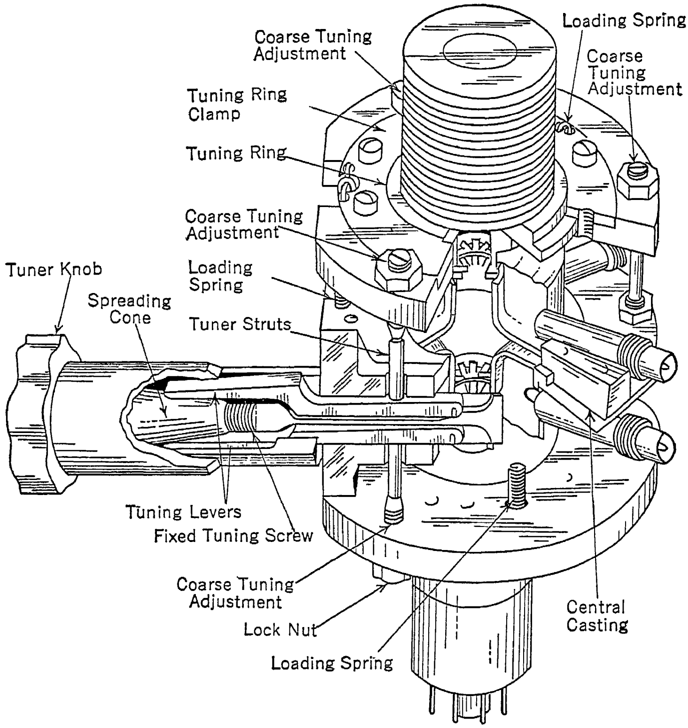

FIG. 1b. The 3K30 Shown in Section with an 11-C Tuner Attached

charge control tetrode. It, therefore, induces currents in the output cavity and delivers power to the output in just the same way that an electron stream delivers energy to the field between the screen and the plate of the conventional tube. The tuning of the output cavity must be adjusted to cause the maximum value of the field to occur in a retarding direction at the time that the effective center of an electron bunch crosses the output gap. Finally, the spent electron stream is collected by a final electrode where the energy remaining in the stream is dissipated as heat. This is to be contrasted with the action in the conventional tube where the plate performs the dual function of providing the output circuit retarding field and of dissipating unused energy as heat.

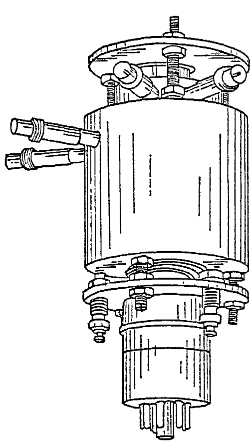

FIG. 2. The Type 2K47 Klystron Frequency Multiplier

An interesting possibility exists in the klystron amplifier of utilizing the electron stream in cascade to provide either a multistage amplifier or a combination function device such, for example, as an oscillator buffer amplifier. When the electron stream traverses the output gap in the simple amplifier, it obtains an augmented velocity modulation as a result of the higher field intensity existing in this cavity—this at the same time that the stream delivers energy to the cavity because of its bunched condition. This augmented modulation is in quadrature with the original

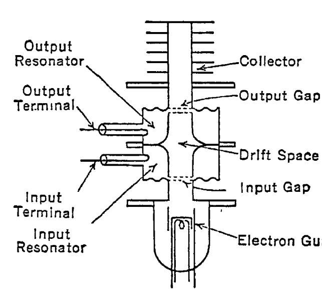

FIG. 3. A Sectional View of a Klystron Amplifier

modulation. At low modulation levels, such as those obtained in an amplifier, it can be thought of as existing quite independently of the original modulation. In the ordinary two-cavity single-stage amplifier, no use is made of this added modulation. However, by providing a second drift space and a third cavity, an additional stage of amplification can be obtained. The middle cavity or cascade cavity need have no external connection, although, if broad band amplification is desired, it is necessary to load this cavity in some fashion to reduce its effective Q to a value comparable to that of the input and output cavities which are loaded by their external circuit connections.

The gain of a klystron amplifier varies with the input signal level in quite a different way from the behavior of other types of amplifiers. At low levels, the gain depends only on the beam current, the beam voltage, and the physical dimensions of the tube. However, as the drive is increased beyond a certain point, the phenomenon of overbunching sets in and the gain begins to decrease. Eventually a maximum output is reached; with a further increase in the input, the output actually decreases. This is illustrated in Fig. 4, where the output as a function of the input is plotted for a typical klystron amplifier.

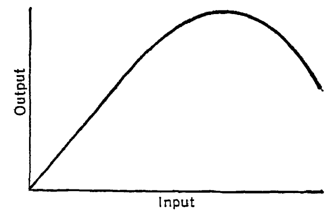

FIG. 4. The Variation in Output Power with the Input Showing the Effect of Overbunching

At low levels, the gain of a klystron amplifier is given by

$$\text{Gain} = Z_1 Z_2 M_1^2 M_2^2 S^2 \tag{1}$$

where Z_1 and Z_2 are the impedances of the input and output cavities respectively as measured across the interaction gaps. The parameters M_1 and M_2 are the absolute values of the input and output beam coupling coefficients or so-called modulation coefficients and express the effectiveness with which the fields in the cavities interact with the electron stream. The parameter S is the absolute value of the beam transadmittance and is a measure of the ratio of current variation produced by the bunching process to the equivalent voltage variation impressed on the beam.

The cavity impedances can be measured directly if desired, or they may be computed from measured values of the characteristic impedance and Q of the cavity.

The absolute value of the beam coupling coefficient for the gap between two axial cylinders without grids varies for different electrons depending upon their distance from the axis of the beam. The value for that portion of the beam lying at a radial distance from the axis of $\theta\rho$ where $\theta\rho$ is expressed in radians at the operating frequency and with tubes having a radius of θ_r (also in radians) is given by

$$M = \frac{\sin(\theta_g/2)}{\theta_g/2} \cdot \frac{I_0(\theta\rho)}{I_0(\theta_r)} \tag{2}$$

where the I_0's are modified Bessel functions of the first kind.

The absolute value of the beam coupling coefficient for an interaction gap between ideal grids is given by

$$M = \frac{\sin(\theta_g/2)}{\theta_g/2} \tag{3}$$

where θ_g is the electron transit angle of the gap defined as the time required for the unmodulated electron beam to cross the gap measured in radians at the operating frequency. The value of θ may be compiled from

$$\theta_g = \frac{3180X}{\lambda\sqrt{V}} \tag{4}$$

where X is the gap spacing, λ is the free space wavelength corresponding to the operating frequency, and V is the voltage corresponding to the velocity of the electron beam. The parameters X and λ are measured in the same units (usually centimeters), and V is in volts.

The absolute value of the beam transadmittance for low signal levels is given by

$$S = \frac{\theta I}{2V_0}\sigma \tag{5}$$

where θ is the electron transit angle in the drift space, I is the beam current in amperes, V_0 is the beam voltage, and σ is a reduction factor to account for certain space-charge effects that will not be discussed. In well-designed amplifiers, the parameter σ is usually of the order of 0.5 at the recommended operating conditions and increases to 1.0 as the beam current (at a given voltage) is decreased to a low value.

At high levels the beam transconductance is sometimes expressed as

$$S = 2IJ_1 \cdot \frac{(V\theta)}{(2V_0)} \tag{6}$$

where V is the value in volts of the velocity modulation impressed on the beam, and J_1 is a Bessel function of the first kind.

This expression is based on kinematic considerations only and neglects space charge and other sources of non-linearity. It may be used as a rough basis for predicting the general behavior of a klystron amplifier for large signals, but it does not agree quantitatively with experimental results.

11. REFLEX KLYSTRONS

A reflex tube or reflex klystron is a special form of the klystron oscillator employing a single cavity with a single interaction gap to perform the functions of both the input and output circuits (see Figs. 5 and 6). The electron stream is velocity modulated on a first transit of this gap and is forced to cross the gap a second time by means of a repelling or reflecting field. The electrons become bunched in the process of reflection, the speeded-up electrons penetrating the field to a great distance and therefore taking longer to return than the slowed-down electrons in just the same way that a ball thrown upward in the earth's gravitational field takes longer to return if thrown with high velocity than if thrown with low velocity. In order for the oscillations to be self-sustained, the returning bunches of electrons must arrive at the interaction gap at the correct phase of the alternating field, that is, when the field has its maximum value in the retarding direction. This requires that the electrons remain in the reflecting field region for a critically valued length of time, a time that is approximately $n + 3/4$ cycles at the operating frequency, where n is any integer equal to or greater than zero. This time can be adjusted by varying the velocity of the beam as it crosses the gap on the first transit or, more usually, by varying the voltage of the repeller. As the voltage of the repeller is varied, a series of operating regions

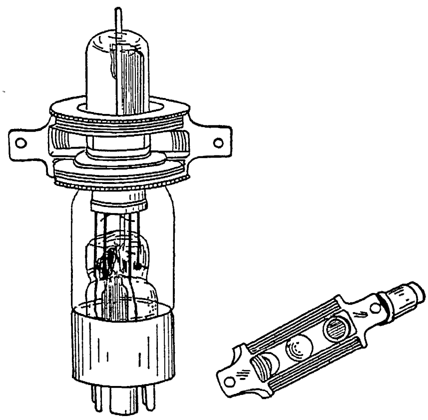

FIG. 5. The 707A Reflex Klystron Employing an External Cavity, Shown with the Cavity Partly Disassembled

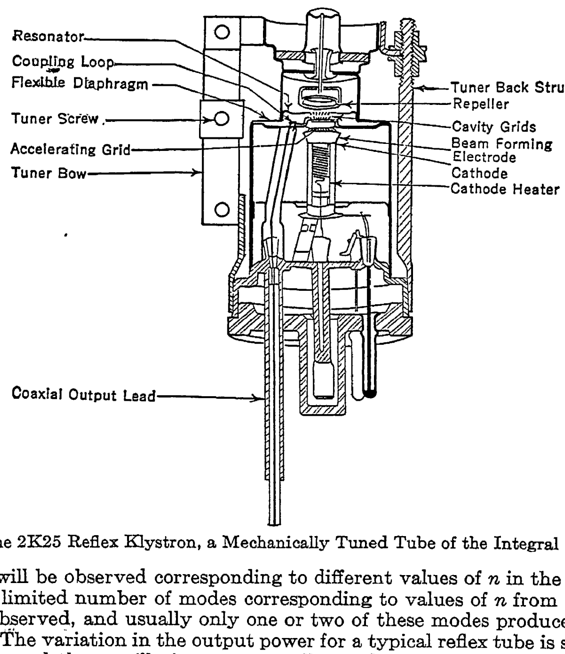

FIG. 6. The 2K25 Reflex Klystron, a Mechanically Tuned Tube of the Integral Cavity Type

called modes will be observed corresponding to different values of n in the above relationship. Only a limited number of modes corresponding to values of n from 1 or 2 to 4 or 5 are actually observed, and usually only one or two of these modes produce enough power to be useful. The variation in the output power for a typical reflex tube is shown in Fig. 7. It will be observed that oscillations are actually produced for a limited range in voltage in the vicinity of the optimum values, and that a variation of frequency occurs as shown by the top curves. This variation in frequency with voltage is called electronic tuning.

Electronic tuning is often employed as a means for critically adjusting the operating frequency in applications where the accompanying variations in the output power can be tolerated, such, for example, as a local oscillator in a superheterodyne receiver. Electronic tuning finds its greatest usefulness in connection with automatic frequency control circuits. Since the mode with the highest output has the smallest electronic tuning band width, a compromise must often be made between output and tuning range. The electronic tuning range is generally small as compared to the usual mechanical tuning range. When electronic tuning is employed, it is essential that the mechanical tuning be adjusted so that the operating point falls somewhere near the middle of the electronic tuning range where the frequency can be shifted a reasonable amount in either direction with the electronic control without too much change in output power. Electronic tuning and other associated phenomena can be explained by considering the way in which the impedance of the electron stream as seen by the cavity varies with the electron transit time in the repeller region.

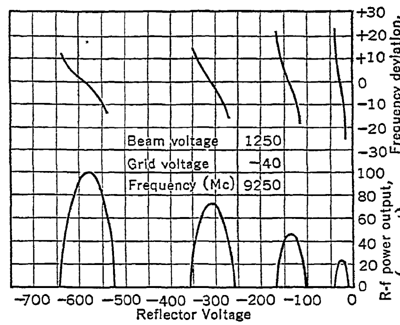

Fig. 7. A Typical Mode Curve for a Reflex Klystron Showing the Variation in Output Power and Frequency with the Reflector Voltage (Data for the 2K41 Tube)

Figure 8 is a plot of the small signal beam conductance showing the relationship

$$Y_g = \frac{M^2\theta I}{2V_0}\frac{J_1(VM\theta/2V_0)}{VM\theta/V_0}e^{j(\pi/2-\theta)} \tag{7}$$

where the first term represents the magnitude of small signal admittance, and the last term is the phase angle. Here θ is the transit angle in the repeller region, and the rest of the symbols have the same significance as in the article on klystrons employing transit time bunching. The second term accounts for the decrease in magnitude of the conductance which occurs for large signal levels and is similar to the compression term appearing in the expression for the small signal transadmittance of the klystron amplifier. The final term gives the phase angle of the conductance.

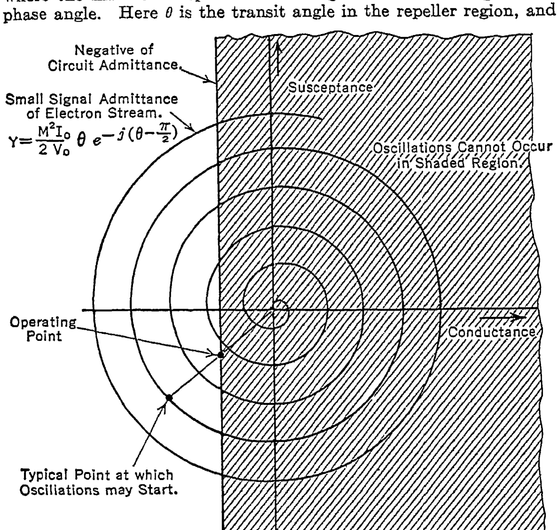

Fig. 8. The Admittance of the Electron Stream as Viewed from the Cavity for a Reflex Klystron. Oscillations can occur only in the region where the negative conductance of the beam exceeds the positive conductance of the circuit.

If the real part of this admittance is negative and larger in magnitude than the positive real component of the cavity admittance, oscillations will build up until limited by the non-linearity given by the second term. Under stable operating conditions, the relationship

$$Y_g + Y_c = 0 \tag{8}$$

must be satisfied, where Y_c is the admittance of the cavity. The cavity may be assumed to behave as a simple shunt tuned circuit in the vicinity of the resonant frequency so that

$$Y_c = G + \frac{j}{Q_0}\left(\frac{\omega}{\omega_0} + \frac{\omega_0}{\omega}\right) \tag{9}$$

where G is the cavity conductance, Q_0 is the cavity Q, ω_0 is the angular frequency at resonance, and ω is the angular frequency corresponding to the particular value of Y_c. The negative of this value is plotted in Fig. 8 and appears as the straight line to the left of the imaginary axis.

Oscillations will not be sustained for all values of Y_g lying in the shaded area on the figure. For values of Y_g lying to the left of the Y_c line, oscillations will build up until Y_g sinks along a radial line arriving at a stable operating point on this line. If the operating point lies on the real axis, the oscillations will occur at the resonant frequency of the cavity. Operating points off the axis correspond to oscillations at a frequency which differs from the resonant frequency by a sufficient amount to provide the necessary reaction component of admittance specified by the operating point. This effect is called electronic tuning.

The output impedance characteristic of a reflex tube can best be illustrated by plotting this characteristic on the reflection coefficient plane (sometimes called a Rieke diagram on a Smith chart). A typical plot is shown in Fig. 9, where lines for constant power are shown solid and lines for constant frequency are plotted on a background of orthogonal circles representing fixed values of the resistive and reactive components of the load impedance. The region on the plot where the constant-frequency lines tend to converge is called the

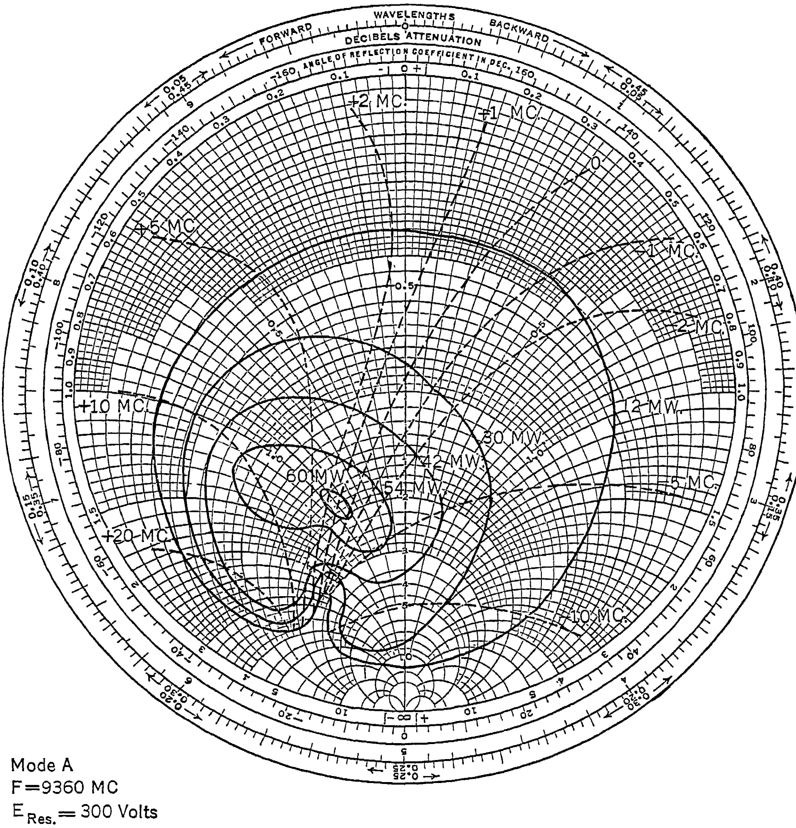

FIG. 9. The Variation in Output Power and Frequency with the Load Impedance for a Typical Reflex Klystron (the 2K25) Shown on the Reflection Coefficient Plane

frequency "sink," and the minimum amplitude of standing wave ratio that will cause the tube to operate in this region of discontinuity is called the "sink margin." It is customary to require a sink margin of 8 db. A second important characteristic is the so-called pulling figure which is defined as the maximum difference in frequency produced when a mismatch, having a reflection coefficient of 0.2 as measured at the prescribed output coupler, is varied through 360°. The pulling figure for the tube shown in Fig. 9 is approximately 4 Mc.

The power output, electronic tuning sink margin, and pulling figure for the typical reflex tube will be found to vary somewhat over the mechanical or thermal tuning range of the tube. Curves showing these variations for any particular tube are customarily supplied in the technical information sheets published by the manufacturers.

The coarse adjustment of frequency is usually made by mechanical means, either by varying the effective size of the external portion of the cavity or by internal changes, usually of the length of the interaction gap, and hence of the effective capacitance loading of the cavity. In most tubes where capacitance tuning is employed, the necessary motion is transmitted through the vacuum envelope by means of a flexible diaphragm. Recently, a number of tubes have been introduced in which mechanical cavity tuning is produced internally by thermal expansion means. This method, called thermal tuning, makes it possible to adjust the frequency of the tube over its entire mechanical tuning range by electrical means, without the large variations in output power that are encountered with electronic tuning. The thermal tuning speed is limited by the thermal capacity of the tuning mechanism, but it is sufficiently fast for many automatic frequency control applications.

12. TUBE TYPES

Many of the tubes listed in Table 1 were made for the armed services during World War II, and some may not be commercially available. The prospective user should consult the manufacturer in regard to their availability and should follow his recommendations regarding operating conditions and ratings. The data of Table 1 are indicative of typical operating conditions and are supplied for general reference purposes only.

GASEOUS CONDUCTION TUBES

By D. S. Peck

For definitions of gas tube, anode, cathode, etc., see pp. 4-03 to 4-06.

Arc. An arc is a discharge of electricity through a gas, characterized by a change in space potential in the immediate vicinity of the cathode which is approximately equal to the ionizing potential of the gas. (Proposed for Standards for Pool-cathode Mercury Arc Power Converters, AIEE.)

13. GASEOUS CONDUCTION

Gaseous discharges may be classified in two groups according to the mechanisms for producing ionization. The first group, "self-sustaining discharges," includes those in which the energy for maintaining the discharge is supplied directly by the discharge. The other group includes those that require some auxiliary power in addition to the energy of the discharge itself.

SELF-SUSTAINING DISCHARGES. One of the earliest known gaseous-discharge devices, the Crookes tube, is a typical example of a self-sustaining discharge. In that tube, cylindrical in form and containing a low gas pressure, a luminous discharge takes place if potential of sufficient value is applied between two electrodes. The appearance of the glow is shown diagrammatically with the corresponding voltage distribution in Fig. 1.

It will be observed that immediately adjacent to the cathode is the Crookes, or cathode, dark space. Across this space a large part of the total tube drop is concentrated. This drop is such that ions moving toward the cathode obtain sufficient energy to remove electrons from the cathode by bombardment and hence maintain ionization in the tube.

Following the cathode dark space is a luminous region, called the negative glow, in which some of the excited atoms are returning to normal, radiating energy in the form of light.

Following the negative glow is another dark space called the Faraday dark space, then another luminous portion called the positive column which extends to the anode.

This general type of discharge is used for the production of light in many neon and argon signs. It is also employed in protective tubes and in glow tubes used for voltage regulation, as well as in cold-cathode relay tubes.

Another form of self-sustaining discharge is found in tubes employing a pool cathode. Here the current densities run much higher than in a glow discharge, and the cathode dark space becomes very small so that extremely high gradients are present close to the emitting "spot." It is thus possible to release electrons without the high drop generally found in so-called glow discharge tubes similar to the Crookes tube. With a pool cathode, emission appears to be true field emission caused by voltage gradient, and not thermal emission caused by the high temperature of the spot.

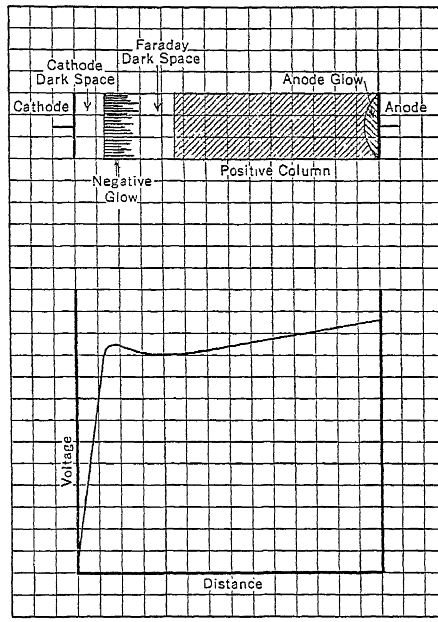

FIG. 1. Voltage and Glow Diistrbution in Glow Discharge

DISCHARGES REQUIRING AUXILIARY ENERGY. One of the commonest forms of this type of discharge is the hot-cathode tube. Here a heated filament or cathode, by virtue of the thermal energy imparted to the surface molecules, is able to release electrons. These electrons are drawn from the cathode by the anode field and after sufficient travel acquire enough energy to ionize the gas atoms by collision. The discharge is very similar in structure to the glow discharge from a cold cathode, except that the region of cathode fall is very much smaller and has a lower voltage drop since the electrons are actually ejected by the emitting properties of the cathode.

Other sources of ionization are possible, such as heat, photoelectrons, and radiation.

CONTROL OF THE DISCHARGE. If, in a simple tube with a cathode and an anode, a third element known as a grid is introduced between cathode and anode, it is possible to control the starting of the discharge. If the grid is made sufficiently negative with respect to the cathode, it produces a retarding field at the cathode in spite of the positive anode potential and most of the electrons emitted from the cathode are turned back without receiving sufficient energy to cause ionization. If the grid is then gradually made less negative, a critical voltage is reached where some electrons acquire enough velocity to ionize the gas. Within a few microseconds the ionization builds up until the current is limited only by the impedance of the external circuit.

Once ionization is complete, further changes in grid voltage have little effect on the discharge in most practical cases. If the grid is made negative, positive ions from the discharge will move toward it, causing a grid current to flow and blanketing the grid sufficiently to prevent its having any further effect on the arc. The grid becomes "sheathed" with positive ions, the thickness of the sheath depending upon the density of ionization and, to some extent, upon the grid voltage. The sheath thickness may be of the order of hundredths or thousandths of a centimeter under normal operating conditions. Only by using grids with very small openings and relatively large negative voltages is it possible to make the sheaths large enough to overlap and extinguish the discharge. If, however, the discharge ceases, as it would when alternating potential is used for the anode supply, the ionization diminishes to a low value or disappears in a relatively short period of time, and the grid may again exercise its control function.

VACUUM-TUBE CONTROL VS. GAS-DISCHARGE CONTROL. The characteristic of a grid-controlled gaseous-discharge tube of passing either no current or full current, together with the normal inability of the grid to stop the discharge, are two important differences from hard-vacuum grid-controlled tubes. Although both types possess the unidirectional conduction properties of a rectifier, the hard-vacuum tube with its continuous control may be likened to a rheostat in series with a circuit, whereas the gas-filled control tube may be considered similar to a switch which can be closed at any time but opened only when current is not flowing. Obviously, the hard-vacuum tube, which functions like a rheostat, must be capable of dissipating the power losses caused by pasage of current through the tube when the voltage across the tube is increased. The low voltage drop (from about 5 to 15 volts in most hot-cathode tubes) existing when the gas tube is passing current results in relatively low losses in the tube, and there is no plate dissipation whatever when the tube is turned off. Thus, a gas tube is capable of handling much heavier currents and more power than a hard-vacuum tube of the same size.

Because of the difference in control characteristic the circuit technique used with gas tubes is entirely different from that employed with hard-vacuum tubes. For instance, the gas tube may be used as a sensitive relay to operate a contactor when the grid voltage of the tube reaches a given value. With a voltage of adjustable phase relation on the grids it may be used as a controlled rectifier tube to control average output voltage. The gas tube may also be used in suitable circuits to change direct current to alternating current or alternating current of one frequency to alternating current of a different frequency.

14. THYRATRON TUBES

A thyratron is a hot-cathode, gas-discharge tube in which one or more electrodes are employed to control electrostatically the starting of the unidirectional current flow. (IRE Standard.)

These types of tubes cover an intermediate power range. Tubes are available in sizes up to 12.5 amp average current and up to 15,000 volts peak. (See Table 1.)

Similar gas tubes are built without grids for use as rectifiers. Since their major single application is in transmitting circuits, they are listed in article 13 with transmitter tubes.

CONSTRUCTION. Figure 2 shows a typical construction of a simple filamentary-type gas tube. The filament is in the form of a ribbon of nickel or nickel-cobalt alloy, formed in a helical or S-shaped form, and coated with an electron-emissive coating. A grid in the form of a cylinder is mounted as shown, and supported by a clamp from the lower stem. The grid may also be mounted on the stem leads and supported additionally from the glass at the top of the tube. The nickel anode in the form of a cup is mounted by means of another glass stem at the top. A washerlike cross piece in the grid determines the control characteristic by its relative spacing between cathode and anode and by the size and shape of a hole in the washer. The sides of the grid shield the control area from effects of charges collected on the glass walls and from extraneous fields. Carbonized nickel is frequently used for these parts because of its heat-radiating properties, but bright nickel is sometimes necessary in inert-gas-filled tubes. Argon, xenon, and mercury vapor are the most common mediums for gas tubes.

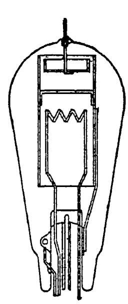

FIG. 2. Filamentary-type Thyratron Tube

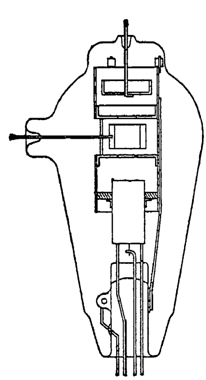

FIG. 3. Shield-grid Type of Thyratron Tube

FOUR-ELECTRODE CONSTRUCTION. Figure 3 shows a sketch of a shield-grid type of construction. The large shield grid, generally held at a fixed potential, permits the use of a small control grid of extremely high effective input resistance. The shield grid shields the control grid from the heat of the cathode and anode and minimizes the possibility of sputtered or evaporated material from the cathode contaminating the grid,

with consequent reduction in grid emission. The shield grid may act also as an electrostatic shield to prevent sudden voltage fluctuations of the anode from inducing transient voltages on the grid with consequent loss of control. Of course, it is also possible to use tubes of this shield-grid type with "signal" voltages on both electrodes so that operation of the tube is a function of both grid potentials.

METAL TUBES. Metal envelopes are used for many industrial tubes, particularly in the larger sizes, because of the greater sturdiness and dependability of metal than of glass and to facilitate mounting the tubes on a panel. In the medium or smaller sizes this construction frequently has no real advantage over glass tubes because internal tube elements may be as subject to breakage as the envelope under conditions of shock or vibration.

15. VOLTAGE LIMITS OF THYRATRONS

PEAK INVERSE ANODE VOLTAGE. Peak inverse anode voltage is the maximum instantaneous anode voltage in the direction opposite to that in which the tube is designed to pass current. (IRE Standards on Electronics, 1938.)

The maximum peak inverse voltage which can be applied is a function of the shape and spacing of the electrodes, the current conducted, and the gas pressure. In thyratrons having argon or xenon or some other inert gas, the arcback potential is relatively independent of the tube temperature. In mercury-vapor tubes, however, the mercury-vapor pressure doubles roughly with every 10 deg cent increase so that the maximum peak inverse voltage is seriously affected. Figure 4 shows a typical curve of arcback voltage vs. temperature for a mercury-vapor tube. In rating a tube of this class, therefore, it is necessary to specify not only the peak inverse voltage but the maximum condensed-mercury temperature as well.

In designing a tube for high-voltage operation, it is sometimes necessary to constrict completely the space at the back, or top, of the anode, so that it is impossible for any discharge to take place between the anode and cathode around the outside of the grid.

PEAK FORWARD VOLTAGE. Peak forward voltage is the maximum instantaneous anode voltage in the direction in which the tube is designed to pass current. (IRE Standards on Electronics, 1938.) The same factors of tube geometry and current affect the maximum permissible peak forward voltage. In addition the grid must be so designed as to maintain the proper characteristics up to the voltage desired.

TESTS. The peak forward voltage may be tested by measuring the control characteristic at the maximum temperature ratings, although a common test is a full-load operation of the tubes in a circuit giving both peak inverse and peak forward voltages. This operation continues at the rated average current of the tubes for a length of time sufficient to stabilize the tube temperature, at which time the grid control is checked. The frequency of arcback is also observed. The severity of the test varies considerably with the current and voltage conditions at the time of current commutation from one tube to the next; therefore the type of operation circuit used is important. When simple circuits are used the voltage is frequently set above the rating to make the test sufficiently severe.

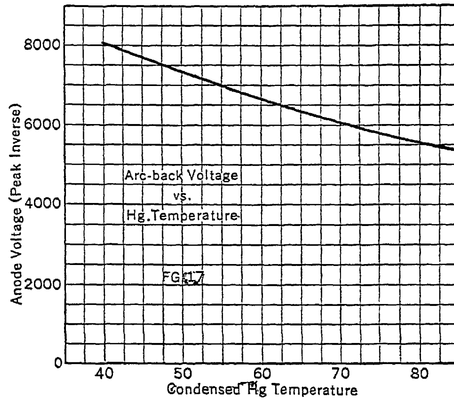

FIG. 4. Relation between Arc-back Voltage and Condensed Mercury Temperature in Typical Thyratron Tube

16. CURRENT LIMITS OF THYRATRONS

Most commercial tubes have cathodes made by coating a base metal such as nickel or a nickel alloy with one of two types of coatings. The first is barium oxide or a mixture of barium, strontium, and calcium oxides, formed by coating with the carbonates and reducing to the oxides by high temperature during the processing. The second is a molecular mixture of barium oxide and nickel oxide known as barium nickelate, formed by coating with barium carbonate and a nickel oxide before processing.

Cathode construction is of two general types, the filamentary and the indirectly heated. The filamentary type is simple in construction and has a relatively short heating time. The usual absence of heat shielding, however, reduces the efficiency, requiring more watts per ampere of emission, and increases the heat that the tube must dissipate. The indirectly heated type inherently lends itself to more efficient use of the cathode surface, thereby reducing the heating power required. It has the disadvantage of greater expense and longer heating time, a factor that is becoming more and more important.

By raising the cathode temperature it is usually possible to raise the emission per unit area and the emission per watt heating power. However, this raises the rate of coating evaporation and, if carried too far, shortens the life of the tube.

PEAK ANODE CURRENT. The peak current that a tube is capable of passing without harm depends upon the area, the temperature, and the geometry of the cathode surface, and somewhat upon the pressure of the gas. If the rated value is exceeded, the tube voltage drop may increase so that destructive ion bombardment of the cathode occurs. Also, particles of coating may be mechanically sputtered from the cathode to the grid, where they are a potential source of grid emission. There is the further possibility of sudden cessation of current flow, particularly at low gas pressure where the ion density is insufficient to neutralize the space charge at points where the discharge is the most dense. This is commonly known as "starvation" and may result in voltage surges in the circuit in which current has been flowing, sometimes breaking down insulation of the circuit components. The barium nickelate coating is less subject to this trouble since the coating is more conductive and will stand a higher arc drop without sputtering or surging.

AVERAGE ANODE CURRENT. Because of the essentially constant tube voltage drop over the current range, tube heating during operation is a function of average current, rather than rms current as in most electrical apparatus. Overloading causes excessive heating of all the tube electrodes and may result in failure because of (1) evolution of sufficient foreign gas to render the tube inoperative, (2) grid emission and loss of control due to high grid temperature, (3) arcback due to the high temperature of the anode, (4) short cathode life due to high evaporation, or (5) mechanical failure of the envelope or seals.

ANODE CURRENT AVERAGING TIME. When the load is fluctuating, as it might with a motor load or welding control, the average current must be calculated over a specified period of time chosen so as to include the worst current conditions. For example, consider two tubes having a maximum average current of 12.5 amp, a maximum peak current rating of 75 amp, and an averaging time of 30 sec in a biphase half-wave rectifier with sufficient inductance to make the d-c ripple negligible. These tubes could supply to the load 75 amp for 10 sec, 50 amp for 15 sec, or 25 amp for 30 sec out of every 30 sec without exceeding either peak or average rating.

GRID CURRENTS. In order to prevent overloading of the cathode or the grid through the grid circuit, a maximum instantaneous grid current and a maximum average grid current rating are generally given. Under most conditions of operation, grid currents are much less than these ratings.

ANODE SURGE CURRENT. The anode surge current is the current which would be conducted through the anode under fault conditions. The maximum surge current rating is a measure of the ability of the tube to withstand extremely high transient currents. The tube should carry the specified current for not longer than a given length of time in the event of short circuit, but it should not be expected to carry repeated short circuits without a reduction of life and the possibility of immediate failure. This rating forms a basis for set design to obtain best tube performance. If sufficient impedance is present to limit the fault current to this rating, not only will the tube be able to carry that current in the event of a fault in the circuit, but also the possibility of a fault in the tube itself seems to be reduced.

TESTS. Tests for maximum average current are generally made by operating the tube at full load and checking the other ratings which are dependent upon tube temperature, as described in other sections.

As has been stated, the peak current rating is a function of the emissive capabilities of the cathode, and the best test of this is, after all, satisfactory life while operating at that peak current. Several methods have been used for testing the emission, however. A simple test is to conduct an average current through the tube of a value between the average and the peak ratings and then measure the tube voltage drop with a d-c meter across the tube or with the deflecting plates of an oscilloscope connected from anode to cathode. This method does not discriminate very well between good tubes and bad except for some small tubes where the average current may be held fairly high for the test. It will suffice for a rough check on any tube, if used within the rating.

If, with the oscilloscope and a suitable d-c amplifier across the tube, the tube is allowed to conduct the peak rated current for only a few half-cycles each second, the cathode temperature is not altered appreciably by the load current, and the tube drop may be used as an accurate indication of cathode quality. Figure 5 shows a typical trace observed on a good tube, and Fig. 6 shows a low-emission tube in which the drop rises to an excessive value at the maximum current point.

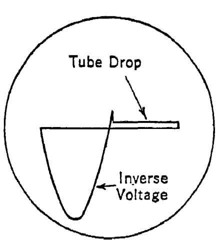

FIG. 5. Trace on Cathode-ray Oscilloscope Indicating Good Emission

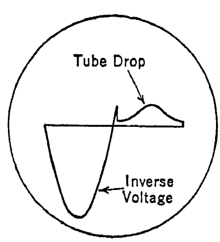

FIG. 6. Trace on Cathode-ray Oscilloscope Indicating Poor Emission

Another method of testing the emission is to conduct half-cycle pulses as above, but of increasing current magnitude, so that the point is finally reached where the cathode "sparks" or sputters, giving a broken voltage drop trace. The "sparking point" can be calibrated against the peak current rating to give a proper test.

In all such tests, the temperature of mercury-vapor tubes should be controlled quite accurately by an oil bath or controlled-flow air bath.

Surge current tests are generally made by the manufacturer on a given design of tube to insure a construction sufficiently rugged for ordinary service. Since these tests detract from the life of the tube, they are not part of the normal test procedure. In general, the test is made by passing the rated surge current through the tube with some protective device or control device arranged to open in a definite time, generally 0.1 sec. After the tube has been subjected to one or more overloads of this type, it is given an operation test for general performance.

17. CONTROL CHARACTERISTICS

Control Characteristic. The control characteristic of a gas tube is a relation, usually shown by a graph, between critical grid voltage and anode voltage. (IRE Standards on Electronics, 1938.)

Critical Grid Voltage. Critical grid voltage in a gas tube is the instantaneous value of grid voltage when the anode current starts to flow. (IRE Standards on Electronics, 1938.)

Critical Anode Voltage. The critical anode voltage of a gas tube is the instantaneous anode voltage when the anode current starts to flow.

As previously explained, once a thyratron is passing anode current the grid has little effect on the anode current, which is then limited only by the impedance of the load in the anode circuit. There are, therefore, no thyratron characteristic curves relating anode potential, grid potential, and anode current as there are for vacuum tubes. The relationship between anode voltage and grid voltage which just permits conduction, known as the control characteristic, is of considerable importance, however.

In an inert-gas-filled tube, there is a negligible change of characteristic with normal temperature changes. There are initial variations between tubes, however, and there are further changes in any given tube with life, the characteristic shifting slightly more negative as the emission becomes completely stable, and then shifting more positive as the end of the tube life approaches. Figure 7 shows the typical control characteristic of a small thyratron, the range of curves covering all variations between tubes and with life. This shows the equipment designer what range he may expect and must design for. In mercury-vapor tubes, the characteristic changes greatly with mercury temperature and the temperature must be specified for such a curve, or the range must be extended to include the variations within the published temperature limits. Figure 8 shows the variation in the control characteristic of a mercury tube with varying temperature.

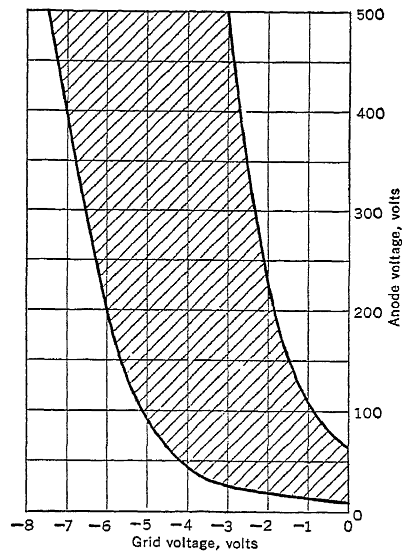

FIG. 7. Typical Thyratron Control Characteristic. (Shaded Area Shows Range of Characteristics.)

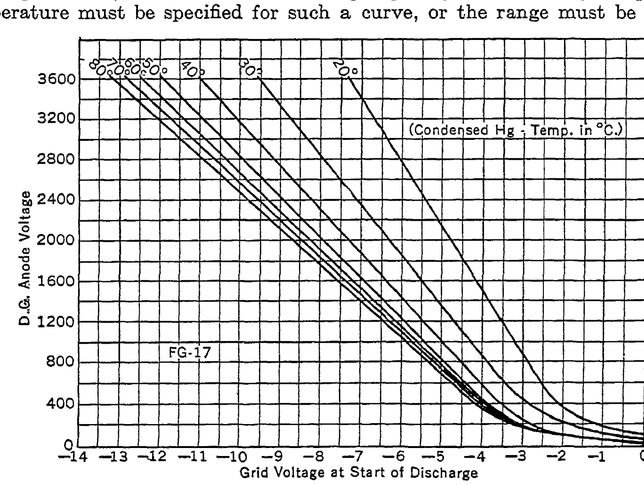

FIG. 8. Control Characteristics for a Mercury-vapor Thyratron

It will be noted that the critical grid voltages of the tubes shown are negative over the greater part of the operating range. As long as the grid is more negative than the cathode, electrons emitted from the cathode cannot flow to the grid, and there is no grid current from this source. Control is possible therefore with the use of a very small amount of grid power, which is the advantage of such a "negative grid" tube.

"Positive grid" tubes are available in which it is necessary to force the grid positive over the entire operating range to fire the tube. To assure non-conduction it is required only that the grid circuit be opened or the grid held at zero voltage or allowed to float. These application advantages are offset, however, by the fact that considerable power must be available to drive this type of tube, and sometimes a discharge takes place between grid and cathode before the anode-cathode path becomes ionized.

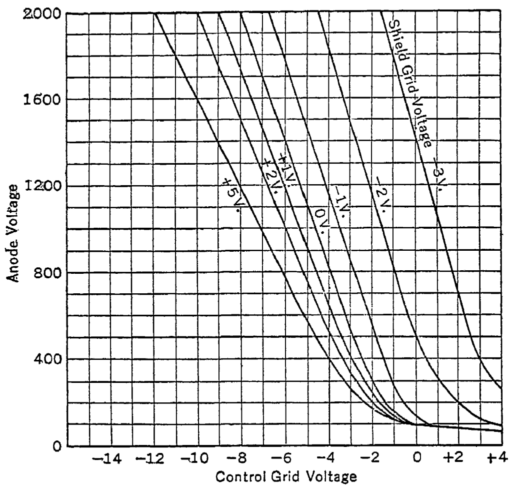

Fig. 9. Control Characteristics for Shield-grid Type of Thyratron, Showing Effect of Shield Potential

SHIELD-GRID CHARACTERISTICS. In four-electrode tubes the firing point becomes a function of the potential of both grids. Figure 9 shows how the control characteristic curve varies with shield-grid potentials. With negative shield-grid potentials, however, the variations between tubes become excessive with many types. The shield-grid signal may be used as a control to switch the characteristic in or out of the operating range of the circuit, and in some cases may even be used, with the necessary adjustments, to obtain a desired control curve.

GRID CURRENTS. The grid currents in a thyratron, both before and after discharge, are extremely important in determining the necessary grid power or the permissible impedance in the grid circuit.

Critical grid current in a gas tube is the instantaneous value of grid current when the anode current starts to flow. If a high grid resistance is used and this critical grid current

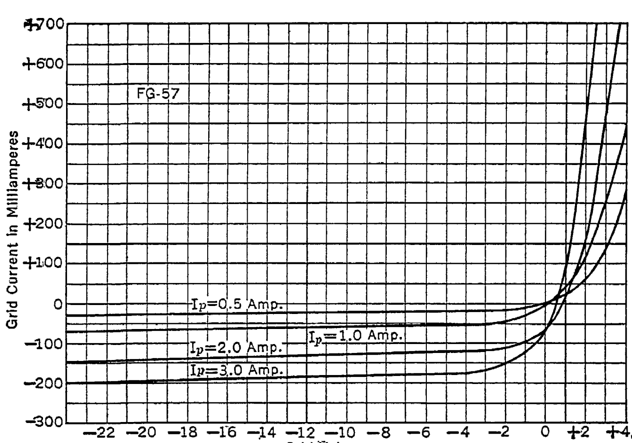

Fig. 10. Grid Voltage–Grid Current Curves after Breakdown in Three-electrode Thyratron

becomes excessive, owing to overheating and grid emission, enough voltage drop across the grid resistance may result so that the available grid supply voltage is not sufficient to control the tube. This current, then, becomes a limitation on the grid supply voltage and impedance and on the time constant with which the grid circuit can operate.

Figure 10 shows the grid current in a 2.5-amp average, three-electrode thyratron after discharge has occurred. Negative values indicate positive ion current to the grid from the discharge, and positive values indicate electron current. A four-electrode tube, otherwise similarly designed, would have roughly one-tenth the amount of grid current under these conditions.

Figure 11 shows the grid current for various anode voltages immediately before the start of discharge on the same three-electrode tube, and Fig. 12 shows the same for the equivalent four-electrode tube.

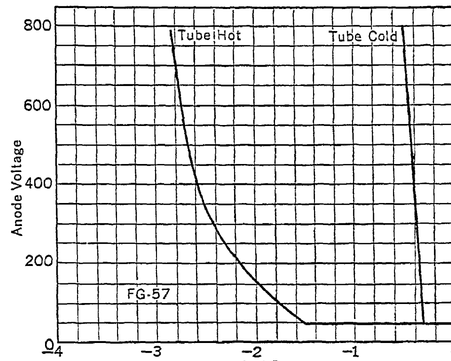

FIG. 11. Grid Current before Breakdown in Three-electrode Thyratron

TESTS. The control characteristic should be tested to the specified limits, usually at two or more values of anode voltage. A sufficient d-c control grid voltage should be applied to prevent conduction (or firing), through a low grid resistance. The specified d-c anode voltage is applied and the control grid gradually made more positive until breakdown occurs to the anode, at which time the critical grid voltage is observed. Condensed-mercury temperature should be controlled.

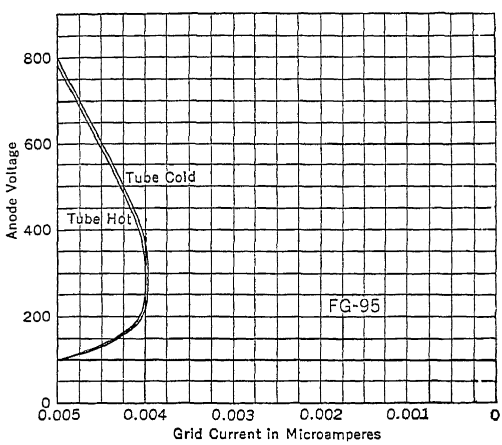

FIG. 12. Grid Current before Breakdown in Shield-grid Thyratron Tube

The critical anode voltage may be observed by holding the grid at zero voltage and increasing the anode supply until firing occurs.

The critical grid current is generally measured as shown in Fig. 13. The tube is first operated at the full average current rating as indicated by a d-c ammeter in the anode circuit, in order to heat all the parts to their operating temperatures. With the grid resistor r_g short-circuited, the grid supply voltage is then made more negative until the tube ceases to conduct. This is possible since an a-c supply is used and the tube does not conduct during the negative half-cycle. This voltage reading is denoted by V_1. Another reading is immediately taken with r_g in the circuit. With most tubes, a value of r_g between 10 and 100 megohms is sufficient to make the second reading, V_2, considerably higher than V_1. Since the actual critical grid voltage measured directly at the grid is the same in both measurements, the difference in the two readings must be accounted for as voltage drop in the resistor r_g. The grid current, therefore, is given as: $i = (V_2 - V_1)/r_g$. This reading of grid current includes currents from the ionized space to the grid, leakage currents, and grid emission. If the test is made without previous operation of the tube, the grid-emission factor will be eliminated.

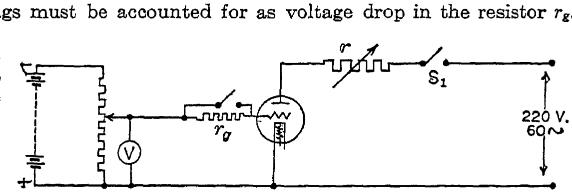

FIG. 13. Circuit Used to Check Grid Emission

DEIONIZATION TIME. Deionization time of a gas tube is the time required for the grid to gain control after interruption of the anode current. This varies with condensed-mercury temperature, anode current, anode voltage immediately after discharge, grid voltage, grid circuit impedance, and a number of other factors. Not only is the peak anode current just before discharge ceases important, but the wave shape is also, since in some cases the ionization due to an earlier peak current may decay less rapidly than the current, thus requiring a longer deionization time. Forcing the anode and grid negative immediately after the discharge has ceased decreases the deionization time since positive ions are then attracted to these electrodes, where they are neutralized.

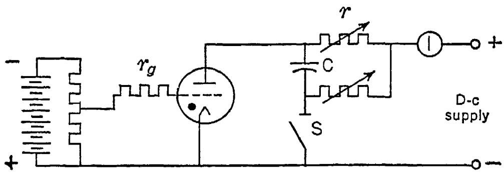

FIG. 14. Circuit Used to Check Deionization Time

To restore control to the grid it is not necessary to remove all the ions from the grid-anode space but only to reduce the number to a value sufficiently low so that the grid sheaths overlap enough to prevent discharge when a positive anode potential is again applied. Ions may still be present near the anode or near the cathode, with the grid having control. This shows why the grid voltage and stiffness of the grid circuit may be relatively more important in deionization than the anode circuit.

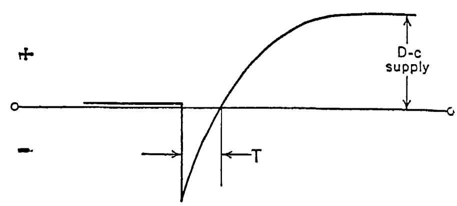

FIG. 15. Typical Anode-cathode Voltage Trace during Deionization Time

Since deionization time varies so widely with all these variables, it is essential to know all these conditions under which a measurement has been made. A recommended circuit for making such tests is shown in Fig. 14. The operation is briefly as follows:

The tube under test is conducting a specified d-c current. The capacitor C is connected in parallel with the load resistor R and therefore charges so that the negative capacitor plate is connected to the tube anode. When the switch S is closed, the capacitor makes the anode voltage of the tube instantly negative, thus stopping the discharge. The capacitor then recharges through the load resistor until the anode voltage of the tube and the capacitor voltage are equal to the supply voltage. The rate at which this anode voltage becomes positive depends upon the value of the capacitor C and of the load resistor, r. These values can easily be used to calculate the length of time from stopping of the discharge until the anode voltage again becomes positive, approximately the point at which the tube would conduct if deionization is not complete. At the capacitor setting at which the tube fails to control, the deionization time can be calculated from the formula $T = 0.693rC$. Any desired grid conditions may be used and the effect of these factors determined. Figure 15 shows a typical anode voltage trace during the test operation.

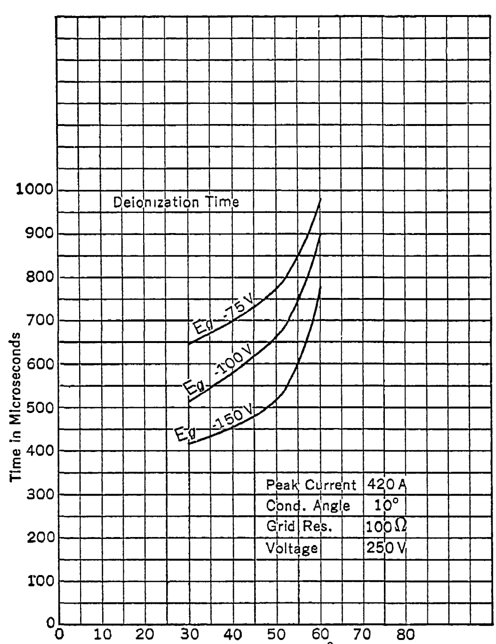

FIG. 16. Deionization Time Shown as a Function of Mercury Temperature

Other modifications of this circuit may be used to allow greater variation of anode voltages, or inverter circuits may be set up which will operate the tubes under more extreme conditions. Figures 16, 17, and 18 show the effect of some of the factors mentioned above.

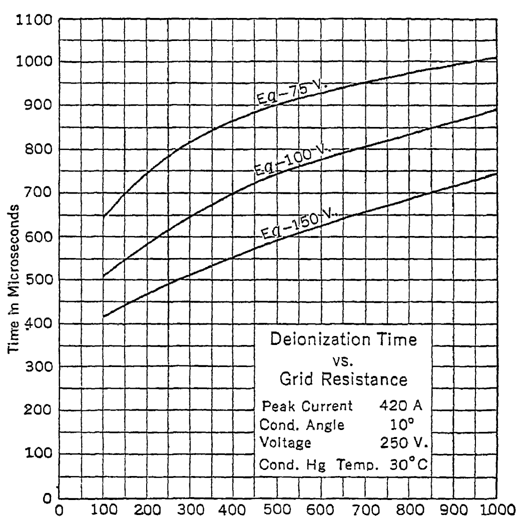

FIG. 18. Deionization Time Shown as a Function of Grid Resistance

18. PULSE THYRATRONS

As described in Section 9, Pulse Techniques, many circuits have been developed in which the currents are essentially square-wave pulses. One application of this sort provides modulated power for driving a magnetron; here a thyratron is used to discharge a pulse-forming line or network, previously charged to a high d-c voltage, through a pulse transformer into the load. The thyratron is in series with the line and load, and it carries a pulse current of magnitude determined by the voltage charge on the line and the combined impedances of the line and load.

PULSE VOLTAGES. During the charging of the line, the thyratron is subjected to the full instantaneous network voltage, so that it must be capable of holding off this voltage. It is generally desirable that this be done with zero grid bias on the tube, and consequently pulse tubes are designed so that they will fire only when considerable positive voltage is applied to the grid. This is generally of the order of 50 to 100 volts, although a higher voltage may be required by the manufacturer's data in order to insure that firing will occur with a minimum of time variation.

Time jitter is a common term for expressing the variation in the length of time from application of the grid firing voltage until start of the anode current pulse. Although the actual amount of this delay time is not so important, any variation tends to destroy the usefulness of systems in which the pulse may be as short as 0.1 microsecond. In order to keep the time jitter appreciably lower than this figure, the trigger pulse applied to the grid should have a steep wave front and a peak voltage appreciably higher than the minimum required to cause ionization. The internal impedance of the trigger supply must also be low enough to provide sufficient grid power to assist in accurate firing.

At the end of the anode-current pulse, depending on the ratio of load and line impedances, the voltage across the line, and hence across the tube, may become negative. The allowable negative voltage is limited because of the possibility of the remaining ionization causing arcback. After deionization is complete, the inverse voltage may be increased, generally to about the forward rating; deionization will generally occur in a fairly small percentage of the total time of application of inverse voltage and will allow the use of a-c charging voltages, other factors being satisfactory.

Tubes are tested for their voltage capacity by operation in a pulse circuit at the required forward voltage, peak pulse current, pulse width and repetition rate, and inverse voltage, and with a grid circuit which represents the minimum driving conditions which may be allowed.

PULSE CURRENTS. Pulse operation for thyratrons was not originally developed for industrial applications, and the life expectancies under such operation have been somewhat lower than those of other uses or other tubes. Cathode processing requirements are different, to the end of obtaining from 10 to 20 times the peak current density that is obtained from industrial tubes. These currents are limited in duration, however, to a pulse width of the order of 5 microseconds.

Many tubes designed for industrial operation are found to operate satisfactorily in low-power pulse circuits at much higher currents than their nominal ratings, and satisfactory pulse ratings have been developed for some industrial tubes.

Pulse tubes are generally rated for a maximum pulse repetition rate, pulse width, average current, and duty. For service in which none of these factors vary with time, the pulse width (in seconds) times the repetition rate (in pulses per second) will give the duty, or fraction of the total time, during which the tube is actually carrying a current pulse. This also serves as a relation between the peak and average currents, and thus limits the heating of the tube electrodes. In some applications it may be desirable to operate the tubes at a varying repetition rate; in this case the duty is sufficient to define the average current, and it becomes necessary to consider the minimum amount of time allowed between adjacent pulses to take care of deionization.

Because of the type of gas used in order to meet the strict deionization requirements, and the current densities used, the tube voltage drop during the pulse is inherently high. In addition, ionization requires some amount of time, during which time the arc voltage will be even higher. As a result, the tube voltage drop may rise to an initial value of 100 to 300 volts and then drop during the pulse to a value of 50 to 100 volts, these figures depending on the type of tube and other factors. A value may be read at some specific time during the pulse as an indication of tube quality, or the tube voltage may be plotted against the tube current on an oscilloscope, the shape of the resultant curve serving as a basis for judgment. In this case the voltage is generally higher during the rising current than during the falling current, and the area enclosed in the corresponding traces is an indication of the amount of ageing of the cathode during conduction. Information for the proper testing of any tube type may be requested of the manufacturer.

CONSTRUCTION. Although some industrial types of tubes have found pulse applications, these have been at low repetition rates and voltages, and most of the usable tubes have been designed specifically for pulse operation.

The cathodes are indirectly heated, since filamentary types have not been found satisfactory. Heating times are generally in the order of 1 to 3 min. This comparatively short heating time has been obtained by winding light heater wire either inside the cathode cylinder or outside a cylinder which is coated on the inside and which may have vanes projecting toward the inside to increase the emitting area. The alkali-earth oxides are used for the emissive coating.

The ionizing medium is usually hydrogen because of its light weight and high ion mobility and consequent speed of deionization. Especial care must be taken in processing, however, because of the susceptibility of hydrogen to cleaning up into the parts, particularly in the presence of contamination. For some of the tubes, high-purity alloys are used which are not required in the ordinary tube.

The anode must be completely shielded from any possible glow discharge or arc except the normal discharge, and it is surrounded at close spacing by the grid. In addition to the usual openings through the grid, an additional shield is placed directly below these openings and connected to the grid proper. This shield assures that the tube will maintain its highly positive characteristic and operate satisfactorily at high voltage.

Most of the applications have been met by three tube types, one operating at a pulse voltage of 3000 volts and a pulse current of 35 amp; the second at 8000 volts, 90 amp; and the third at 16,000 volts and 325 amp.

19. INSTALLATION AND OPERATION OF HOT-CATHODE THYRATRON TUBES

For any particular application complete data should be obtained from the tube manufacturer. Observation of the instructions will be amply repaid in satisfactory operation and long tube life.

FILAMENT CIRCUIT. The greatest single cause of unsatisfactory tube operation in the past has been incorrect filament voltage. Too low a filament voltage results in low emission and sputtering of the cathode which will give very short tube life and may prevent the tube from ever operating satisfactorily. Too high a filament voltage results in an excessive rate of evaporation of cathode material which results in short tube life. A filament-voltage variation of ± 5 per cent is generally permitted. Line-voltage variations outside the specified ± 5 per cent limits for a very short time, such as 5 or 10 sec, are not generally very harmful in the cathode-type tubes where the cathode temperature changes rather slowly. If excessive voltage variations are experienced and no corrective apparatus is available, it is sometimes possible to put the apparatus into operation by so adjusting the filament voltage that it does not drop more than 5 per cent below the rated value during the worst periods of sustained low voltage. Under these conditions the average filament voltage will probably be high and tube life will be shortened but not to the same extent as with too low a voltage.

CATHODE HEATING TIME. In some of the smaller quick-heating filamentary thyratrons it is possible, under some conditions of operation when the anode voltage and current are rather low, to apply both filament and plate voltages simultaneously without causing excessive damage. However, when full rated current is to be drawn or when a slower indirectly heated cathode is used, it is essential to provide some means whereby the tube will not pass anode current until the cathode is up to operating temperature. This may be accomplished by a switch in either the anode or load circuit or by proper bias on the grid. Wherever it can be economically justified, a time-delay relay or circuit may be used to give this protection. Such a relay will also provide protection in the event of a power failure.

TUBE HEATING TIME. An inert-gas-filled thyratron is ready to operate as soon as the cathode comes up to temperature. It should be noted, however, that in a mercury-vapor tube this is not always true. The condensed-mercury temperature must be within the rated limits before the tube is operated. Under conditions of low ambient temperature where it is desired to bring the tubes up to operating temperature quickly, tube enclosures and external heaters may be advantageous.

INITIAL HEATING. During shipment of mercury-vapor tubes the mercury may have become spattered over the tube electrodes. When first put into service the tube should be allowed to heat long enough to evaporate the mercury from the electrodes and to distribute it properly before anode voltage is applied. This may take a half hour or longer, depending upon the size of the tube.

ANODE CIRCUIT. Tubes should not be used in circuits where the voltages are higher than the rated peak inverse or peak forward voltages of the tubes. If there is a possibility that transients may be present, a cathode-ray oscilloscope or calibrated sphere gap across the tube may prove very useful in determining to just what voltages the tube is subjected.

CURRENT OVERLOADS. The low, essentially constant, voltage drop common to gas-filled tubes makes it possible to overload them injuriously to a greater extent than most hard-vacuum tubes, which have a rising voltage drop with increasing current. Once a thyratron tube is conducting, the current is limited only by the impedance of the load circuit. If it should be connected to a very low-reactance source of power with no load interposed, an abnormal current might flow, destroying the tube in a fraction of a second. A number of tubes are ruined in this way by experimenters, particularly those who are familiar with hard-vacuum tubes but who do not appreciate fully this important difference. For this reason *it is very important to make sure that some current-limiting impedance is in series with both the anode and grid leads when voltage is applied.*

This low, constant voltage drop makes it possible to impose heavy peak current overloads on the tubes without drawing excessive average current as indicated by a d-c ammeter directly in series with the tube. Unless sufficient reactance is present in the circuit, these peaks may be experienced when tubes are used in rectifier applications with capacitors connected directly across the output, when tubes are used to charge storage batteries, or when they are operating into any type of counter emf load. Although calculations may sometimes be made, it is generally safest to check tube currents with an oscilloscope when high peak currents are suspected.

REACTANCE OF POWER SOURCE. It is desirable to include enough reactance in the anode transformers or other sources of power to limit the tube short-circuit currents under any type of fault or failure to a value not greater than the surge current rating of the tube and to provide protective fuses or other interrupting devices to open the circuit in a reasonably short time, generally not in excess of 0.1 sec. Experience has shown that tubes operate much more satisfactorily in circuits in which this precaution is taken than in ones in which no such protection is provided. Various theories have been offered in explanation, but the fact has been well proved that high-reactance circuits give long tube life and low-reactance circuits give short tube life. In multitube circuits arcback of one tube often overloads the others, and again the circuit reactance must be depended upon to prevent permanent injury to these tubes. If excessively low-reactance transformers are used and if tube failures are encountered which show evidence of heavy overloads, such as blown-up stems or cracked seals, a small resistance or inductance placed directly in the anode lead of each tube will often stop the trouble.

GRID CIRCUIT. Usually the source of grid power itself has sufficient impedance to prevent excessive grid current from damaging the tube. If any doubt is felt on this score a grid resistor should be used to prevent accidents. However, in certain types of inverter circuits it is advisable to use a relatively stiff grid circuit to help speed up deionization. In the selection of a resistor the grid-current specification of the particular tube to be used should be considered so that difficulty will not be experienced through the loss of bias caused by the flow of grid current in the grid resistor. This resistor should, however, be large enough so that the voltage measured directly at the grid with the tube conducting does not exceed its rated value with the normal operating grid-supply voltage.

20. COLD-CATHODE TUBES

The term "cold-cathode tube" refers to tubes in which, in general, the discharge is the self-sustaining glow type previously described.

Since no cathode heating is required, the cathode life is not affected by standby operation, and these tubes are particularly adapted to relay circuits of infrequent operation, if the current requirement is sufficiently small, in addition to the familiar regulator and rectifier applications.

Cold Cathode. A cold cathode is a cathode operating at a temperature at which thermionic emission is negligible.

Starter (or control anode). A starter of a cold-cathode tube is an electrode ordinarily used in conjunction with a cathode to initiate conduction

Control Gap. A control gap of a cold-cathode tube is the conduction path between a starter and cathode in which conduction is ordinarily initiated.

Main Gap. A main gap of a cold-cathode tube is the conduction path between a cathode and a principal anode in which the principal conduction ordinarily takes place.

Anode Breakdown Voltage. The anode breakdown voltage of a cold-cathode tube is the anode voltage required to cause conduction to take place in the main gap when the control gap is not conducting.

Starter Breakdown Voltage. The starter breakdown voltage of a cold-cathode tube is the starter voltage required to cause conduction to take place in the control gap.

Transfer Current. The transfer current of a cold-cathode tube is the control-gap current required to cause conduction in the main gap with positive voltage applied to the anode.

Regulation. Regulation of a cold-cathode tube is the difference in voltage drop obtained over a range of conducted current.

Inverse Anode Current. The inverse anode (or starter) current is the electron current flowing from the associated circuit to the anode (or starter) of a cold-cathode tube.

Anode Drop. The anode drop of a cold-cathode tube is the main-gap voltage drop after conduction is established in this gap.

Starter Drop. The starter drop of a cold-cathode tube is the control-gap voltage drop after conduction is established in this gap.

VOLTAGE REGULATOR TUBES. Two-electrode, inert-gas-filled cold-cathode tubes are generally operated within a certain range of d-c load currents within which the tube voltage drop remains essentially constant. For instance, such a tube might break down or become ionized with a potential of 125 volts on the anode and then operate within 3 or 4 volts of a 90-volt tube drop within the specified current range. As with the hot-cathode tubes, the variation in supply voltage therefore appears across the load resistance, and it is essential that this resistance be sufficient to maintain the load current within the required value. Some calculations are generally necessary to insure that adequate starting voltage is also available when the supply voltage to be regulated falls to its minimum value.

Since regulator tubes are designed to conduct current in one direction only, they generally have one small electrode and one large electrode, the large one acting as the cathode. Tube life depends upon the current density on the cathode (and therefore the size of the cathode), since sputtering of the metal will occur if the element is overloaded.

THREE-ELECTRODE COLD-CATHODE TUBES. A third electrode or starter may be introduced into a cold-cathode tube to control the starting of the discharge. As with hot-cathode tubes the starter has no appreciable control once the discharge has occurred in the main gap until the anode potential has dropped below the tube voltage drop (sometimes called sustaining voltage).

The use of these tubes as relays is obvious because of their control characteristics. Another property of such a tube is that, although some inverse anode current will be conducted with negative anode voltage, the breakdown voltage in this direction is somewhat high and the anode drop increases rapidly as current increases. Figure 19 shows this characteristic. With the starter connected to the anode through a high resistance, the forward breakdown voltage will be much below the normal main-gap breakdown value and the tube will operate satisfactorily as a rectifier. The circuit must be such, of course, that peak inverse anode current or voltage ratings are not exceeded.

The starter drop is quite independent of control-gap current, and the tubes are used as voltage regulators with the cathode and starter as electrodes.

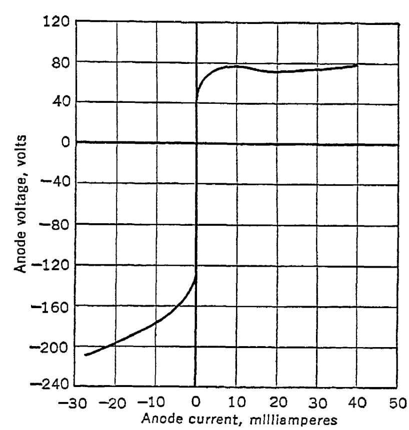

Fig. 19. Typical Cold-cathode-tube Characteristic

The mechanism of operation of the starter is similar to that of the grid in a positive-grid thyratron. When positive voltage is applied to the starter, a small electron current known as a Townsend current will flow from the cathode. As the voltage and the Townsend current are increased, a point is reached at which ionization occurs in the control gap. The control-gap current may then be increased by the control circuit until the transfer current is reached, at which point (depending upon the anode voltage) conduction occurs to the anode. At the anode breakdown voltage, conduction will occur without ionization in the control gap, and therefore the transfer current is zero. At the other extreme, the tube will not sustain a discharge at less than the anode drop, and hence the transfer current required at this point is infinite. Figure 20 shows a typical transfer-current characteristic. It is apparent that the anode operating voltage, when starter control is expected, must lie somewhere between the anode drop and the anode breakdown voltage.

The control characteristics are subject to variation during life but may be expected to remain constant within 5 or 6 volts during most of life. Variation during shelf life may be of the same order of magnitude depending upon the length of storage and the light conditions for those tubes which do not have an opaque coating. The effect of light is negligible for medium light levels but will be appreciable at levels approaching darkness or direct sunlight, the numerical value of breakdown voltages decreasing as light intensity is increased, and conversely with decreased intensity. Most variations occurring during storage will disappear after a few seconds of operation.

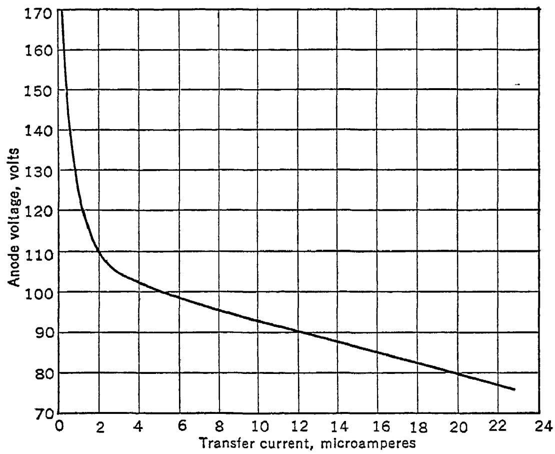

FIG. 20. Typical Transfer Current Characteristic

TEST FOR COLD-CATHODE TUBES. Because of the effect of light and storage upon control characteristics, it is generally advisable that all tests be made with moderate illumination and with a few seconds of current conduction immediately before the test in order to stabilize the readings. Because of the low values of transfer current some errors may be introduced if capacitance effects are ignored, and it is therefore important that the starter resistance be placed immediately adjacent to the starter electrode.

Breakdown voltage is measured by applying a positive d-c voltage to the anode and increasing it until the tube conducts current. The minimum value of voltage required to start conduction is measured. After the tube conducts, the tube drop may be measured at specified current values and the regulation thereby determined. For three-electrode tubes the anode breakdown voltage is measured as above, except with the starter connected to the anode through a resistance generally not exceeding 50,000 ohms.

Transfer current is measured by applying the specified d-c anode potential and a positive starter voltage, with sufficient starter resistance to limit the starter current to less than the transfer value. The starter current is then increased until conduction takes place in the main gap, at which point the transfer current is measured by means of a microammeter in series with the starter. Care must be exercised to insure that the starter is electrically connected at every instant during this test.

STROBOTRON TUBES. A modification of the three-electrode cold-cathode tube described is commercially called the Strobotron. This tube commonly has two control electrodes or grids together with the cathode and anode. The cathode is coated with a cesium compound, which breaks down during conduction and liberates free cesium. The tube is inert-gas-filled, and conduction occurs by formation of a cathode spot on the metallic cathode surface by concentration of a glow discharge. The voltage drop is therefore much lower than that of a glow discharge. These tubes are commonly used with neon gas as a source of high-intensity light for stroboscopic purposes but may also be used for control or relay purposes. Capacity is limited by cathode heating during conduction and by ion bombardment of the cathode as with other cold-cathode tubes. For this reason, although very high peak currents can be handled, the average current rating is generally quite low.

A capacitance is generally used across the tube in operation. This capacitance is discharged through the tube in order to provide very high instantaneous current. It also serves as a means of stopping the discharge, since, as the capacitance discharges to the tube drop, the conduction changes to a glow rather than an arc. This immediately raises the tube drop and the conduction ceases, the tube becoming deionized before the capacitor recharges to sufficient voltage to maintain even a glow discharge. Operation at too high a frequency, or with improper circuit conditions, will frequently maintain a glow discharge in the tube and lose the advantage of the tube's capacity for high peak currents.

With this tube as with other cold-cathode tubes life is a function of average current and conduction time, there being no appreciable deterioration during storage.

Available types of tubes are shown in Table 2.

Table 2. Available Types of Cold-cathode Tubes

Type	Desig-nation	Cathode Current, milliamperes		Anode Voltage Drop	Breakdown Voltage s = starter a = anode	Remarks

21. POOL-CATHODE TUBES

Pool Cathode. A pool cathode is a cathode in which the principal source of electron emission is a cathode spot on a metallic pool electrode.

Cathode Spot. A cathode spot is an area on the cathode of an arc from which electron emission takes place at a current density of thousands of amperes per square centimeter and where the temperature of the electrode is too low to account for such currents by thermionic emission.

Pool Tube. A pool tube is a gas tube with a pool cathode.

Single-anode Tube. A single-anode tube is an electron tube having a single main anode.

Multianode Tube. A multianode tube is an electron tube having two or more main anodes and a single cathode.

Ignitron. An ignitron is a single-anode pool tube in which an ignitor is employed to initiate the cathode spot for each conducting period.

Excitron. An excitron is a single-anode pool tube provided with means for maintaining a continuous cathode spot.

Pumped Rectifier. A pumped rectifier is a rectifier which is continuously connected to evacuating equipment during operation.

Sealed Tube. A sealed tube is a tube which is hermetically sealed after degassing.

Ignitor. An ignitor is a stationary electrode which is partially immersed in the cathode pool and has the function of initiating a cathode spot.

As mentioned previously, tubes of the pool-cathode type make use of the self-sustaining form of discharge. The cathode dark space is very small because of the high current density, and the resulting high voltage gradient is assumed to cause field emission and thus maintain the high current density at an arc voltage drop near that of the ionization voltage.

Since there is no emissive material to be damaged, the pool cathode is capable of carrying extremely high currents without any deterioration. Tubes having such cathodes can therefore be used in applications where very high peak currents are required for short periods of time, or where it is desirable that a high short-circuit or arcback current be allowed without damage to the tube. This current can be much higher proportionally than for a hot-cathode tube. The pool cathode also has the advantage of not requiring heating time.

On the other hand, the pool tube requires auxiliary circuits for maintaining ionization or for starting the ionization during each operating cycle. The size of the tube and the corresponding volume of ionization increases the difficulty of building high-voltage tubes, or those with rapid deionization. Further, because of the amount of current capacity, water cooling is required for most types, and corresponding protection must be provided to insure proper water flow and water temperature at all times.

Available types of pool tubes are listed in Table 3.

* These are typical operating conditions rather than absolute maximum ratings.

WL-, prefix used by Westinghouse Electric Corporation; GL-, prefix used by General Electric Company.

CLASSIFICATION. Pool-cathode tubes may be classified as sealed or pumped units. In general, the single-anode sealed units are of comparatively lower current capacity, now being built in the range from about 50 amp average to about 400 amp average. After the initial exhaust treatment these tubes are permanently sealed and no further pumping is required. Pumped units have been built largely of metal in either single-anode units or in a multianode form commonly called a tank. These units have a pump or system of pumps operating to maintain vacuum. Current capacity of these tanks is in the order of 1000 amp average. Pool tubes may be classified still further as tubes in which there is continuous ionization and those in which the arc is initiated each time conduction starts and is extinguished at the end of each conducting period.

MERCURY-ARC RECTIFIERS. The mercury-arc rectifier is a familiar example of a pool tube in which continuous ionization is maintained.

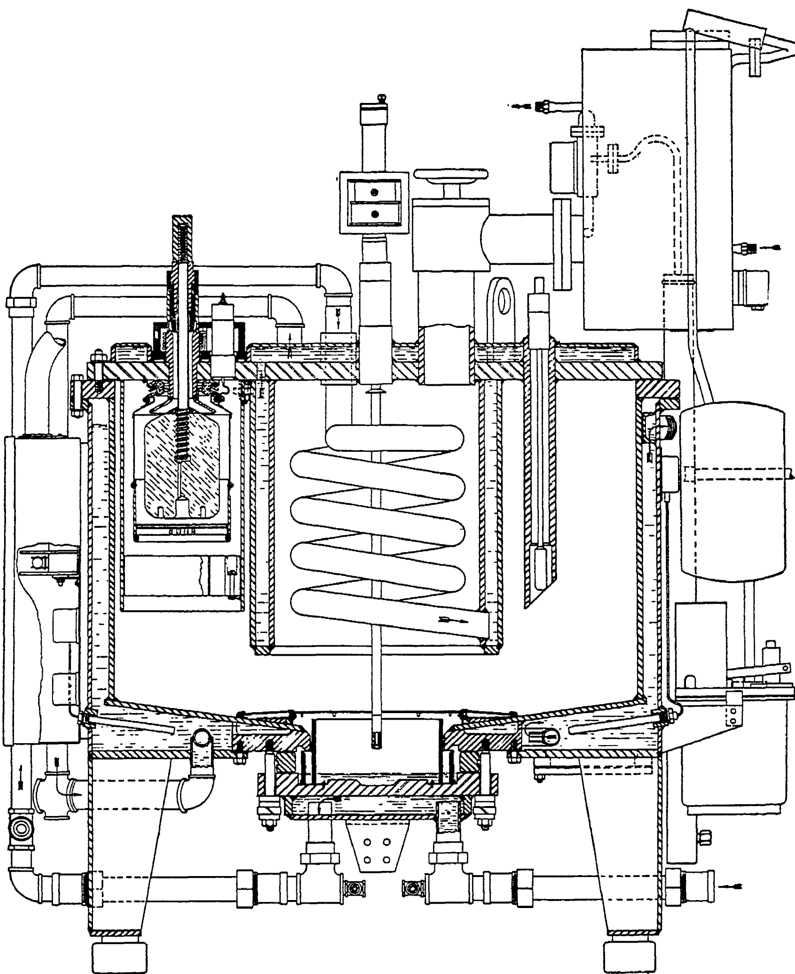

Fig. 21. Typical Pumped Mercury-arc Rectifier Tank. (Courtesy of G. E. Co.)

These types are made in both glass and metal. The glass types are sealed units with the mercury pool in the bottom and with glass arms extending out from the main body of the tube, slightly above the pool level. An anode is sealed into the end of each arm, which may or may not be bent, depending on the inverse voltage rating of the tube. Some two-anode types are made for lighting and railway service, but the more extensive applications are in three- or six-anode designs. These applications are mainly outside the United States and are in railway service and other power usage. A typical six-anode tube would have a capacity of the order of 400 amp average at 600 volts.

The arc spot of such tubes is generally formed by tilting the tube so that the mercury pool forms a circuit with a starting electrode. When this circuit is broken an arc is initiated and is maintained by one or more auxiliary anodes. These anodes form with the pool a low-voltage rectifier the purpose of which is to keep enough current (6 or 7 amp) flowing through the tube to maintain the cathode spot. As the tube current increases, the cathode spot breaks up into several spots each carrying about the same amount of current.

These tubes may be given grid-control characteristics by the addition of a grid around the anode in each arm.

Figure 21 shows an example of a metal multianode pumped rectifier tank rated for 1000 kw at 600 volts. Such tanks operate like the glass tubes except that the arc is initiated by a probe electrode in the center of the pool. This electrode is magnetically controlled and makes and breaks contact with the pool in order to form the arc spot. Ionization is then maintained by auxiliary anodes such as the one shown on the right-hand side of the tank, extending from the top cover into the main volume. One of the main anodes is shown at the left, with a suitable grid structure surrounding and with additional baffling below. The bottom surface of the tank slopes to allow the return of condensed mercury to the pool in the center, and a water-cooling system extends completely around the outside of the tank, under the mercury pool, and through a cooling coil and cylinder in the center of the tank. This provides a maximum of cooling area in contact with the arc and thus provides the best control of operation. Direction of water flow is indicated by arrows in the cooling system. The exhaust connection, vacuum controls, and pumps are shown at the top and right of the tank.

Such tanks are built with voltage ratings as high as 3000 volts direct current and with currents of the order of 1000 amp.

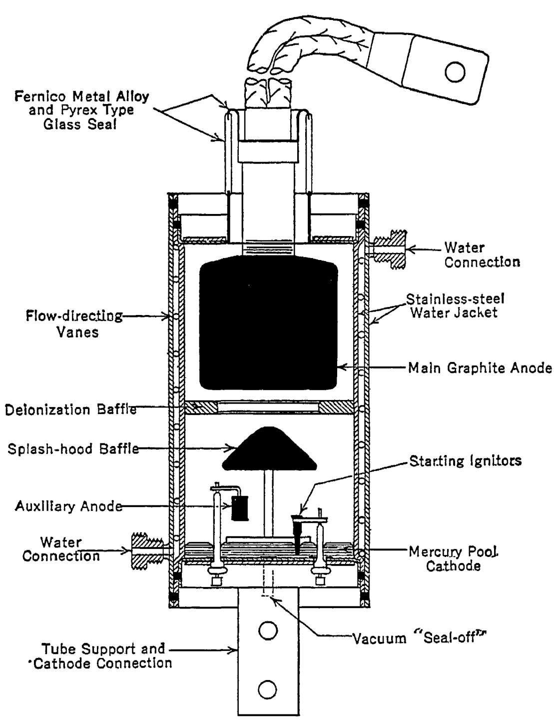

FIG. 22. Sealed Ignitron for Power Rectifier Service. (Courtesy of G. E. Co.)

IGNITRONS. Figure 22 shows a typical sealed ignitron tube. The two enclosing cylinders provide a path for cooling water, and, since the temperature of the inner tube wall is important in determining mercury-vapor pressure and operating capacity of the tube, it is essential that the required water flow be provided during operation. The graphite anode is designed for a maximum transfer of heat from its face and for a minimum of heat generation from the high current flow. Mercury is thrown up from the pool by the action of the cathode spots, and a splash-hood baffle is placed directly above the center of the cathode to prevent splashes of mercury from hitting the anode or upper tube walls and thereby increasing the possibility of arcback. The purpose of a deionization baffle is easily seen, since it reduces the distance from the ionized area to a metal part. This part is particularly important in tubes designed for rectifier service, where the deionization requirements are more severe than in welder use. The auxiliary anode, also, is used for rectifier service, where it is desirable to maintain ionization over the conducting period in order to provide for main anode currents below the value at which the arc becomes un-

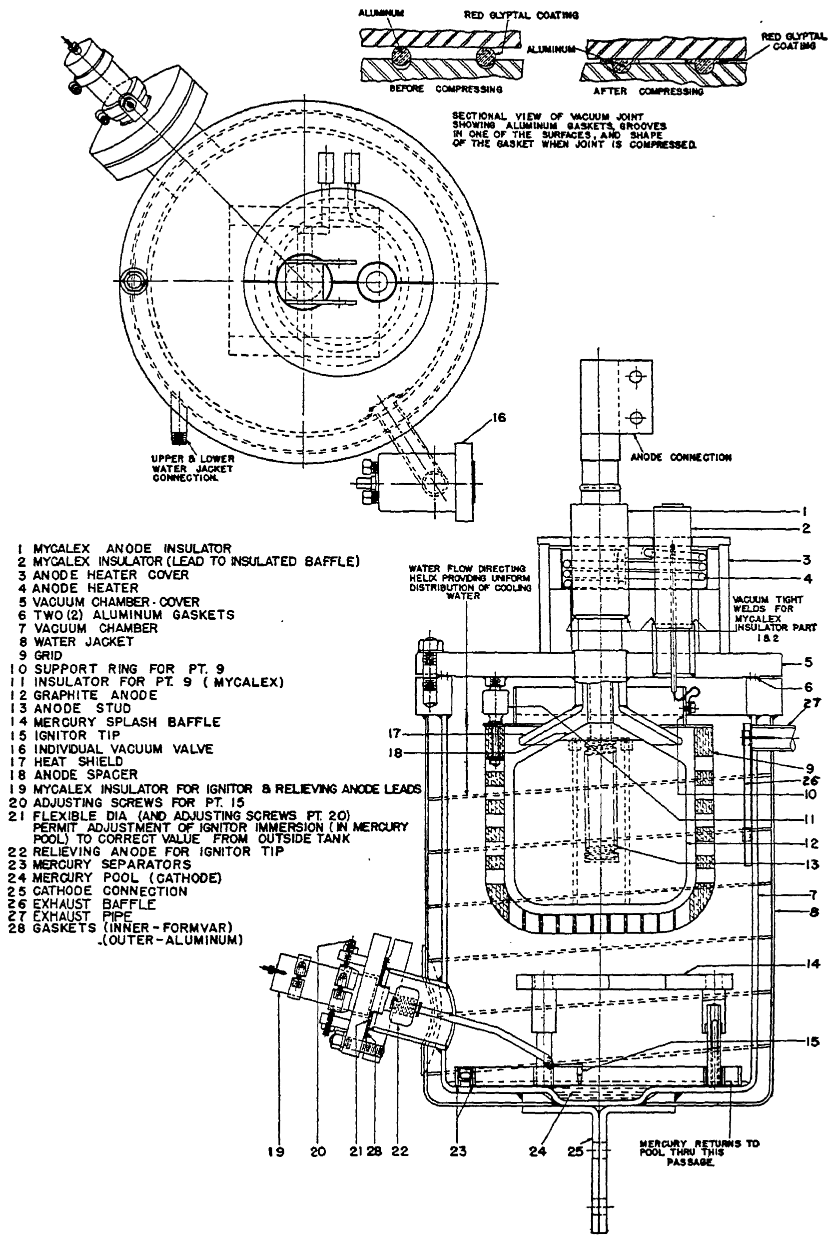

FIG. 23. Pumped Ignitron Tank. (Courtesy of G. E. Co.)

stable, usually 3 to 4 amp. Tubes for welder applications may be built without the two baffles and the auxiliary anode. On the other hand, tubes built for high-voltage rectifier use may have several baffles or grids surrounding the anode in order to provide high-voltage control and to reduce deionization time, and they may also have two or more ignitors in order to assure operation in the event of an ignitor failure.

Figure 23 shows a typical pumped ignitron tank, with vacuum-tight joints and flexible ignitor support to allow adjustment of the ignitor position; the other parts are similar in use to those in the sealed tube. The sealed and pumped units are used in similar applications.

IGNITOR CHARACTERISTICS. The ignitor as shown in Fig. 22 is shaped somewhat in the form of a pencil and is composed largely of boron carbide. The composition is such that the high temperature of the arc has practically no effect upon the ignitor surface, and there is no tendency for the mercury to wet the surface unless foreign material becomes deposited at the contact area.

The ignitor acts simply as a resistor; a current flows through it into the cathode pool when voltage is applied between the ignitor terminal and the cathode. When sufficient current flows, an arc is started between ignitor and pool, and conduction is established through the tube provided that positive anode voltage is applied. Resistance of the ignitor may vary from 10 to 100 ohms, and ignition may occur at instantaneous currents of 1 or 2 amp with 100 to 200 volts or at 15 to 30 amp with but a few volts applied. The manufacturer's data should be consulted to determine the exact ignitor requirements to insure proper operation throughout the life of the tube.

Formation of the arc may be caused by one or both of two mechanisms. At the point where the ignitor is immersed the mercury forms a meniscus, so that its surface is separated from the ignitor surface by very small distances at some points. High-voltage gradients exist across this space and cause a discharge to start. Another possible method of ignitor operation is that of developing heat at the several contact points of the rough ignitor surface with the mercury surface. The rapid heating at these sharp contacts due to the ignitor current flow causes the mercury to vaporize rapidly and break contact, thereby starting the desired arc.

Conduction to the anode occurs in the order of 20 to 200 microseconds after application of the critical ignitor voltage or current.

Ignitor ratings include the maximum allowable peak voltage and peak current ratings, which insure that the ignitor will not be eroded or otherwise affected during operation. A maximum average current rating limits the heating which may contribute to short life. The maximum required peak voltage and current specify the worst conditions of current or voltage expected for consistent firing, and a circuit designed to provide at least these requirements will provide satisfactory operation during the tube life.

Since the arcback characteristic of ignitrons depends upon current, voltage and temperature, the tubes are rated for more than one load current depending upon the operating voltage and duty cycle. For tubes in rectifier service these ratings take the form of two or more discrete current ratings at corresponding voltages or length of time of operation. For welding tubes, a curve of demand kva (rms current times rms circuit voltage) vs. average tube current is used, thus taking into account the on and off times of the welder as well as the maximum current carried.

IGNITRON TESTS. Because of the size of the tubes and equipment involved ignitrons are tested where possible in an operation circuit which closely approximates the application conditions. Tests at the maximum current, voltage, and duty cycle should give an indication, within a very short time, of the quality of the tube. The arcback rate is frequently used as a determining factor of this quality. The water-cooling coils are tested for their capacity to withstand expected water pressures, but more important than this test may be the user's test of the purity of the water being used, since sediment or scale will seriously reduce heat transfer from the inner wall of the tube.

Ignitors are generally tested in a simple manner by measuring the resistance from ignitor terminal to cathode pool under conditions of normal mercury level. A much more severe test is to apply a specified firing voltage and measure the time required for the tube to conduct current, or to measure both the ignitor current and ignitor voltage at which conduction takes place.

EXCITRONS. The excitron is a currently available type of metal rectifier, built in both sealed and pumped units. This type has the advantages of other single-anode rectifiers for production and maintenance and has the firing characteristics of the multianode tanks in which ionization is maintained continuously.

In general construction, commercially available excitrons are similar to the sealed or pumped ignitron except that the cathode is insulated from the tube wall, as it is in the metal mercury-arc rectifiers. This prevents travel of the arc to the wall where the metal may be vaporized and deposited over other parts of the tube. In the ignitron type of tube the arc is extinguished every cycle, and this problem is not of major importance.

The arc is established in the excitron by a jet of mercury propelled up from the cathode to contact an excitation anode, causing a temporary short circuit and arc formation. A magnetically controlled plunger operates the mercury jet when required, and the arc is maintained, once established, by the excitation anode circuit.

In the use of a control grid around the anode and suitable baffling the excitron is similar to ignitrons and other rectifiers.

X-RAY TUBES

By S. Reid Warren, Jr.

22. GENERAL PHYSICAL REQUIREMENTS

X-ray tubes may be divided into three general classes: (1) cold-cathode, gas-filled tubes; (2) hot-cathode, high-vacuum tubes; (3) cold-cathode, high-vacuum tubes. The last-named tube has been used to produce x-ray exposures of short duration (approximately 1 μsec) by field emission (see reference 8). Hot-cathode x-ray tubes are now used almost exclusively. Nevertheless a description of gas-filled x-ray tubes is of more than historical interest, since the phenomena of electric discharge in these tubes show clearly the limitations and the necessity for the careful design of all x-ray tubes.

The x-ray tubes employed by Roentgen and his successors in the field of x-ray research up to 1912 contained an anode, a cold cathode, and sometimes an electrode called the "anticathode." Only two electrodes are necessary, although it was alleged that the presence of the third electrode was accompanied by greater stability of the electric discharge through the tube. They are arranged in a glass bulb in the manner shown in Fig. 1. The tube is exhausted to a pressure of a few microns of mercury. The gas contains a number of free electrons. If there is a potential difference of the order of 40 to 80 kv across the electrodes of the x-ray tube, these free electrons are accelerated in the direction of the positive terminal or anode. They acquire sufficient velocity to remove one or more electrons from atoms of gas in their path. The ions formed by the ejection of these electrons from gas atoms have net positive charges. Under the action of the electric field these positive ions are accelerated toward the cathode. When the positive ions impinge upon the cathode, electrons are ejected from it. They in turn are attracted toward the anode and acquire a velocity depending upon the anode-cathode voltage. The electrons which impinge upon the anode at high velocity cause the generation of x-rays near the surface of the anode. As a result of the positive-ion stream passing toward the cathode and the electron stream passing to the anode, a current flows through

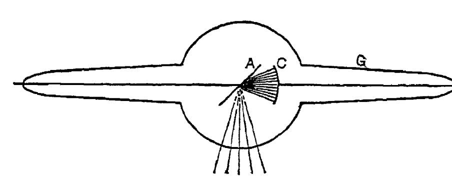

FIG. 1. Basic Elements of an X-ray Tube in Which Electrons are Ejected from a Cold Cathode C by Ionic Bombardment. G, the glass envelope. A, the anode disk of platinum, tungsten, or molybdenum. C, the cathode, made in the form of a segment of a sphere to focus the electrode stream upon a small area of the anode surface or focal spot.

the x-ray tube, which, in accordance with convention concerning the direction of current flow, is said to pass from anode to cathode.

The process involved in the generation of x-rays at voltages of the order of 100 kv is extremely inefficient. Of the total electrical energy supplied to an x-ray tube only about 0.01 per cent is transformed into useful x-rays. Of the remainder, the greatest part is dissipated as heat from the x-ray tube anode.

The current through an x-ray tube of this type cannot be controlled independently of the voltage. As the parts become heated during operation the gas pressure within the tube changes, often in an unpredictable manner, apparently influenced as much by the previous history of the tube as by the contemporary electrical input conditions. If the pressure within the tube decreases, a higher anode-cathode voltage is required to cause the flow of a given current. The x-rays generated at high voltage with low gas pressures are more penetrating than those generated at lower voltages with higher gas pressures. Low-pressure, cold-cathode tubes and the highly penetrating x-rays generated by operating them at high voltages are called *hard* tubes and *hard* x-rays. Tubes with relatively high pressure operated at low voltages are called *soft*, and the radiation so generated is called *soft* radiation. The terms *hard* and *soft* are purely qualitative.

In spite of ingenious attempts to make a practically useful cold-cathode x-ray tube, it has been used very little since the invention in 1913 of the hot-cathode x-ray tube by W. D. Coolidge and his co-workers.

Two important investigations during the period 1908–1913 contributed to the development of an x-ray tube in which the current can be varied independently of the voltage. Langmuir had investigated thoroughly the electronic emission from hot metallic filaments noted by Edison and earlier by Elster and Geitel. Briefly, to summarize this work, the following important findings are noted:

1. Unless the pressure of the gas within the tube is less than about 1 micron of mercury, positive ions produced in the same manner as those in the gas x-ray tube described above cause an important variation in the electron output of the filaments. At pressures lower than this the electrons emitted by the hot body are due apparently entirely to thermionic emission, and therefore their number depends only upon the cathode material and its temperature.

2. In general the introduction of various gases causes a considerable decrease in electron emission, particularly at low filament temperatures. This effect should not be confused with the effects due to ions formed in the added gas.

3. At very low gas pressures the thermionic current from a tungsten filament varies with the temperature in the following manner:

$$i = aT^2e^{-(b/T)}$$

T is the absolute temperature; i, the current in amperes per square meter of cathode surface; for tungsten $a = 6.02 \times 10^5$ amp per sq m per (degree)^2; $b = 52{,}400$ deg K. An expression similar to this was first developed by Richardson.

4. The operation of a tube with high vacuum is greatly influenced by a space charge consisting of a cloud of electrons surrounding the hot filament.

Investigators have found that x-rays are generated more efficiently by elements with high atomic number. Therefore they attempted to find a metal with the following characteristics:

1. High atomic number, to provide efficient x-ray generation.
2. High heat conductivity, to allow for dissipation of the heat generated at the x-ray tube anode.
3. Low vapor pressure, to assure stable operation.
4. High melting point, to provide sufficient capacity.
5. Ease of machining and relatively low cost.

X-ray tubes employed by workers who immediately followed Roentgen contained anodes of platinum. It was found subsequently that tungsten was better suited than platinum in all respects except that it was impossible, by means developed up to that time, to purify and to machine. A period of several years was required to devise methods for producing and working tungsten. The manufacture of uniform, standard x-ray tubes depends upon the carefully controlled processing of the component metal and glass parts. The method now generally used requires the removal and purification of an oxide of tungsten from the ore wolframite. The powdered oxide is formed into blocks and heated in the presence of hydrogen. After such treatment, the oxide is reduced to metallic tungsten; the bar contracts but remains extremely weak mechanically. It is, however, sufficiently strong so that bars about 2 cm square and 15 to 20 cm long may be supported at one end by a water-cooled copper electrode, while the other end rests in a pool of mercury which is also cooled. This system is surrounded by a jar through which hydrogen passes. An electric current is passed through the tungsten bar, heating it to about 2800 deg cent. Gradually the metal contracts and becomes mechanically stronger. It is then heated to red heat in air and swaged. This process consists of operating upon the tungsten bar with tools which pound it radially from several directions. By this treatment the tungsten becomes hard, homogeneous, and ductile. It is possible to continue the swaging process until the bar has been reduced to a diameter of a few millimeters. It may then be drawn into tungsten wire by means of diamond dies. The larger bars may be cut or polished by means of Carborundum. Solid tungsten anodes for x-ray tubes may be constructed from such bars. Smaller sections can be cut by means of thin (0.01 in.) rubber disks a few inches in diameter containing 240-grit Carborundum and operating, wet, at high speeds (9000 rpm).

W. D. Coolidge devised an x-ray tube like the one shown in Fig. 2. He found that it had the following characteristics:

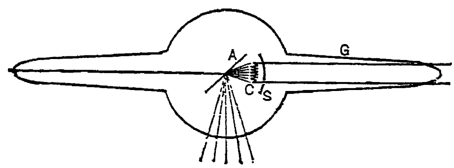

FIG. 2. Basic Elements of an X-ray Tube in Which Electrons are Ejected from a Hot Cathode *C* by Thermionic Action. *G*, the glass envelope. *A*, the anode disk, usually of tungsten. *C*, the cathode coil of tungsten wire. *S*, the metal focusing shield connected electrically to one of the cathode leads.

1. The tube allows current to pass only in the direction from anode to cathode.
2. The current through the x-ray tube is practically independent of the voltage applied to the anode and cathode for voltages of 30 to 200 kvp. The current may be varied by changing the temperature of the tungsten cathode.
3. The area upon the anode over which electrons impinge may be controlled by the cathode shield *S* and by the position of the cathode coil *C* within this shield.

X-ray tubes are employed for the following purposes:

Purpose	Voltage Limits	Current Limits
1. Generation of x-rays for the treatment of disease (x-ray therapy)	12–2000 kvp	0.1– 30 ma
2. The production of x-ray shadow pictures for medical diagnosis (roentgenography)	30– 110 kvp	10 –500 ma
3. Industrial roentgenography	30–2000 kvp	0.1–100 ma
4. X-ray diffraction	10– 100 kvp	2 –100 ma

Tubes for these various purposes differ considerably in structure. Some of the tubes now available are described in the following sections.

23. TUBES FOR X-RAY THERAPY

Roentgenologists require, for general x-ray therapy, tubes that will operate under the following conditions:

1. Tube voltages of 50 to 400 kvp and tube currents of 2 to 30 ma (average), supplied by constant-potential, full-wave pulsating, or half-wave pulsating high-voltage generators.
2. Exposures of 0.5 to 30 min duration are used.
3. Insulation to minimize the hazard of electrical shocks to patient and operator are essential.
4. X-rays must be confined to a cone the axis of which passes through the tube target and the part of the patient's body to be treated, to minimize the possibility of x-ray burn to the operator and patient.

The length of an x-ray tube depends upon the maximum anode-cathode voltage to which it may be subjected. The ends of the tube, to which the electrical connections are made, must be separated sufficiently to prevent sparkover. The electrical stress in the glass envelope must be sufficiently low to prevent puncture. The tube must be mechanically strong enough to support the anode and cathode assemblies rigidly. Therapy tubes, for use at 50 to 400 kvp, immersed in oil, are 0.2 to 1.5 m long. Formerly the glass envelopes were made of soft glass. Manufacturing methods devised recently have led to the use of a hard glass such as Pyrex. Pyrex has superior heat-resisting qualities, greater dielectric strength, and greater mechanical strength than soft glass. Air-cooled therapy tubes have a spherical glass bulb, 15 to 25 cm in diameter, surrounding the anode and cathode. This method of construction has the following advantages:

1. The sphere radiates more heat than a small cylindrical envelope.
2. The glass is far enough from the anode and cathode so that it is not stressed by strong electric fields caused by the applied anode-cathode voltage.

3. Stray electrons do not collect on the interior of the spherical surface in sufficient quantity to cause unstable operation or puncture of the tube.

In the so-called *Universal* tube, Fig. 3, a bar of molybdenum 0.5 cm in diameter is supported by glass at the end of the anode stem and extends into the tube, concentric with its axis, to a point about 5 cm from the tube center. At this end of the bar a solid tungsten block is fastened. This block is truncated at an angle of 45° with the tube axis. The minor axis of the elliptical face thus formed is 2 cm long. The minor axis of the target or focal spot is approximately 1.8 cm. Heat is dissipated chiefly by radiation. A spherical glass bulb is required to aid this heat dissipation.

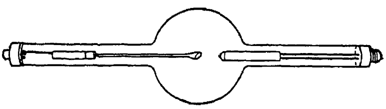

FIG. 3. *Universal* Therapy Tube, Solid Tungsten Anode. Air-cooled.

The tubes with spherical bulbs are difficult to mount and to shield by reason of their size. Modern therapy tubes are therefore designed for operation immersed in oil, with cooling of the anode by means of oil that is forced against the back of the anode by a pump. Special design of the electrodes, the use of hard-glass envelopes, and oil immersion result in tubes that are considerably smaller than tubes designed for mounting in air. An example of such a tube is shown in Figs. 4 and 5, designed to operate, in oil, at 250 kvp, 15 ma. Note the hollow cylindrical projection (hood) from the region of the tungsten target toward the cathode; this hood prevents secondary electrons from impinging on the inner surface of the glass envelope.

The cathode coil is usually a tungsten spiral which operates at 5 to 10 volts, 3 to 6 amp. The coil is supported and surrounded by a metal cup to shield the glass from secondary electrons and to focus the electron stream upon the target or focal spot of the anode. In a therapy tube a small focal spot or source of x-rays is not necessary. The focusing action of the cup is limited to preventing electrons from going past the anode face into the anode stem.

Tubes, such as that shown in Figs. 4 and 5, are often placed in a grounded metal tube head, supported by means of a tube stand that permits easy mechanical manipulation of the tube. High-voltage leads are flexible shockproof cables with a grounded external sheath. Figure 6 shows an apparatus of this kind being adjusted to make an x-ray film of a weld; therapy tube stands are essentially similar. The tube head and the rectangular cone extending from the head toward the weld are lead lined; thus the x-ray output is confined to a relatively sharply defined beam through the cone.

All x-ray tubes used for the routine treatment of deep-seated tumors are evacuated to a pressure of 10^{-2} micron of mercury or less. It is necessary not only to evacuate to this pressure while the anode and cathode are cold but also to heat the metal parts by means of high-frequency induction while the pumping proceeds. Before being sealed off, the tube is operated at an anode-cathode voltage and current slightly in excess of the tube rating to insure thorough degassing of the metal parts.

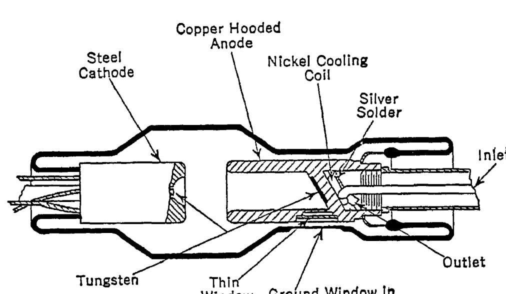

FIG. 5. Axial Section of Tube Shown in Fig. 4. (Courtesy General Electric X-ray Corporation.)

HIGH-VOLTAGE THERAPY TUBES. X-ray apparatus for therapy and for industrial radiography at tube voltages of 1000 and 2000 kvp are contained in steel tanks, in which air or "Freon" is maintained at a pressure equivalent to several atmospheres. The source of high-voltage, mounted in the tank with the x-ray tube, is a van de Graaff generator or a specially designed transformer operating at 180 cycles per second. The tubes are sealed, with the anode placed at one end of the cylinder; the cathode is placed at the other end. The anode is grounded, and the focal spot is cooled by water that flows over the end of the tube. A tube rated at 2000 kvp is shown in Fig. 7. This tube has a gold target; there is some evidence that the surface of the focal spot is molten during operation, although there is no evidence of the instability that might be expected to accompany this condition. Note that the tube is equipped with a series (180) of accelerating anodes. These are required to maintain uniform potential gradient along the tube and to minimize the effects of electrons' diverging from the beam. The magnetic focusing coil shown in Fig. 7 insures stable size, shape, and position of the focal spot on the gold target. The tube is approximately 9 ft long; the extension from the lowest accelerating anode to the target is 3 ft. The rating is 2000 kvp, 300 μamp.; the focal spot, with magnetic focusing, is approximately 2.5 mm in diameter.

24. TUBES FOR MEDICAL ROENTGENOGRAPHY AND ROENTGENOSCOPY

To produce diagnostically useful roentgenograms of parts of the human body, x-ray tubes with the following characteristics are required:

1. The focal spot or source of x-rays must be as small as possible in order to obtain sharp shadow borders.
2. The technique of roentgenography prescribes x-ray tube voltages of 30 to 110 kvp, x-ray tube currents of 10 to 500 ma (average), and exposure times of $^1/_{30}$ to 30 sec.
3. The primary x-ray beam must be confined to a cone with the focal spot at the apex and the film at the base to protect the operator from x-ray burn.
4. Insulation of the tube and high-voltage leads is advisable but not necessary (except in dental roentgenography) since the focal spot-film distances generally used are greater than 60 cm.

Except for the requirement that the focal spot be small, the same principles are applied in designing roentgenographic tubes as those described above for therapy tubes. The need for minimizing the focal spot size having been prescribed, certain practical factors are found to oppose this decrease:

1. For any particular method of anode construction the energy dissipated at the focal spot during an exposure cannot exceed the value which will melt the tungsten target. The melting point of tungsten is 3370 deg cent.
2. Owing to the thickness of the part to be roentgenographed, the shadows of parts farthest from the film are more distorted than those near the film. The focal spot-film distance must be increased to decrease this effect. The energy supplied to the tube increases in proportion to the square of the focal spot-film distance. Therefore, the focal spot area must be increased in like proportion. In other words, if the focal spot-film distance is increased to reduce the magnification of shadows of parts at a distance from the film, the focal spot must be enlarged, the energy supplied to the tube must be increased, and the sharpness of the shadows remains unchanged.
3. Parts of the body are continually in motion. Roentgenograms of such parts must be made in as short a time as possible to minimize the unsharpness or blurring caused by motion during exposure. The minimization of exposure time requires an increase in focal spot size, all other factors remaining constant. For example, roentgenogram of the chest of a cadaver may be made with a tube having a focal spot less than 1 mm square. To make a roentgenogram of the chest of a normal adult requires a tube with a focal spot at least 3 mm square. Even this is a compromise, for no matter how short the exposure time some unsharpness is produced by motion.

Nearly all roentgenographic tubes now manufactured are constructed and used so that the line from the focal spot to the center of the film makes an angle of 10° to 45° with the anode face. The projection of the actual focal spot (the source of x-rays) upon a particular point in the film is called the effective focal spot area at that point. Figure 8 illustrates three types commonly used. The effective focal spot F_2 for the 45° tube is a circle 6 mm in diameter. The effective focal spots for the 20° and 10° tubes *having the same target areas as the 45° tube* are squares with sides of 3.7 mm and 2.6 mm, respectively. The maximum allowable exposure energies (for exposure times less than 0.2 sec) are equal for the three tubes, since the actual focal spot areas are equal. Therefore, for a given maximum rating the sharpness of the roentgenographic image increases as the angle between the focal spot and central x-ray beam decreases. Two limitations prescribe the minimum focal spot-film distances at which a tube may be used:

1. The intensity of x-rays emanating from the focal spot within a few degrees of the tangent to the anode face is less than the intensity of the central beam at the same distance from the tube. The intensity must be practically uniform over the area of the x-ray film, in the absence of absorbing objects between tube and film.
2. The effective focal spot size and the distortion vary over the film area. This variation must be minimized to insure that the roentgenogram is diagnostically useful over its entire area.

The design of roentgenographic tubes is determined in general by the criteria described above in article 23, "Tubes for X-ray Therapy." There are three requirements which differ qualitatively:

1. The anode-cathode voltages are less for roentgenography than for therapy.
2. It is extremely important to produce a small, uniform effective focal spot in roentgenographic tubes.
3. Exposure times for roentgenography are relatively short, requiring that the anode have a high heat capacity.

Modern roentgenographic tubes use the line or band focus shown in the 20° and 10° sketches, Fig. 8. The target is a disk of tungsten about 1.5 mm thick, usually with an area two or three times the actual focal spot area. The tungsten is embedded in a heavy copper bar. Suitable thermal contact between the tungsten and copper is difficult to obtain. The usual procedure involves fixing the tungsten disk at the bottom of a graphite crucible and pouring molten electrolytic copper over the disk. The casting is accomplished

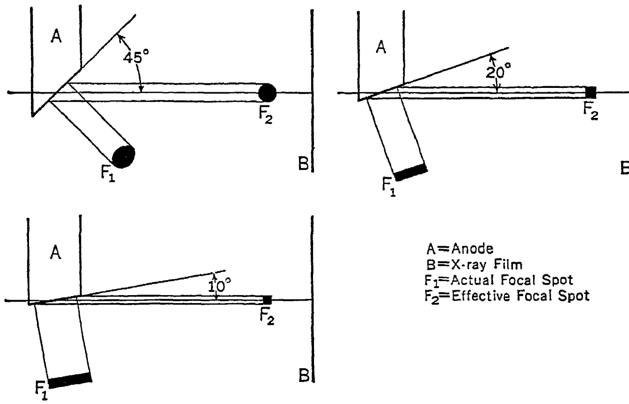

FIG. 8. Relations of Actual Focal Spots, F_1, and Effective Focal Spots, F_2, for Roentgenographic Tube Anodes. Actual focal spot areas of all three tubes are equal.

in an evacuated chamber to prevent the formation of any compounds that might prohibit the adherence of the copper to the tungsten.

With the type of construction just described, the maximum allowable exposure rating for exposures of 1 sec or less is 250 watts per square millimeter of actual focal spot area. For long exposures the rating depends upon the efficiency of the heat-radiating system, and therefore it is specified for each type of tube by the manufacturer. These data are given in graphical form, called tube rating charts.

Shock-proof roentgenographic tubes are constructed similarly to the therapy tube shown in Fig. 6.

To increase the rating for a focal spot of a given size, tubes have been developed with rotating anodes, the cathode stream being so directed that the focal spot is separated several millimeters from the tube axis. Different areas of the rotating anode therefore act as focal spot during the exposure. Two such tubes are shown in Figs. 9–12. The anode

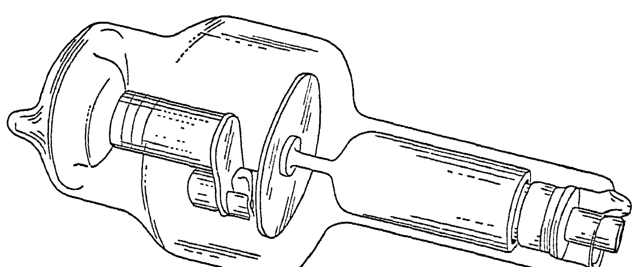

FIG. 9. Rotating-anode Roentgenographic Tube. Ratings (in oil-insulated tubehead): 2-mm focal spot, maximum voltage 100 kvp, 500 ma at 90 kvp for 1/30 sec, 400 ma at 80 kvp for 1/5 sec; 1-mm focal spot, maximum voltage 100 kvp, 200 ma at 90 kvp for 1/20 sec, 100 ma at 90 kvp for 3 sec. (Courtesy Machlett Laboratories.)

within the evacuated tube envelope operates as the rotor of a split-phase induction motor. These tubes are equipped with two cathodes; one produces an effective focal spot 1 mm square; the other, 2 mm square. The rotors operate at approximately 3000 rpm.

The tube shown in Figs. 9 and 10 is equipped with an anode comprising a tungsten disk approximately 6 cm in diameter and 2.3 mm thick. This disk is mechanically connected to the rotor of the driving motor by means of a short molybdenum shaft; the entire assembly is blackened to promote radiation of heat to the oil surrounding the tube when it is operating in its shockproof tube head. The balls of the bearing within the vacuum tube are coated with a thin, uniform film of silver, which reduces bearing friction. Samples of the manufacturer's ratings are listed below Fig. 9.

The anode structure of the tube shown in Figs. 11 and 12 consists of a tungsten cap backed by a heavy copper blackened cylinder, the purpose of which is to provide high heat storage and a large area for the radiation of heat to the oil surrounding the tube envelope. The ball bearings of this tube are lubricated by thin films of barium.

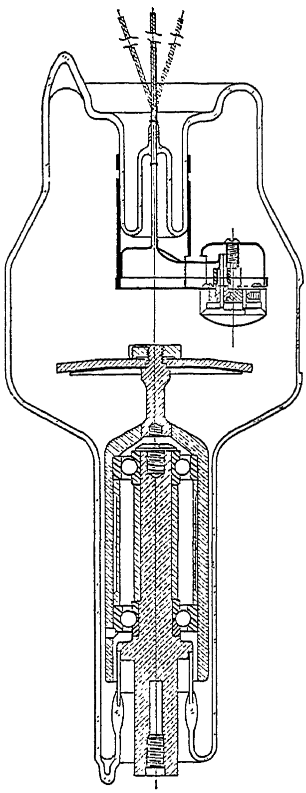

Fig. 10. Section of Rotating Anode Tube Shown in Fig. 9. (Courtesy Machlett Laboratories.)

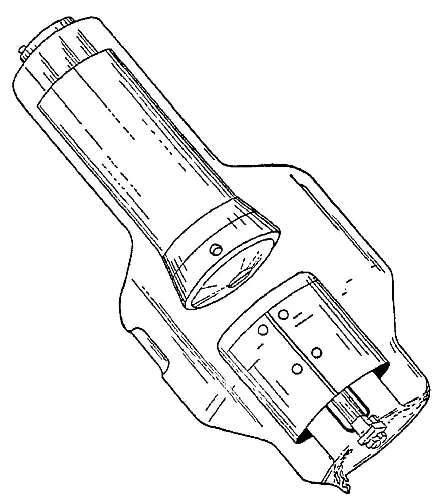

Fig. 11. Rotating-anode Roentgenographic Tube. Ratings (in oil-insulated tubehead): 2-mm focal spot, maximum voltage 100 kvp, 500 ma at 90 kvp for 1/30 sec, 400 ma at 80 kvp for 2/5 sec; 1-mm focal spot, maximum voltage 100 kvp, 200 ma at 94 kvp for 1/20 sec, 100 ma at 90 kvp for 5.6 sec. (Courtesy General Electric X-ray Corporation.)

Rotating-anode tubes are usually equipped with counters to record the number of exposures, and with control circuits that prevent high-voltage excitation of the tube unless the anode is rotating at rated speed (approximately 3000 rpm).

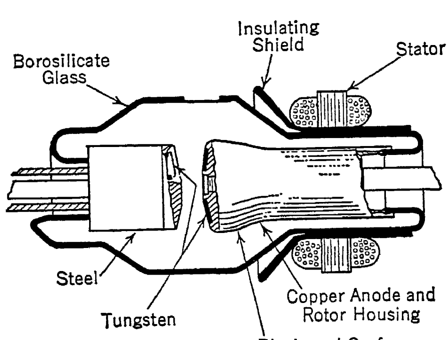

Fig. 12. Section of the Rotating-anode Tube Shown in Fig. 11. (Courtesy General Electric X-ray Corporation.)

Tubes used for roentgenoscopy (viewing of x-ray shadows by means of a fluorescent screen) are similar to the stationary-anode tubes described above, except that focal spots less than 2 mm square may be used, since the current seldom exceeds 10 ma. These tubes are often non-shockproof, since they are commonly mounted under a fluoroscopic table, out of reach of operator and patient.

Modern roentgenographic and fluoroscopic tubes should be used about 10–20 per cent below the manufacturers' ratings to guarantee a long useful life. Roentgenographic tubes, so operated, often can be used for 100,000 exposures or more.

25. TUBES FOR INDUSTRIAL ROENTGENOGRAPHY AND FLUOROSCOPY, AND FOR X-RAY DIFFRACTION

The use of x-rays (and of gamma rays) for the examination of commercial products has greatly increased, particularly during World War II; such examinations are quick and non-destructive. The following are representative of the diverse applications of this method of inspection: the examination for flaws in castings and welded joints; the inspection of packaged foods for foreign bodies; the final checking of manufacturing tolerances in such items as golf balls and multielectrode vacuum tubes; the inspection of packages for contraband; the inspection of citrus fruits suspected of being damaged by frost; the inspection of paintings and mummies.

X-ray tubes for industrial radiography and fluoroscopy are similar to those described in articles 23 and 24. The desire to use x-ray tube voltages up to 2 Mv for radiography of thick (as much as 0.3–0.4 m) steel was, in fact, a major stimulus to the development of the high-voltage tubes described in article 23 (Fig. 7). In all industrial radiographic tubes, regardless of voltage, as small a focal spot as possible must be produced to minimize the unsharpness of shadow borders, just as in medical roentgenography.

FIG. 13. Shockproof X-ray Diffraction Tube, with Grounded, Water-cooled Anode of Molybdenum, Copper, Cobalt, or Iron, and a Window of Beryllium. Ratings 50 kvp, 10–20 ma, continuous. (Courtesy Machlett Laboratories.)

Since industrial radiographic equipment may have to be moved about in a factory to use it near a heavy object to be inspected, design of equipment is based upon movability, flexibility of adjustment, and adequate protection of personnel from electric shock and excessive exposure to x-rays. Thus all industrial radiographic apparatus now manufactured is shockproof and shielded with lead or other x-ray-absorbing material, except in the direction of the useful beam.

The investigation of the structure of crystalline materials by means of x-ray diffraction has been developed from the early (1908–1915) theoretical analysis and experiments of von Laue, Friedrich, Knipping, W. H. and W. L. Bragg, and their colleagues. In recent years, x-ray diffraction apparatus suitable for routine analyses of crystal structure has been used in industry. X-ray tubes for this purpose consist of an anode of tungsten, molybdenum, copper, iron, or cobalt, a conventional incandescent tungsten cathode, and one or more windows of beryllium, which has an extremely low x-ray absorption coefficient.

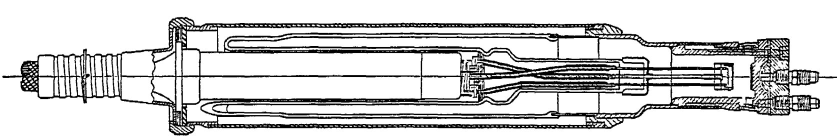

FIG. 14. Section of X-ray Diffraction Tube Shown in Fig. 13. (Courtesy Machlett Laboratories.)

The tubes operate at 10–50 kvp, 10–50 ma. A selective filter may be used to isolate the characteristic radiation from the anode, thereby producing a relatively intense, almost monochromatic beam of x-rays. A photograph of an x-ray diffraction tube and a cross-section of the tube are shown in Figs. 13 and 14.

ELECTRIC CIRCUITS, LINES, AND FIELDS

ELECTRIC CIRCUITS, LINES, AND FIELDS

THEORY OF LINEAR PASSIVE NETWORKS

By P. H. Richardson

The networks to be considered are assumed to consist of resistances, inductances, capacitances, and mutual inductances connected or coupled together in some manner. The problem is to determine the steady-state response of the network to an impressed voltage, or current, of any complexity. It is presupposed that the driving voltage has been impressed on the network at a time far enough in the past to have permitted any transients to die out.

To facilitate the solution of the problem the following assumptions are made:

1. The impressed voltage is periodic.
2. The network is *linear*. The values of the component elements are independent of the current through them.
3. The network is *passive*. There are no sources of energy interior to the network, and no energy is dissipated other than by the resistance elements of the network.

1. NON-SINUSOIDAL CURRENTS AND VOLTAGES

As a consequence of the linearity of the networks the coefficients of the differential equations are real constants. The equations express the equilibrium conditions which exist between the instantaneous driving voltages and the countervoltages in the circuit. For example, in the circuit of Fig. 1, consisting of R, L, and C $(= 1/D)$ in series, the differential equation is

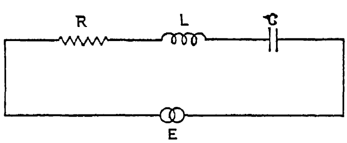

FIG. 1. Single-mesh Circuit

$$L\frac{d^2q}{dt^2} + R\frac{dq}{dt} + Dq = e \tag{1}$$

where q is the charge on the condenser, and $i = dq/dt$. If q_1 is the charge corresponding to an impressed voltage e_1, and q_2 is the charge corresponding to an impressed voltage e_2, it is evident that

$$L\frac{d^2q_1}{dt^2} + R\frac{dq_1}{dt} + Dq_1 = e_1$$

and

$$L\frac{d^2q_2}{dt^2} + R\frac{dq_2}{dt} + Dq_2 = e_2$$

By simple addition it follows that

$$L\frac{d^2(q_1 + q_2)}{dt^2} + R\frac{d(q_1 + q_2)}{dt} + D(q_1 + q_2) = e_1 + e_2 \tag{2}$$

Thus, for a linear network the *principle of superposition* holds. In other words, the current (or voltage) at any point flowing in response to several driving voltages acting together is the sum of the currents (or voltages) at that point which would flow in response to the driving voltages acting separately. This principle is of major importance in network analysis.

FOURIER'S THEOREM. A second important concept in the analysis of the steady state is Fourier's theorem, which states that any single-valued continuous periodic function can be expressed as an infinite series of sine waves. In particular, if $f(x)$ is a function which is finite in the interval from $-c$ to $+c$ and has only a finite number of discontinuities in that interval, then for any value of x in the interval

$$f(x) = \frac{a_0}{2} + a_1\cos\frac{\pi x}{c} + a_2\cos\frac{2\pi x}{c} + \cdots$$
$$+ b_1\sin\frac{\pi x}{c} + b_2\sin\frac{2\pi x}{c} + \cdots \tag{3}$$

where the coefficients $a_0, a_1, a_2, \cdots b_1, b_2, \cdots$ are determined as follows:

$$a_n = \frac{1}{c}\int_{-c}^{c} f(x)\cos\frac{n\pi x}{c}\,dx; \qquad b_n = \frac{1}{c}\int_{-c}^{c} f(x)\sin\frac{n\pi x}{c}\,dx$$

Or, equivalently,

$$f(x) = \frac{a_0}{2} + A_1 \sin\left(\frac{\pi x}{c} + \beta_1\right) + A_2 \sin\left(\frac{2\pi x}{c} + \beta_2\right) + \cdots \tag{4}$$

where

$$A_n = \sqrt{a_n^2 + b_n^2} \quad \text{and} \quad \beta_n = \tan^{-1}\left(\frac{a_n}{b_n}\right)$$

A proof of this theorem will be found in any standard book on calculus.

This theorem, taken in conjunction with the principle of superposition, makes it possible to obtain the response of a linear network to a periodic voltage of any complexity, provided that a solution is available for the case in which the driving voltage is a simple sinusoid. The complicated wave form of the impressed voltage is first resolved into its component sine waves, the solution of the equation is obtained for each component, and the solutions are added to obtain the final current or voltage required.

2. SINGLE-MESH CIRCUIT

Before proceeding to the general problem it will be profitable to examine in detail the response of the single-mesh circuit of Fig. 1. As already noted the differential equation is

$$L\frac{d^2q}{dt^2} + R\frac{dq}{dt} + Dq = E_0\epsilon^{j\omega t} \tag{5}$$

where the complex exponential form has been written for the impressed voltage. The notation is the usual one, where $\omega = 2\pi f$, f = frequency in cycles per second, E_0 is a constant, either real or complex, and $j = \sqrt{-1}$.

Assuming a solution of the form $q = q_0\epsilon^{pt}$ leads to the result that

$$(Lp^2 + Rp + D)q_0\epsilon^{pt} = E_0\epsilon^{j\omega t} \tag{6}$$

which is evidently a solution provided that $p = j\omega$. Then

$$q_0 = \frac{E_0}{Lp^2 + Rp + D}$$

and

$$i = I_0\epsilon^{pt} = \frac{E_0\epsilon^{pt}}{Lp + R + D/p} = \frac{e}{Z} \tag{7}$$

where $I_0 = E_0/Z$, $Z = R + Lp + D/p$, and $p = j\omega$.

Upon substituting $j\omega$ for p the result is the familiar one that

$$i = \frac{E_0}{Z}\epsilon^{j\omega t} \tag{8}$$

where $Z = R + jx$ and $x = (L\omega - D/\omega)$.

The use of the complex exponential form for the impressed voltage converts the differential equation at once to an algebraic equation. The resultant current is a complex exponential form of the same frequency as the impressed voltage. The impressed voltage is made up of two components in quadrature, and the resultant current is also made up of two currents in quadrature. Since the coefficients of eq. (5) are real, it is evident that the response to a real voltage is also real, while the current in response to an imaginary voltage is imaginary. Consequently, by the principle of superposition, the physical current flowing in response to a voltage $E_0 \cos \omega t$ is given by the real part of eq. (8). The imaginary part of the current, with the j discarded, is the physical current that flows in response to an impressed voltage $E_0 \sin \omega t$. Hence

$$i = \frac{|E_0|}{|Z|}\epsilon^{j(\omega t + \alpha - \beta)}$$

$$i_{\text{real}} = \frac{|E_0|}{|Z|}\cos(\omega t + \alpha - \beta) \tag{9}$$

and

$$i_{\text{imag}} = \frac{|E_0|}{|Z|}\sin(\omega t + \alpha - \beta)$$

where $Z = |Z| \underline{/\beta}$, $E_0 = |E_0| \underline{/\alpha}$, and $\beta = \tan^{-1}(x/R)$. The quantity $|E_0|$ is the maximum value of e, and similarly $|I_0|$ is the maximum value of i. By proper choice of units $|E_0|$ may be the rms voltage, and then $|I_0|$ is the rms current. Hence the ratio $|E_0/I_0|$ becomes the absolute value of the steady-state a-c impedance. The complex quantity $Z = e/i = E_0/I_0$ is defined as the complex steady-state impedance and may be studied as a function of $p = j\omega$.

3. THE COMPLEX FREQUENCY PLANE

The definition of the parameter $p = j2\pi f$ can be usefully extended for analytic purposes to situations in which f and p are complex. Suppose a voltage $E_0\epsilon^{pt}$ is assumed where $E_0 = |E_0| \underline{/\alpha}$ and $p = p_1 + jp_2$. Then

$$E_0\epsilon^{pt} = |E_0| \, \epsilon^{p_1 t}\epsilon^{j(p_2 t + \alpha)} \tag{10}$$

In accordance with the above discussion the physical voltage is taken as the real part of this, which is a sinusoidal oscillation with positive or negative damping depending on p_1. The corresponding steady-state physical current is obtained by dividing the complex voltage by the impedance and taking the real part of the result. This is a damped sinusoid of the same frequency and damping as the voltage.

Complex frequencies can be represented on a plane as shown in Fig. 2. The horizontal axis represents real values of p, and the vertical axis imaginary values of p, or real values

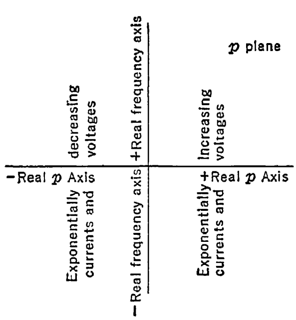

FIG. 2. Complex Frequency Plane

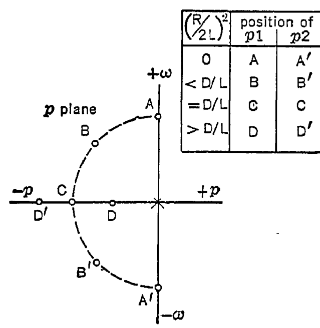

FIG. 3. Distribution of Zeros and Poles in Complex Plane

of frequency. In network analysis a distinction of primary importance is made between the right and left halves of the p plane, since on the left half-plane the voltages and currents correspond to functions which *decrease* exponentially with time, whereas on the right half-plane they *increase* exponentially with time. There is a close connection between the steady-state characteristics of a network and its transient response. Since a network whose transients increase with time is unstable, the characteristics of physical networks in the right half-plane are necessarily limited. There is no such distinction between the upper and lower halves of the plane.

As an illustration of this discussion consider the impedance of the single-mesh network of Fig. 1. Here the impedance

$$Z = \frac{L}{p}\left(p^2 + \frac{R}{L}p + \frac{D}{L}\right) \tag{11}$$

$$= \frac{L}{p}(p - p_1)(p - p_2)$$

where

$$p_1 = -\frac{R}{2L} + \sqrt{\left(\frac{R}{2L}\right)^2 - \frac{D}{L}} \quad \text{and} \quad p_2 = -\frac{R}{2L} - \sqrt{\left(\frac{R}{2L}\right)^2 - \frac{D}{L}}$$

are the *zeros* of the impedance expression. They are seen to be real when $(R/2L)^2 \geq D/L$, while they are conjugate complex numbers when $(R/2L)^2 < D/L$. The locations of the zeros p_1 and p_2 are indicated on Fig. 3 as R/L is varied and D/L is held fixed. It should be noted that the values of p_1 and p_2 always have negative real parts; they are always in the left half-plane. The impedance becomes infinite, that is, it has a *pole*, when p is zero, as represented by the cross at the origin. A second pole occurs at infinity where the impedance again becomes infinite.

4. MESH EQUATIONS

The response of a complicated network of the type shown in Fig. 4 is determined by making use of the equilibrium conditions which must be satisfied by the instantaneous currents and voltages. There are several methods of writing the equations; one uses branch equations, a second mesh equations, and a third nodal equations. In writing branch equations the current in each branch, Z_{10}, Z_{12}, etc., is separately specified, and the sum of the instantaneous voltages in each branch is equated to the voltage applied to the ends of the branch. There are B such equations, where B is the number of branches. At each node, or junction point between branches, the sum of the currents entering the node must be equal to the sum of the currents leaving the node. Therefore, J relations of this kind can be found, where J is the number of junction points. If there are S separate parts (not conductively connected to one another, as mesh 7 in Fig. 4) only $J - S$ of these equations are useful, since, if the law of the conservation of charge is satisfied at all but one node in each of the S parts, it is automatically satisfied at the last one also. There are then $B + J - S$ independent equations.

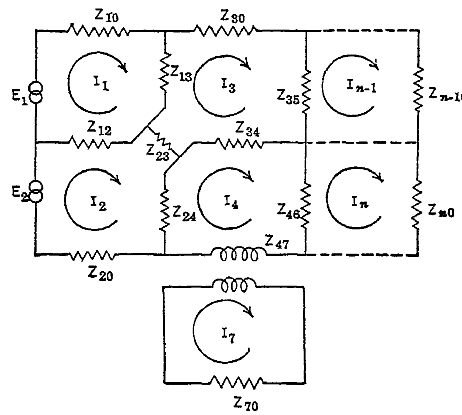

FIG. 4. Multi-mesh Network

The original branch equations include, in addition to the B branch currents, only differences in the node voltages. S of these can be arbitrarily assumed, and there will remain exactly $B + J - S$ unknowns to be determined.

By adding together the branch voltage equations around a complete loop, or mesh, and eliminating the superfluous branch currents by means of the nodal current equations, an equation is found for each mesh. A similar equation can be found for each of the N meshes of the network, where $N = B - J + S$.

A considerable simplification can be achieved by originally specifying only one current for each mesh of the network as shown in Fig. 4. By choosing circulating currents the nodal equations are automatically eliminated, as are the voltage differences which appear in the branch equations. The minimum number of mesh currents that can be used is, of course, $B - J + S$. For example, in Fig. 4 there are 15 branches, 10 junctions, and 2 parts, hence 7 meshes. It is important to note that a closed loop, consisting of a single branch with its two terminals coinciding, is considered to have one junction.

By adopting a set of conventions, regularity of notation is introduced into the equations. Those generally used are that all currents are assumed clockwise; branches common to two meshes a and b will carry as subscript the symbols of both meshes, as Z_{ab}; branches appearing in one mesh only will be designated Z_{a0}; and the sum of all the branches in a particular mesh will be designated as Z_{aa}. In computing Z_{aa}, the self-impedance of a mesh, all the self-inductance in the mesh is included but mutual inductances to other meshes are not.

Then for any linear network of N meshes a set of N equations is found as follows:

$$
\begin{aligned}
Z_{11}I_1 + Z_{12}I_2 + Z_{13}I_3 + \cdots Z_{1n}I_n &= E_1 \\
Z_{21}I_2 + Z_{22}I_2 + Z_{23}I_3 + \cdots Z_{2n}I_n &= E_2 \\
\cdots\cdots\cdots\cdots\cdots\cdots\cdots & \\
Z_{n1}I_1 + Z_{n2}I_2 + Z_{n3}I_3 + \cdots Z_{nn}I_n &= E_n
\end{aligned}
\tag{12}
$$

where each of the Z's is of the form

$$Z_{ab} = pL_{ab} + R_{ab} + \frac{1}{p}D_{ab}$$

and p and $1/p$ represent differentiation and integration with respect to time.

The mesh equations developed thus far have represented the differential equations of the circuit. The set of differential equations is transformed to an identical set of algebraic equations by the assumption made in article 2, that each of the sinusoidal voltages and currents can be written as $E\epsilon^{j\omega t}$ or $I\epsilon^{j\omega t}$, where E and I are constants, $\omega = 2\pi f$, f = frequency in cycles per second, and $j = \sqrt{-1}$. This transformation results from the fact that differentiation and integration of $\epsilon^{j\omega t}$ replaces each p in eq. (12) by $j\omega$. The time factors $\epsilon^{j\omega t}$ appear on both sides of the equation and can be divided out. The Z's are then the complex self- and mutual impedances of the meshes. And the I's and E's are regarded as representing merely the constant coefficients in the more general expressions $I\epsilon^{j\omega t}$ and $E\epsilon^{j\omega t}$.

DRIVING POINT AND TRANSFER IMPEDANCES. The determination of any particular current flowing in response to a particular voltage is equivalent to the solution of a set of ordinary linear equations. The current in the first mesh flowing in response to the voltage $E_1\epsilon^{j\omega t}$, also in that mesh, is given by the method of determinants (see *Handbook of Engineering Fundamentals*, Eshbach, John Wiley) as

$$I_1\epsilon^{j\omega t} = \frac{\Delta_{11}}{\Delta} E_1\epsilon^{j\omega t} \tag{13}$$

where Δ is the determinant of the coefficients in the left-hand side of eq. (12) and Δ_{11} is the determinant obtained by omitting the first row and first column of Δ. The *driving point impedance* in the first mesh is by definition the ratio of the voltage to the current in eq. (13). Thus

$$Z = \frac{E_1}{I_1} = \frac{\Delta}{\Delta_{11}} \tag{14}$$

In similar fashion the current in the second mesh flowing in response to the voltage E_1 in the first mesh is given by

$$I_2\epsilon^{j\omega t} = -\frac{\Delta_{12}}{\Delta} E_1\epsilon^{j\omega t} \tag{15}$$

where Δ_{12} is the minor of Δ obtained by removing the first row and second column. The *transfer impedance* from the first to the second mesh is defined as

$$Z_T = \frac{E_1}{I_2} = -\frac{\Delta}{\Delta_{12}} \tag{16}$$

It should be noted also, since in a passive network $Z_{ab} = Z_{ba}$, that

$$Z_T' = \frac{E_2}{I_1} = -\frac{\Delta}{\Delta_{21}} = -\frac{\Delta}{\Delta_{12}} \tag{17}$$

5. NODAL EQUATIONS

An analogous system of equations can be set up in terms of driving currents at the nodes and nodal voltages. In this analysis the fundamental equations are conditions of current equilibrium. In the circuit of Fig. 5, I_1, I_2, I_3, and I_4 are the driving currents, and Y_{14}, Y_{12}, Y_{13}, etc., are the admittances (reciprocal impedances) of the various branches. Node 4 has been assumed at ground potential. At node 1, then,

$$Y_{14}E_1 + Y_{12}(E_1 - E_2) + Y_{13}(E_1 - E_3) = I_1$$

or (18)

$$Y_{11}E_1 - Y_{12}E_2 - Y_{13}E_3 = I_1$$

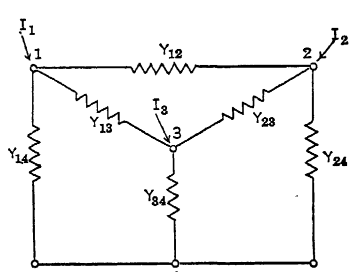

FIG. 5. Illustration for Method of Nodal Analysis

where $Y_{11} = Y_{14} + Y_{12} + Y_{13}$ is evidently the sum of the admittances of all the branches connected to 1 with all the other nodes connected together. Y_{11} is therefore a *self-admittance* analogous to the self-impedance in the mesh analysis. Similarly Y_{12} and Y_{13} are *mutual admittances* analogous to *mutual impedances*.*

* For a treatment of nodal analysis for circuits involving mutual inductance the reader is referred to Gardner and Barnes, *Transients in Linear Systems*, Vol. I.

In any conductively united network having J nodes a set of $J - 1$ independent equations of the above form can be written. The complete set becomes

$$\begin{aligned} Y_{11}E_1 - Y_{12}E_2 - \cdots - Y_{1n}E_n &= I_1 \\ -Y_{21}E_1 + Y_{22}E_2 - \cdots - Y_{2n}E_n &= I_2 \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ -Y_{n1}E_1 - Y_{n2}E_2 - \cdots + Y_{nn}E_n &= I_n \end{aligned} \tag{19}$$

where the Y's are of the form

$$Y_{ab} = C_{ab}p + G_{ab} + \frac{1}{L_{ab}} \cdot \frac{1}{p}$$

and p and $1/p$ have the meanings previously ascribed to them.

A solution of the set of nodal equations to find the steady-state voltage corresponding to a given set of sinusoidal driving currents can be obtained by the processes already used. The *driving point admittance* Y between the first node and ground is defined as

$$Y = \frac{I_1}{E_1} = \frac{\Delta'}{\Delta_{11}'} \tag{20}$$

where the primes indicate that the Δ's refer to the set of equations (19).

Similarly the *transfer admittance* between the first and second nodes is defined as

$$Y_T = \frac{I_1}{E_2} = -\frac{\Delta'}{\Delta_{12}'} \tag{21}$$

In this case, also, since $Y_{ab} = Y_{ba}$,

$$Y_T' = \frac{I_2}{E_1} = -\frac{\Delta'}{\Delta_{21}'} = -\frac{\Delta'}{\Delta_{12}'} \tag{22}$$

One consequence of the analogy between the mesh and nodal equations is that the selection of one of the two methods of solution in any particular problem is entirely a matter of convenience. The symmetry of the two methods is further emphasized by the equivalence of Fig. 6, in which a constant-voltage generator in series with an impedance Z is shown as replaceable by a constant-current generator in parallel with an impedance Z.

A second consequence of the analogy leads to the *principle of duality* in network theory. The symmetry in the current and voltage methods of analysis includes the individual terms in the equations. The general term Z_{ab} of eq. (12) is replaced by Y_{ab} of eq. (19) if

$$L_{ab} = C_{ab},\ R_{ab} = G_{ab} \quad \text{and} \quad D_{ab} = \left(\frac{1}{C_{ab}}\right) = \frac{1}{L_{ab}}$$

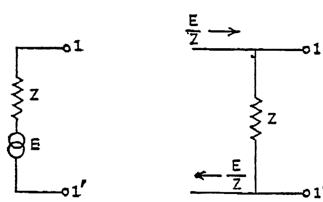

FIG. 6. Replacement of Constant-voltage Generator by an Equivalent Constant-current Generator

Consequently a set of nodal equations can be obtained identical with a given set of mesh equations by interchanging r and g, and L and C, wherever they appear. For every impedance function, therefore, there is a corresponding admittance function. If the mesh equations for one network correspond, term by term, with the nodal equations for another, the two networks are called *inverse* structures, or *duals*.

6. TWO-TERMINAL IMPEDANCES

The driving point impedance, or admittance, of a network can be expressed as the ratio of determinants whose elements are relatively simple functions of $p = j\omega$. In the mesh system the general impedance coefficient can be written as $Z_{ab} = L_{ab}p + R_{ab} + D_{ab}\,1/p$. Since the terms Δ, Δ_{11}, and Δ_{22} used in defining driving point impedances can be expressed as products of terms of this type, it follows that they are polynomials in p divided by some power of p. That is,

$$Z = \frac{A_m p^m + A_{m-1}p^{m-1} + \cdots + A_1 p + A_0}{B_n p^n + B_{n-1}p^{n-1} + \cdots + B_1 p + B_0} \tag{23}$$

Put in terms of the zeros and poles the expression is

$$Z = \frac{A_m(p - p_1)(p - p_2) \cdots (p - p_m)}{B_n(p - p_1')(p - p_2') \cdots (p - p_n')} \tag{24}$$

where ordinarily the p_a's are all different. Note that the p_a's and p_a''s are the roots of the polynomials in the numerator and the denominator. In special cases two or more zeros or poles may coincide. The zeros and poles may be thought of as corresponding to the resonances and antiresonances of purely reactive networks except that they may occur at complex frequencies.

RESTRICTIONS FOR PHYSICAL REALIZABILITY. A passive two-terminal or driving point impedance is subject to the following restrictions:

1. In terms of the frequency variable $p = j\omega$ the zeros and poles are either real or they occur in conjugate complex pairs.
2. The real and imaginary components are respectively even and odd functions of frequency on the real frequency axis.
3. None of the zeros and poles can be found in the right half of the p plane.
4. Zeros and poles on the real frequency axis must be simple.
5. The real component of the driving point impedance cannot be negative at real frequencies.

General methods for finding physical networks corresponding to any impedance function meeting these restrictions have been devised.* A method due to Brune depends on the fact that the minimum value of resistance, or conductance, at real frequencies is less than any value in the right half-plane. If the function is diminished by a real positive constant equal to the minimum value of the resistance, the remainder corresponds to a passive impedance having a zero resistance at a real frequency. This remainder is termed a *minimum resistance*, or *minimum conductance* expression. Similarly it can be shown that an impedance expression having zeros or poles on the real frequency axis can be diminished by the reactance, or susceptance, corresponding to its real frequency zeros and poles. An impedance having no poles at real frequencies is called a *minimum reactance* expression, while one having no zeros at real frequencies is called a *minimum susceptance* expression. If an impedance is both minimum resistance and minimum reactance, there is a unique relation between the resistance and reactance; if either is known at all frequencies the other can be determined.

NETWORKS OF PURE REACTANCES. If it is specified that the zeros and poles of an impedance expression occur at real frequencies, or imaginary values of p, the form of the impedance expression becomes

$$Z = \frac{kp(p^2 - p_2^2)(p^2 - p_4^2) \cdots (p^2 - p_m^2)}{(p^2 - p_1^2)(p^2 - p_3^2) \cdots (p^2 - p_{m-1}^2)} \tag{25}$$

where k is a positive real constant, while p_1^2, p_2^2, etc., are negative real quantities. Each of the factors represents a pair of zeros, or poles, at positive and negative real frequencies. The zeros and poles are restricted in that

$$-p_m^2 \geqq -p_{m-1}^2 \geqq - \cdots \geqq -p_2^2 \geqq -p_1^2 \geqq 0 \tag{26}$$

or the zeros and poles must alternate.

As written the impedance is specified as an inductive reactance at both zero and infinite values of frequency. To obtain complete generality it must be allowable to specify $p_1^2 = 0$ (which introduces a pole at $p = 0$), or that the factor $p^2 - p_m^2$ can be omitted (which leads to a zero at infinite frequency).

It has been demonstrated † that the impedance of eq. (25) corresponds to a physical network containing only inductances and capacitances. The network can be found either by representing the poles as antiresonant networks in series or by representing the zeros as resonant networks in parallel. For a detailed discussion of these impedances see Section 6, Article 17.

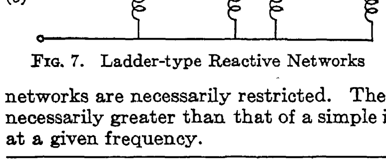

FIG. 7. Ladder-type Reactive Networks

The reactive networks can also be realized in other configurations of which Figs. 7*a* and 7*b* are typical. These are obtained as the result of continued fraction expansions in which the zeros and poles at zero and infinite frequency are removed alternately.

Because of the restrictions on the zeros and poles the impedance characteristics of reactive networks are necessarily restricted. The slope of the characteristic is always positive and necessarily greater than that of a simple inductance or capacity having the same reactance at a given frequency.

NETWORKS OF RESISTANCES AND INDUCTANCES OR RESISTANCES AND CAPACITANCES. Very similar to the purely reactive networks which result when the zeros or poles are specified at real frequencies, a simple series of networks results when it is specified that the zeros and poles occur at imaginary frequencies, or real values of p. Again only two kinds of elements, either resistances and inductances or resistances and capacitances, are required to realize such impedances.

If the expression corresponds to a network of resistances and inductances, it is of the form

$$Z = \frac{kp(p - a_2)(p - a_4) \cdots (p - a_m)}{(p - a_1)(p - a_3) \cdots (p - a_{m-1})} \tag{27}$$

and $|Z|$ increases as p increases. If, on the other hand, the expression corresponds to a network of resistances and capacitances $|Z|$ decreases as p increases. An alternative form for Z is

$$Z = \frac{k(p - a_2)(p - a_4) \cdots (p - a_m)}{(p - a_1)(p - a_3) \cdots (p - a_{m-1})} \tag{28}$$

In both expressions the zeros and poles occur alternately and a_1, a_2, etc., are negative real quantities or zero.

As in the case of the reactive network the impedances may be represented in partial fraction form. For example, the impedance of eq. (28) can be expanded in the form

$$Z = \frac{D_1}{p - a_1} + \frac{D_3}{p - a_3} + \cdots + \frac{D_{m-1}}{p - a_{m-1}} + R \tag{29}$$

where $D_a = [(p - a_a)Z]_{p=a_a}$ and R is the resistance at infinite frequency. Each of the terms $D_a/(p - a_a)$ is identifiable with the parallel combination of resistance and capacitance, where $r_a = -D_a/a_a$ and $C_a = 1/D_a$.

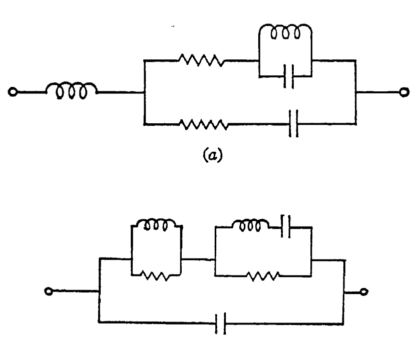
INVERSE OR RECIPROCAL IMPEDANCES. The duality between the impedance and admittance methods of analyzing a network suggests the possibility that to every network there corresponds an inverse. The requirement that the real part of an impedance be positive is merely another way of stating that the real part of the corresponding admittance be positive. Also, the restrictions on the zeros and poles are identical, so that the interchange of zeros and poles when an impedance is replaced by its reciprocal does not change the conditions for physical realizability. It follows, then, that, if a passive impedance is physically realizable, its reciprocal is also.

The reciprocal impedance for the structure of Fig. 8*a* is found, for example, as follows:

1. Each series connection is replaced by a parallel connection, and vice versa.
2. The individual resistances, inductances, and capacitances are respectively replaced by resistances, capacitances, and inductances in such a way that

$$R_1R_1' = \frac{L}{C'} = \frac{L'}{C} = R_0^2$$

The structural inverse of Fig. 8*a* is therefore given by 8*b*. This process is evidently not general since it considers only series and parallel connections. An extension of the method



(*a*) (*b*)

FIG. 8. Inverse Two-terminal Networks

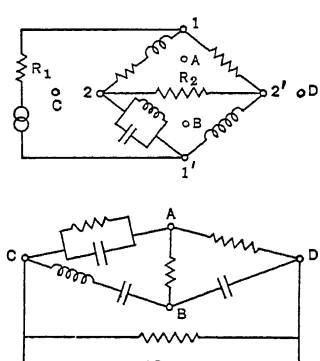


FIG. 9. Inverse Bridge Networks

depends on a consideration of the geometry of the network. The branches of the network are considered as lines between the junction points, dividing the plane of the diagram into areas. The process consists of interchanging areas and points. A new point is taken interior to each area and is connected to each similar point by a branch inverse to the branch separating the areas. The inverse of a bridge network is found by this process to be another bridge, as shown in Fig. 9. Even this process is not entirely general.*

COMPLEMENTARY IMPEDANCES. In addition to the inverse of a given impedance function one can also speak of its *complement*. The complement is defined by the requirement that the sum of the original impedance and its complement is a real constant. The complement of a passive impedance can be found if the prescribed impedance has no poles on the real frequency axis, and if the sum of the impedance and its complement is chosen at least as great as the maximum value of the resistance of the original impedance. The constant resistance combination of Fig. 10 represents a simple example of the relationship.

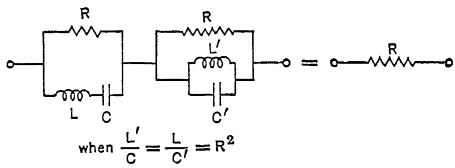

FIG. 10. Complementary Impedances in Series

7. FOUR-TERMINAL NETWORKS

The four-terminal network, or two-terminal pair, is a special form of general network of major importance. The external characteristics of the network are completely specified in terms of I_1, E_1, I_2, and E_2 of Fig. 11. A solution is obtained from eq. (12) with the assumption that all voltages except E_1 and E_2 are zero. Thus

$$I_1 = \frac{\Delta_{11}}{\Delta} E_1 - \frac{\Delta_{12}}{\Delta} E_2 \tag{30a}$$

$$I_2 = -\frac{\Delta_{12}}{\Delta} E_1 + \frac{\Delta_{22}}{\Delta} E_2 \tag{30b}$$

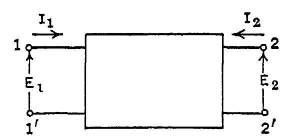

FIG. 11. General Four-terminal Network

Or, solving explicitly for E_1 and E_2, and noting that $\Delta\Delta_{1122} = \Delta_{11}\Delta_{22} - \Delta_{12}^2$

$$E_1 = \frac{\Delta_{22}}{\Delta_{1122}} I_1 + \frac{\Delta_{12}}{\Delta_{1122}} I_2 \tag{31a}$$

$$E_2 = \frac{\Delta_{12}}{\Delta_{1122}} I_1 + \frac{\Delta_{11}}{\Delta_{1122}} I_2 \tag{31b}$$

The currents of eqs. (30) are determined by the voltages E_1 and E_2 and the quantities Δ_{11}/Δ, Δ_{22}/Δ, and $-\Delta_{12}/\Delta$.

DRIVING POINT AND TRANSFER IMPEDANCES. The physical significance of the ratios is seen by successively setting E_2 and E_1 equal to zero. Thus

$\frac{\Delta_{11}}{\Delta} = Y_{s1}$ = admittance at terminals 1–1′ with 2–2′ shorted

$\frac{\Delta_{22}}{\Delta} = Y_{s2}$ = admittance at terminals 2–2′ with 1–1′ shorted

$-\frac{\Delta_{12}}{\Delta} = Y_{s12} = Y_{s21}$ = transfer admittance from either end with the opposite end shorted

Similarly, if I_2 and I_1 of eqs. (31a) and (31b) are successively set equal to zero,

$\frac{\Delta_{22}}{\Delta_{1122}} = Z_{01}$ = impedance at terminals 1–1′ with 2–2′ open

$\frac{\Delta_{11}}{\Delta_{1122}} = Z_{02}$ = impedance at terminals 2–2′ with 1–1′ open

$\frac{\Delta_{12}}{\Delta_{1122}} = Z_{012} = Z_{021}$ = transfer impedance from either end with the opposite end open

Thus the network may be described by either of these sets of three parameters, or by other sets of three parameters properly related to them.

* Foster, Geometrical Circuits of Electrical Networks, *Trans. A.I.E.E.*, June 1932.

The driving point impedances and admittances are subject to the same restrictions as any other two-terminal networks, if they are to correspond to physical networks. The transfer functions, however, differ in several important respects and require further consideration.

For the terminated network of Fig. 12 it can be shown that

$$E = \left(Z_1 + \frac{\Delta_{22}}{\Delta_{1122}}\right) I_1 + \frac{\Delta_{12}}{\Delta_{1122}} I_2 \qquad (32a)$$

$$E' = \frac{\Delta_{12}}{\Delta_{1122}} I_1 + \left(Z_2 + \frac{\Delta_{11}}{\Delta_{1122}}\right) I_2 \qquad (32b)$$

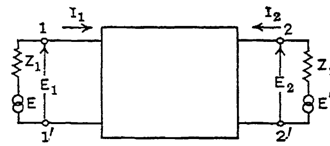

FIG. 12. Terminated Four-terminal Network

The response of the network evidently depends on the terminations Z_1 and Z_2, as well as on the network parameters themselves. Thus the driving point impedances become

$$Z_{1-1'} = \frac{\Delta + Z_2\Delta_{22}}{\Delta_{11} + Z_2\Delta_{1122}}; \qquad Z_{2-2'} = \frac{\Delta + Z_1\Delta_{11}}{\Delta_{22} + Z_1\Delta_{1122}} \qquad (33)$$

And the transfer impedances $Z_T = E'/I_1 = E/I_2$

$$Z_T = -\frac{1}{\Delta_{12}}[\Delta + Z_1\Delta_{11} + Z_2\Delta_{22} + Z_1Z_2\Delta_{1122}] \qquad (34)$$

The form of the transfer impedance expression is seen to be the ratio of determinants (since eq. [34] can be written $Z_T = -\Delta/\Delta_{12}$ if Δ is understood to be the network determinant including the terminations Z_1 and Z_2). The general impedance coefficient is $Z_{ab} = L_{ab}p + R_{ab} + D_{ab}(1/p)$ as before. In terms of the frequency variable $p = j\omega$, therefore, the transfer impedance is the ratio of polynomials in p and can be written in terms of its zeros and poles with a constant multiplier, just as in the case of driving point impedances. Thus

$$Z_T = \frac{A_m(p - a_1)(p - a_2) \cdots (p - a_m)}{B_n(p - b_1)(p - b_2) \cdots (p - b_n)} \qquad (35)$$

Since Z_T represents a transmission it is usually stated as a logarithm. And also, since the most efficient possible transmission between two impedances Z_1 and Z_2 is obtained if, first, the reactances of Z_1 and Z_2 are annulled, and then a transformer of optimum ratio is inserted between the two, this condition is used as a reference. Then the general transfer impedance is

$$Z_T = 2\sqrt{R_1R_2}\epsilon^\theta \qquad (36)$$

where

$$\epsilon^\theta = \epsilon^{A+jB} = \frac{k(p - a_1)(p - a_2) \cdots (p - a_m)}{(p - b_1)(p - b_2) \cdots (p - b_n)} \qquad (37)$$

and R_1 and R_2 are the real parts of Z_1 and Z_2. The a's and b's are the zeros and poles of Z_T, or the points of infinite gain or loss in terms of θ. It is evident from eq. (37) that two transfer impedances having the same zeros and poles can differ only by a constant loss or gain.

RESTRICTIONS FOR PHYSICAL REALIZABILITY. The restrictions which must be met if Z_T is to correspond to a physical network are as follows:

1. In terms of the frequency variable p both the zeros and the poles must be real or must occur in conjugate complex pairs.

2. The real and imaginary components are respectively even and odd functions of frequency.

3. The zeros must be located in the left half of the p plane; the poles may occur in any part of the plane.

4. The real part of $\theta = A + jB$ is positive at real frequencies; otherwise, the network serves as a source of power.

On comparing these restrictions to those given for two-terminal impedances two important differences are noted. First, the poles of the transfer impedance are not restricted to the left half-plane, and second, the real part of the transfer impedance may be negative. The previous restriction that the real part of a driving point impedance be positive is replaced by the new restriction that the real part of θ must be positive.

A structure which may be used to represent the general passive transfer function is shown in Fig. 13. The arms of the symmetrical lattice are assumed to be inverse such that $Z_x Z_y = R_2^2$. For this structure the ratio

$$\frac{E_1}{I_2} = Z_T = 2\sqrt{R_1 R_2}\epsilon^\theta \tag{38}$$

where

$$\epsilon^\theta = \frac{R_2 + Z_x}{R_2 - Z_x} \tag{39a}$$

or

$$Z_x = R_2 \frac{\epsilon^\theta - 1}{\epsilon^\theta + 1} \tag{39b}$$

It can be shown that Z_x represents a physical impedance as long as θ satisfies the restrictions listed above. In particular, Z_x will be physical as long as the transfer loss A is greater than zero at real frequencies. Consequently, in any case in which the minimum value of A is finite, the loss may be reduced by a constant corresponding to this minimum value. The reduced expression having zero loss at a real frequency is called a *minimum loss* or *minimum attenuation* function.

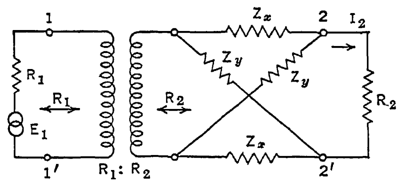

FIG. 13. Network Having Any Prescribed Passive Transfer Function

It is also possible to modify the transfer phase B without affecting the loss by introducing, or eliminating, terms corresponding to phase-shifting networks. Physical networks can be found (article 10) corresponding to the combinations of factors

$$\frac{p + a}{p - a} \quad \text{and} \quad \frac{(p + a + jb)(p + a - jb)}{(p - a - jb)(p - a + jb)} \tag{40}$$

Note that the poles in these expressions occur in the right half of the p plane, and that the zeros and poles are the negatives of one another. The absolute value of these expressions is evidently unity for all values of p, but the phase angle depends on p.

If the function Z_T contains a single pole on the positive real axis,

$$Z_T = \frac{F(p)}{p - a} = \frac{F(p)}{p + a}\left(\frac{p + a}{p - a}\right)$$
$$= Z_T'\left(\frac{p + a}{p - a}\right) \tag{41}$$

The transfer impedance Z_T is thus the product of a new transfer impedance Z_T' and a phase-shifting term, and can be shown to correspond to a new network of transfer impedance Z_T' in tandem with a simple phase network. A similar treatment is possible for a pair of complex poles in the right half-plane. The modified transfer impedance having no poles in the right half-plane is termed a *minimum phase* function. No further reduction can be made in the phase characteristic of such a function without at the same time affecting the loss characteristic.

NETWORK THEOREMS. Several useful theorems can be stated for the general linear network as follows:

The Compensation Theorem. If an impedance ΔZ is inserted in a branch of a network the resulting current increment produced at any point in the network is equal to the current that would be produced at that point by a compensating voltage $-I\Delta Z$ acting in series with the modified branch, where I is the current in the original branch.

The Reciprocity Theorem. If an electromotive force E of zero internal impedance applied between two terminals of a network produces a current I in some branch of the network, then the same voltage E acting in series with the second branch will produce the current I through the first pair of terminals shorted together. This follows from eqs. (30) since the short-circuit transfer admittance is the same from either end of the network.

Thévenin's Theorem. With respect to any pair of terminals considered as output terminals the network can be replaced by a branch having an impedance Z_{s2}, equal to the driving point impedance at these terminals, in series with an electromotive force E, equal to the open-circuit voltage across these terminals. An analogous theorem can be expressed in terms of the short-circuit current entering the output node of the network.

These results follow from eq. (30*b*) and the definitions of the open-circuit impedances and short-circuit admittances. Thus, if $E_2 = -I_2Z_2$,

$$I_2 = \frac{-E_1Y_{s12}}{Y_{s2}(Z_{s2}+Z_2)} = \frac{-E_1Z_{012}}{Z_{01}(Z_{s2}+Z_2)}$$

The open-circuit voltage at terminals $2 - 2'$ is $-I_2Z_2$ when $Z_2 \to \infty$, whence

$$I_2 = \frac{E_{20}}{Z_{s2}+Z_2} \tag{42}$$

The short-circuit current at terminals $2 - 2'$ is $-E_1Y_{s12}$, whence

$$E_2 = \frac{I_{2s}}{Y_2 + Y_{s2}} \tag{43}$$

EQUIVALENT QUADRIPOLES. A useful concept in network analysis is that of "equivalence." Two four-terminal networks, or quadripoles, are considered to be equivalent when the fundamental relations describing the behavior of the networks with respect to their input and output terminals are identical. Such equivalences can be expressed in terms of the network determinant and its minors, the open-circuit impedances, the short-circuit admittances, or any other set of three convenient and properly related parameters.

IMAGE PARAMETERS. An important and useful set of parameters is based on the idea that the terminations of the network be so related to the network itself that the impedances looking in both directions from the input terminals, or in both directions from the output terminals, are the same. Referring to Fig. 12 and eq. (33) this means that $Z_{1-1}' = Z_1$ and $Z_{2-2}' = Z_2$. The impedances $Z_1 = Z_{I_1}$ and $Z_2 = Z_{I_2}$ are called image impedances and are functions of the network itself, since

$$Z_{I_1} = \sqrt{\frac{\Delta\Delta_{22}}{\Delta_{1122}\Delta_{11}}} \quad \text{and} \quad Z_{I_2} = \sqrt{\frac{\Delta\Delta_{11}}{\Delta_{1122}\Delta_{22}}} \tag{44}$$

The third parameter necessary to characterize the network is called the image transfer constant and is defined as

$$\theta = \frac{1}{2}\log\frac{I_1^2Z_{I_1}}{I_2^2Z_{I_2}} \tag{45}$$

That is, θ is one-half the logarithm of the ratio of the volt-amperes entering the network to the volt-amperes leaving the network when it is terminated in its image impedances. In terms of the network determinant

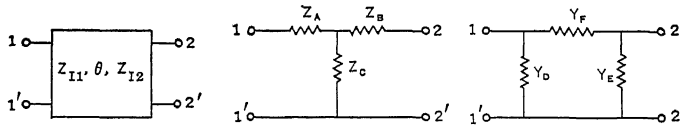
$$\theta = \frac{1}{2}\log\left[\frac{1+\sqrt{\Delta\Delta_{1122}/\Delta_{11}\Delta_{22}}}{1-\sqrt{\Delta\Delta_{1122}/\Delta_{11}\Delta_{22}}}\right] \tag{46}$$

The value of these parameters lies in the fact that they offer approximations to the actual network behavior and serve to relate the behavior of a network to that of a transmission line.

T AND π NETWORKS. The interrelation of several sets of network parameters is shown for two fundamental types of four-terminal networks in Fig. 14. The branches of the T and π networks equivalent to the general network are given in terms of the network determinant and its minors, the open- and short-circuit impedances, and the image parameters. These branch impedances and admittances themselves constitute complete sets of network parameters, even though they may not be physically realizable as two-terminal networks at all frequencies.

The T and π networks are important since they can be used to represent any quadripole for purposes of analysis and computation. They may evidently be used to represent any three-terminal network, or segment of a network, without loss of generality. The L-type network is considered to be a degenerate case of the T or π networks, and it is significant in that only two independent parameters are required to specify its behavior.

LATTICE OR BRIDGE NETWORKS. A network of major importance is the symmetrical balanced lattice shown in Fig. 15. It can be shown that this network is the most general of all symmetrical networks, and that any passive symmetrical four-terminal network, or quadripole, can be represented by a physically realizable lattice. Further, since the image impedance depends only on the product and the image transfer constant only on the ratio of the branch impedances, it is possible to control the transmission and impedance characteristics independently. See Section 6, article 23.



$$Z_A = \frac{\Delta_{22} - \Delta_{12}}{\Delta_{1122}} = Z_{01} - Z_{012} = \frac{Z_{I1}}{\tanh\theta} - \frac{\sqrt{Z_{I1}Z_{I2}}}{\sinh\theta} = \frac{Z_D Z_F}{Z_D + Z_E + Z_F}$$

$$Z_B = \frac{\Delta_{11} - \Delta_{12}}{\Delta_{1122}} = Z_{02} - Z_{012} = \frac{Z_{I2}}{\tanh\theta} - \frac{\sqrt{Z_{I1}Z_{I2}}}{\sinh\theta} = \frac{Z_E Z_F}{Z_D + Z_E + Z_F}$$

$$Z_C = \frac{\Delta_{12}}{\Delta_{1122}} = Z_{012} = \frac{\sqrt{Z_{I1}Z_{I2}}}{\sinh\theta} = \frac{Z_D Z_E}{Z_D + Z_E + Z_F}$$

$$Y_D = \frac{\Delta_{11} + \Delta_{12}}{\Delta} = Y_{s1} - Y_{s12} = \frac{Y_{I1}}{\tanh\theta} - \frac{\sqrt{Y_{I1}Y_{I2}}}{\sinh\theta} = \frac{Y_A Y_C}{Y_A + Y_B + Y_C}$$

$$Y_E = \frac{\Delta_{22} + \Delta_{12}}{\Delta} = Y_{s2} - Y_{s12} = \frac{Y_{I2}}{\tanh\theta} - \frac{\sqrt{Y_{I1}Y_{I2}}}{\sinh\theta} = \frac{Y_B Y_C}{Y_A + Y_B + Y_C}$$

$$Y_F = -\frac{\Delta_{12}}{\Delta} = Y_{s12} = \frac{\sqrt{Y_{I1}Y_{I2}}}{\sinh\theta} = \frac{Y_A Y_B}{Y_A + Y_B + Y_C}$$

$$Z_{I1} = \sqrt{\frac{\Delta\Delta_{22}}{\Delta_{1122}\Delta_{11}}} = \sqrt{Z_{s1}Z_{01}}$$

$$Z_{I2} = \sqrt{\frac{\Delta\Delta_{11}}{\Delta_{1122}\Delta_{22}}} = \sqrt{Z_{s2}Z_{02}}$$

$$\tanh\theta = \sqrt{\frac{\Delta\Delta_{11}}{\Delta_{11}\Delta_{22}}} = \sqrt{\frac{Z_{s1}}{Z_{01}}} = \sqrt{\frac{Z_{s2}}{Z_{02}}} = \sqrt{1 - \frac{Z_{s1}Z_{s2}}{Z_{s12}^2}} = \sqrt{1 - \frac{Z_{012}^2}{Z_{01}Z_{02}}}$$

$$Z_{s1} = Z_A + \frac{Z_B Z_C}{Z_B + Z_C} = \frac{1}{Y_D + Y_F}; \quad Z_{s2} = Z_B + \frac{Z_A Z_C}{Z_A + Z_C} = \frac{1}{Y_E + Y_F}$$

$$Z_{01} = Z_A + Z_C = \frac{1}{Y_D + \dfrac{Y_E Y_F}{Y_E + Y_F}}; \quad Z_{02} = Z_B + Z_C = \frac{1}{Y_E + \dfrac{Y_D Y_F}{Y_D + Y_F}}$$

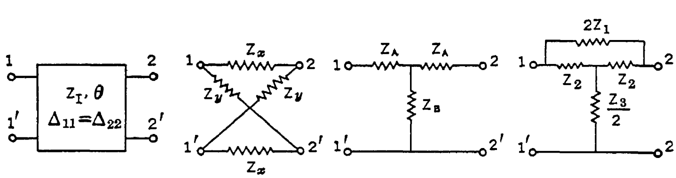
Symmetrical: ($\Delta_{11} = \Delta_{22}$, $Z_{01} = Z_{02}$, $Z_{s1} = Z_{s2}$)

$$Z_A = Z_B = Z_I \tanh\frac{\theta}{2} \qquad Y_D = Y_E = Y_I \tanh\frac{\theta}{2}$$

$$Z_C = \frac{Z_I}{\sinh\theta} \qquad Y_F = \frac{Y_I}{\sinh\theta}$$

$$Z_I = \sqrt{Z_A(Z_A + 2Z_C)} \qquad Y_I = \sqrt{Y_D(Y_D + 2Y_F)}$$

FIG. 14. T and π Networks Equivalent to a General Dissymmetrical Network



$$Z_x = \frac{\Delta_{11} - \Delta_{12}}{\Delta_{1122}} = Z_I \tanh\frac{\theta}{2} = Z_A = \frac{Z_1 Z_2}{Z_1 + Z_2}$$

$$Z_y = \frac{\Delta_{11} + \Delta_{12}}{\Delta_{1122}} = \frac{Z_I}{\tanh\theta/2} = Z_A + 2Z_B = Z_2 + Z_3$$

$$Z_I = \sqrt{Z_x Z_y} \qquad \tanh\frac{\theta}{2} = \sqrt{\frac{Z_x}{Z_y}}$$

FIG. 15. Lattice Network Equivalent to Any Symmetrical Network and to T and Bridged-T Networks

The lattice equivalent to the symmetrical T and bridged T structures of Fig. 15 is seen to be physical as long as the branch impedances of these structures are physical. The converse is not necessarily true, since each of these networks requires that the arms of the lattice contain a common impedance.

8. POWER TRANSFER

Transmission through a network is usually expressed as a logarithm with respect to a suitable reference condition.

Transition Loss. The condition for maximum power transfer from a generator to a load is indicated in Fig. 16. The series reactances $-X_1$ and $-X_2$ are inserted to annul the corresponding reactances of the generator and load impedances, and the ideal transformer of optimum ratio matches the resistance of the generator to that of the load. This structure is termed an *ideal transducer*, and the loss in power which is eliminated when it is inserted between a generator and a load is called the *transition loss* or the *transducer loss*. In decibels the

$$\text{Transition loss} = 10\log_{10}\frac{P_{20}}{P_2}$$

$$= 20\log_{10}|Z_1 + Z_2| - 10\log_{10}4R_1R_2 \quad (47)$$

where $P_{20} = E^2/4R_1$ is the reference power in the load (= available power) and $P_2 = E^2R_2/|Z_1 + Z_2|^2$ is the actual power in the load.

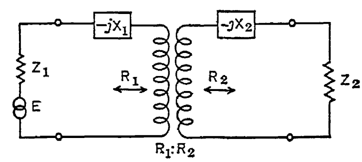


FIG. 16. Ideal Transducer

Insertion Loss and Phase. When a network is inserted between a sending impedance Z_1 and a receiving impedance Z_2 a change occurs in the current (or voltage) in the load. The ratio of the original load current I_{20} to the new load current I_2 is defined as the *insertion loss factor* or the *insertion factor*. In terms of the image parameters this becomes

$$\frac{I_{20}}{I_2} = \epsilon^{\Gamma} = \frac{k\epsilon^{\theta}}{k_1k_2S} \quad (48)$$

where

$$k_1 = \frac{2\sqrt{Z_1Z_{I_1}}}{Z_1 + Z_{I_1}} = \text{the sending end } \textit{reflection factor}$$

$$k_2 = \frac{2\sqrt{Z_2Z_{I_2}}}{Z_2 + Z_{I_2}} = \text{the receiving end } \textit{reflection factor}$$

$$k = \frac{2\sqrt{Z_1Z_2}}{Z_1 + Z_2} = \text{the } \textit{reflection factor} \text{ between } Z_1 \text{ and } Z_2$$

$$\theta = \text{the image transfer constant}$$

$$S = \frac{1}{\left[1 - \left(\frac{Z_1 - Z_{I_1}}{Z_1 + Z_{I_1}}\right)\left(\frac{Z_2 - Z_{I_2}}{Z_2 + Z_{I_2}}\right)\epsilon^{-2\theta}\right]} = \text{the } \textit{interaction factor}$$

The reflection factors represent modifications in the load current caused by reflections at the input and output junctions. The factor k, sometimes called the *symmetry factor*, represents a reflection factor that was eliminated when the network was inserted. Each of these factors involved only the ratio of two impedances, and each becomes unity when the impedances are equal.

The interaction factor, S, is a second-order effect which takes account of a wave reflected from the load back to the generator and then back to the load. It reduces to unity when either termination matches the image impedance adjacent to it, or when the attenuation of the network is high.

The insertion factor becomes equal to ϵ^{θ} when one of the terminating impedances and the image impedances are equal to one another.

The *insertion loss* (in decibels)

$$= 20\log_{10}\left|\frac{k\epsilon^{\theta}}{k_1k_2S}\right|$$

$$= 20\left[-\log_{10}\frac{1}{|k|} + \log_{10}\frac{1}{|k_1|} + \log_{10}\frac{1}{|k_2|} + \log_{10}\frac{1}{|S|} + \log_{10}|\epsilon^{\theta}|\right] \quad (49)$$

The first three terms, involving the reciprocals of the reflection factors, are called *reflection losses*. The fourth term is called the *interaction loss*, and the last term represents the real part of the image transfer constant in decibels.

The insertion phase shift is the phase angle of the current ratio given by eq. (48).

9. DISTORTION

When a voltage of complicated wave form is introduced into an electric circuit, a current will flow whose wave form will depend on that of the voltage and on the transmission characteristics of the circuit itself. It is frequently desired that the wave form of the current through a particular circuit element shall be the same as the wave form of the original voltage. If the complicated impressed voltage is regarded as a series of sine waves of various frequencies the conditions under which the output current will be a faithful reproduction of the input voltage may be stated as follows:

1. The response of the circuit must be the same for all frequency components present in the impressed voltage.
2. The relative phase relations of the various frequency components must not be altered.
3. The circuit must be linear.

FREQUENCY DISTORTION. When the first condition is not satisfied and the relative amplitudes of the various frequency components are altered, it is said that *frequency distortion* occurs. This type of distortion occurs when the voltage-current characteristic, that is the transfer impedance characteristic, is a function of frequency. Where the whole transmission apparatus (including any mechanical and acoustic portions) is considered, there are two methods by which the effect may be minimized. Each component part of the system may be so designed as to have its response independent of frequency, or some elements of the system may be designed to correct for the distortion introduced elsewhere. Both methods of design have been widely and successfully used, the choice for a particular case being decided usually by economic considerations.

DELAY DISTORTION. The requirement that the relative phases of the various components be unaltered is equivalent to the requirement that the time of transmission of the system be independent of frequency. To see this, consider a voltage consisting of a group of sine waves applied to the system. In complex notation

$$e = \sum_{k_1}^{k_2} E_k \epsilon^{j(\omega_k t + \theta_k)} \tag{50}$$

The received current will be

$$i = \sum_{k_1}^{k_2} \frac{E_k}{|Z_k|} \epsilon^{j(\omega_k t + \theta_k - \beta_k)} \tag{51}$$

where $Z_k = |Z_k| \underline{/\beta_k}$ is the transfer impedance of the circuit at each frequency $\omega_k/2\pi$.

It is evident that frequency distortion will be present if $|Z_k|$ is a function of frequency within the band of frequencies considered. If it be assumed that $|Z_k| = R$ and that $\beta_k = \omega t_1 \pm n\pi$, where R and t_1 are constants and $n = 0, 1, 2, \cdots$, then

$$i = \pm \frac{1}{R} \sum_{k_1}^{k_2} E_k \epsilon^{j[\omega_k(t - t_1) + \theta_k]} \tag{52}$$

The effect of the transfer impedance is to delay each component by an amount t_1 but to leave the relative phases unaltered. The change in sign which occurs when n is odd is usually not important.

If, on the other hand, $\beta_k = \omega_k t_1 + \sigma(\omega) \pm n\pi$, where $\sigma(\omega)$ is not a linear function of frequency, the wave form of the received current will be different from that of the impressed voltage even though the relative amplitudes of the current components are correct. (For a discussion of non-linear distortion see Non-linear Electric Circuits.)

10. CORRECTIVE NETWORKS

A corrective network, or equalizer, is a network inserted between a generator and a load such that the current in the load will vary with frequency in a predetermined manner. A loss, or attenuation, equalizer is one which is used to control the amplitude of the received current as a function of frequency without regard to phase relations. A phase equalizer is one which ideally introduces no loss but does introduce phase shift as a function of frequency.

In most cases it is sufficient to equalize only for changes in loss. If, however, both loss and phase equalization are required, it is usual first to equalize for loss, and then to correct the phase of the system plus the loss equalizers. The incidental loss characteristic introduced by the phase equalizer (because of power dissipated in the ideally reactive elements) is usually ignored. If necessary, this distortion is corrected by an additional loss equalizer designed as an integral part of the phase equalizer.

LOSS-PHASE RELATION. It is generally true that no unique relation can exist between the loss and phase characteristics of a four-terminal network. However, as noted in article 7, there is a unique relation between a given loss characteristic and the *minimum phase shift* that can be associated with it. This relation is of value in the design of corrective networks and feedback amplifiers, where it is necessary to control both loss and phase over wide frequency ranges.

For the minimum phase condition it is possible to derive a number of relations between loss and phase. One of the simplest is

$$\int_{-\infty}^{+\infty} \beta \, du = \frac{\pi}{2}(A_\infty - A_0) \tag{53}$$

where $u = \log \omega/\omega_0$, f_0 $(= \omega_0/2\pi)$ being an arbitrary reference frequency, β is the phase shift in radians, and A_0 and A_∞ are the losses in nepers at zero and infinite frequency respectively. This states that the area under the phase curve, when plotted on a logarithmic scale, depends only on the difference in the losses at zero and infinite frequency.

A second and possibly more useful relation is given by

$$\beta_0 = \frac{1}{\pi}\int_{-\infty}^{\infty} \frac{dA}{du} \log \coth \frac{|u|}{2} \, du \tag{54}$$

where β_0 represents the phase shift in radians at any arbitrary frequency f_0 $(= \omega_0/2\pi)$ and $u = \log \omega/\omega_0$. This result states that the phase shift at any frequency is proportional to the derivative of the loss, on a logarithmic frequency scale, at all frequencies. It involves an integration over the entire frequency spectrum. The function $\log \coth |u|/2$ is in the nature of a weighting function and is shown in Fig. 17. Its value is much larger near the point $\omega = \omega_0$ and tends to emphasize the effect of the loss characteristic in the immediate vicinity.

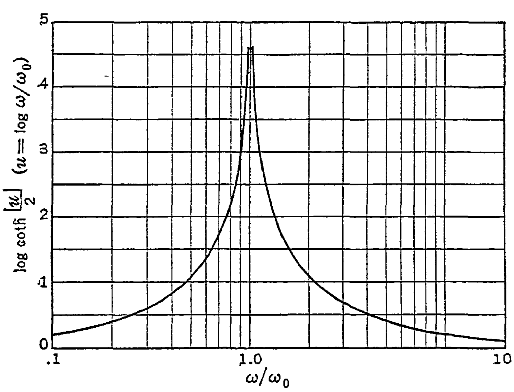

FIG. 17. Weighting Function in Loss-phase Formula

As an illustration of the utility of eq. (54) let it be supposed that $A = ku$, which describes a loss curve of constant slope on a logarithmic scale of $20k$ db per decade ($6k$ db per octave). The associated phase shift is readily found to be $k\pi/2$ radians. As a second example consider the discontinuous loss characteristic of Fig. 18. Here the loss is assumed to be zero below a specified frequency f_0 $(= \omega_0/2\pi)$, and has a constant slope of $6k$ db per octave above $\omega_0/2\pi$. The associated phase shift shown in Fig. 18 is symmetrical about the frequency f_0, at which point $\beta = k\pi/4$, and approaches the value $k\pi/2$ radians as frequency increases. At low frequencies the phase shift is substantially linear and is given by $\beta \doteq 2k\omega/(\pi\omega_0)$.

Since the phase characteristic corresponding to the sum of two loss characteristics is the sum of the two phase characteristics corresponding to the separate loss characteristics, it is possible to add a number of such simple characteristics together to simulate more complicated loss characteristics and to evaluate the corresponding phase shift. An example is furnished by Fig. 19, which shows a phase curve derived as the algebraic sum of three simple solutions of the type shown in Fig. 18. By proceeding in similar fashion it is possible to derive the phase shift corresponding to almost any loss characteristic without actually performing the integration indicated in eq. (54). In this connection it should be observed that, if both the loss and the corresponding phase can be specified at all frequencies, the problem of designing an equalizer having the inverse characteristics is immediately reduced to that of finding a two-terminal impedance for which both resistance and reactance are known. See article 7.

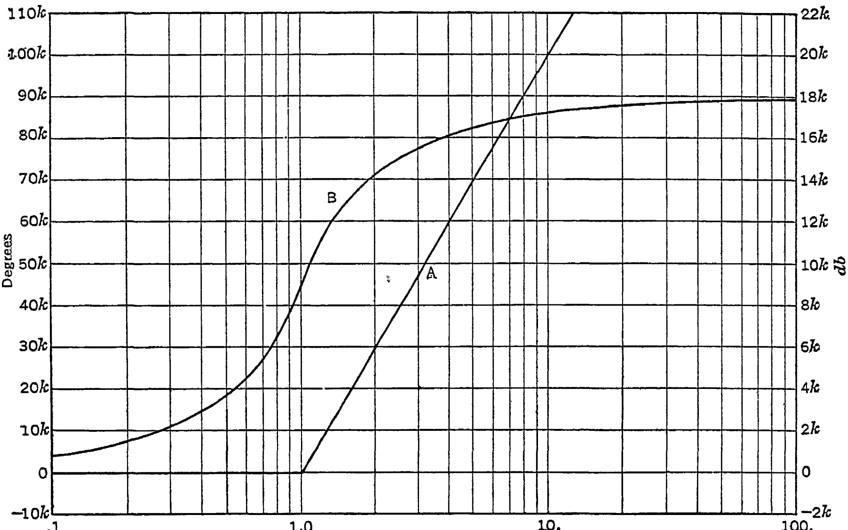

FIG. 18. Semi-infinite Slope of Attenuation (A) and Corresponding Phase Shift (B)

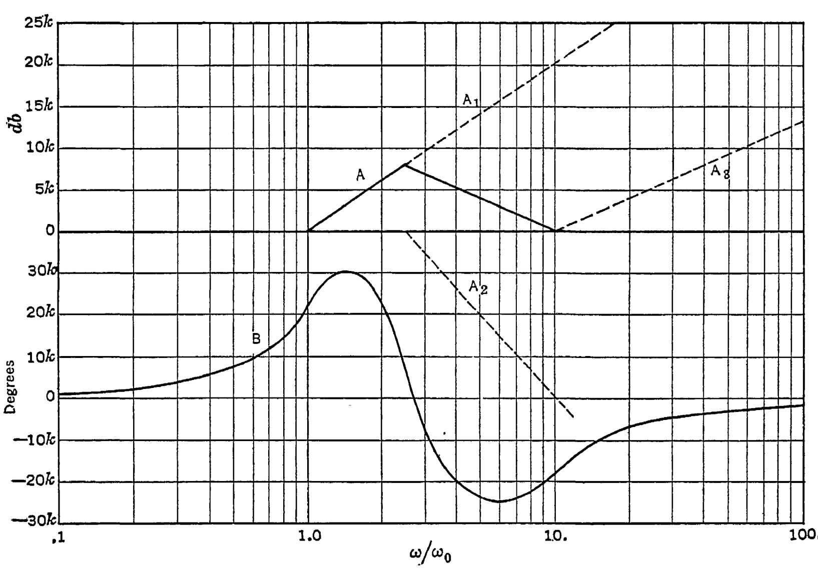

FIG. 19. Phase Curve Corresponding to Sum of Three Semi-infinite Attenuation Slopes

LOSS EQUALIZERS. The networks commonly used as loss, or attenuation, equalizers are shown in Fig. 20, which also gives the expressions for the insertion loss factor.

The networks shown are divided into classes based on their transmission and impedance properties. The simple series and shunt networks designated Ia and Ib are most useful for simple problems. Their transmission characteristics depend, of course, on both terminations.

The L-type networks designated as II*a* and II*b* have the same form for the insertion loss factor as I*a* and I*b*. They have the additional property, however, that the input impedance is equal to a constant, R_0, when they are terminated in R_0 on the output. Consequently, several sections can be operated in tandem without interaction, and the insertion loss of each section is independent of the generator impedance.

The symmetrical T, π, bridged T, and lattice networks shown as III*a*, III*b*, III*c*, and III*d* have insertion loss factors identical to the preceding network. However, they have constant-resistance image impedances. As a consequence the insertion loss factor has the form shown if either the generator or load impedance has the value R_0. Network III*c* is the most generally used because it requires fewer elements than any of the others.

The network shown as IV is a general constant-resistance lattice structure of which III*d* is a special case. This is the most general form of constant-resistance network, since any transmission characteristic which can be realized can be obtained with a structure of this form. See article 7. It is possible, therefore, to base the design of all equalizers on this structure, even though the network may be built in one of the other forms when such a conversion leads to a physical network.

The insertion loss factor, ϵ^θ, is somewhat more complicated for this network than for the others listed.

In terms of the admittance of the Z_1 arm

$$\epsilon^\theta = \frac{R_0Y_1 + 1}{R_0Y_1 - 1}$$

$$= \frac{R_0G_1 + 1 + jR_0B_1}{R_0G_1 - 1 + jR_0B_1} \quad (55a)$$

where $Y_1 = G_1 + jB_1$.

If G_1 is assumed to be constant with frequency, the network can be shown to behave as either a minimum phase or a non-minimum phase network as

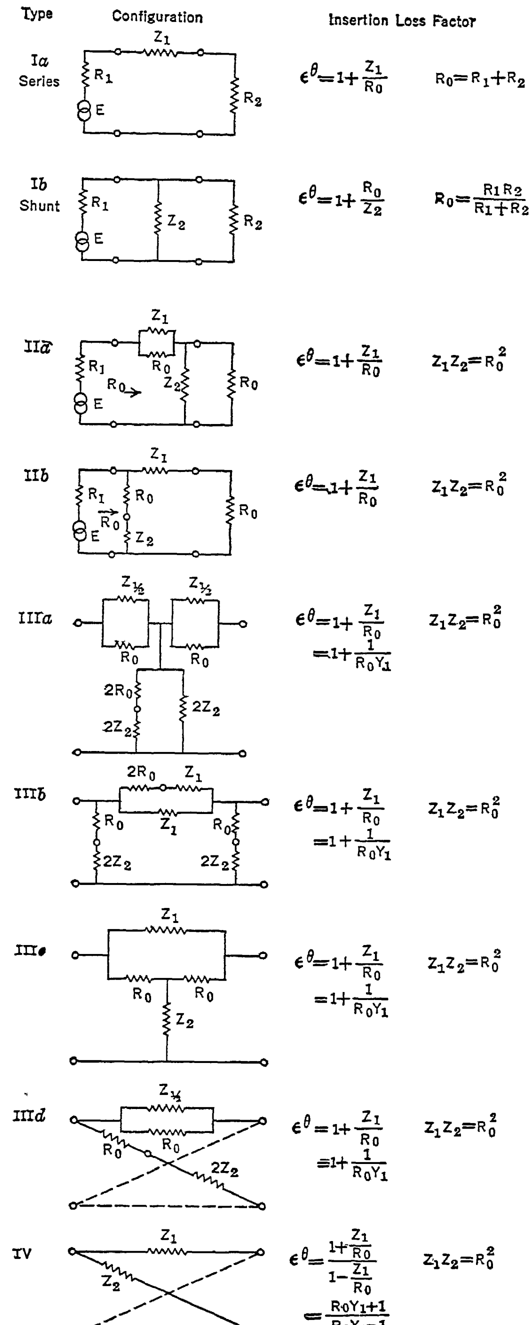

FIG. 20. Equalizer Configurations and Insertion Loss Factors

the product R_0G_1 is greater or less than unity. An explicit expression for Y_1R_0 in terms of θ is evidently

$$R_0Y_1 = \frac{\epsilon^\theta + 1}{\epsilon^\theta - 1} = \coth\frac{\theta}{2} \tag{55b}$$

A fairly general approach to equalizer design based on the constant-resistance lattice structure has been discussed by O. J. Zobel.* This method provides a systematic means of determining a network to satisfy a given loss requirement.

Referring to eq. (55a) it is a relatively simple matter to evaluate ϵ^θ corresponding to a given admittance Y_1. A more difficult problem is to determine Y_1 for a given set of values for α, since in a typical problem the corresponding value of β is usually unknown.

The design procedure is briefly as follows. The insertion power ratio is written as a function of frequency thus

$$\epsilon^{2\alpha} = \frac{a_0 + a_1\omega^2 + a_2\omega^4 + \cdots}{b_0 + b_1\omega^2 + b_2\omega^4 + \cdots} \tag{56}$$

where the a's and b's are real constants. A set of linear equations in the a's and b's is determined by assigning values to $\epsilon^{2\alpha}$ at specific frequencies. As many frequencies are selected as the number of coefficients to be determined. The solution of this set of equations gives the values of the a's and b's required, and the function $\epsilon^{2\alpha}$ is determined. The roots of the numerator and denominator of $\epsilon^{2\alpha}$ are then found in terms of $p^2 = -\omega^2$.

Since the function must lead to a physical network in order that it be useful the conditions must be satisfied that

1. $\epsilon^{2\alpha}$ be greater than 1.0 for all values of ω.
2. The roots of the numerator may not occur at real frequencies—otherwise $\epsilon^{2\alpha}$ would have a point of infinite gain.
3. The roots may be real or conjugate complex pairs.
4. The roots of the denominator may be anywhere in the p^2 plane, but those that fall on the negative real axis must be of even multiplicity—otherwise $\epsilon^{2\alpha}$ will jump from $+\infty$ to $-\infty$ in this region, and so violate restriction 1.

If these conditions are satisfied the design proceeds. If not, a change is required; either the assumed form for $\epsilon^{2\alpha}$ or the matching points must be altered.

To specify the network the function ϵ^θ is formed. The roots of $\epsilon^{2\alpha}$ are known in terms of p^2, and the corresponding roots in terms of p are readily available, since they occur in + and − pairs.

The roots of the numerator used to form ϵ^θ must be in the left-half of the p plane. The roots of the denominator are not necessarily so restricted. However, if this restriction is applied to them also, the solution for ϵ^θ will lead to a minimum phase network.

Utilizing the resulting function ϵ^θ the lattice arm impedance Z_1, or admittance Y_1, is determined from eq. (55b). The network which exhibits this impedance may be found in a variety of ways. A general method for solving this problem has been described by O. Brune.†

As an example of the design process consider that the function to be matched is

$$\epsilon^{2\alpha} = 1 + \omega^6$$

In terms of $p^2 = -\omega^2$ this becomes

$$\epsilon^{2\alpha} = 1 - p^6$$

The roots of $\epsilon^{2\alpha}$ are given by $p^2 = 1.0$ and $p^2 = -0.5 \pm j0.866$. In terms of p the roots having negative real parts are then $p = -1$ and $p = -0.5 \pm j0.866$, and

$$\begin{aligned}\epsilon^\theta &= (p + 0.5 - j0.866)(p + 0.5 + j0.866)(p + 1)\\ &= p^3 + 2p^2 + 2p + 1\end{aligned}$$

whence

$$R_0Y_1 = \frac{p^3 + 2p^2 + 2p + 2}{p^3 + 2p^2 + 2p}$$

Expanding this as a continued fraction by removing alternately poles and zeros the result is obtained that

$$R_0Y_1 = \frac{1}{p} + \frac{1}{2/p + p/(p + 1)}$$

The corresponding impedance of the series arm of the lattice is shown in Fig. 21 for unit impedance and unit frequency.

† *Journal of Mathematics and Physics, M.I.T.*, Vol. X, October 1931.

For many problems the analytic method of design which has been discussed is cumbersome and unsuitable. For example, if it be required to equalize a measured characteristic with only a fair degree of accuracy, the effort required to obtain a precise solution is not justified. In such cases a knowledge of the behavior of the simpler forms of two-terminal impedances can be usefully applied. The ability to visualize the frequency characteristic of a configuration of coils, condensers, and resistances is an essential part of the designer's equipment.

Probably the most useful configuration for design purposes, since it is one of the simplest, is that shown as IIIc in Fig. 20, in which the impedance Z_1 consists of a reactance shunted by a resistance. For this network

$$\epsilon^{\theta} = 1 + \frac{1}{R_0 Y_1}$$

$$= 1 + \frac{1}{R_0(G_1 + jB_1)} \tag{57}$$

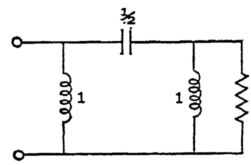

FIG. 21. Lattice Arm Impedance

where G_1 is a constant. Maximum loss occurs when $B_1 = 0$, while minimum loss ($\alpha = 0$) occurs when $B_1 \to \infty$. The design problem is reduced, once a selection has been made of the maximum loss required, to finding a suitable reactance, or susceptance, to match the loss curve over the required interval. From eq. (57) it is evident that

$$\epsilon^{2\alpha} = 1 + \frac{1 + 2R_0 G_1}{R_0^2(G_1^2 + B_1^2)} \tag{58}$$

whence

$$R_0 B_1 = \pm\sqrt{\frac{1 + 2R_0 G_1}{\epsilon^{2\alpha} - 1} - (R_0 G_1)^2} \tag{59}$$

For known values of $\epsilon^{2\alpha}$ corresponding values of B_1 can be found. A relatively slight effort is required to determine the required susceptance. The conditions for physical realizability are here merely that the zeros and poles occur at real frequencies, that they alternate, and that the reactance function behave as a simple coil or condenser at zero or infinite frequency.

In applying this process to build up complicated loss frequency characteristics as the sum of several equalizer sections the skill of the designer is evidenced by his ability to select easily realizable characteristics for the component sections.

PHASE EQUALIZERS. The constant-resistance lattice network IV of Fig. 20 bebecomes an "all-pass" network when the impedances Z_1 and Z_2 are specified as pure reactances. Then

$$\epsilon^{\theta} = \epsilon^{\alpha + j\beta} = \frac{R_0 + jX_1}{R_0 - jX_1}$$

$$\epsilon^{2\alpha} = 1.0 \quad \text{and} \quad \tan\frac{\beta}{2} = \pm\frac{X_1}{R}$$

There are two basic networks of this type, which are shown in Fig. 22. For the first of these (Type I)

$$\epsilon^{\theta} = \frac{R_0 + Lp}{R_0 - Lp} = -\frac{p + R_0/L}{p - R_0/L} \tag{60}$$

The zero of this expression is real and negative, and the pole is real and positive. In the p plane they occur symmetrically on either side of the origin. The phase curve corresponding to this network is shown in Fig. 22; the critical frequency $\omega_0 = R_0/L$.

In the more complicated network shown as Type II in Fig. 22

$$\epsilon^{\theta} = \frac{R_0 + \dfrac{Lp}{1 + LCp^2}}{R_0 - \dfrac{Lp}{1 + LCp^2}} = \frac{(p - p_1)(p - p_3)}{(p - p_2)(p - p_4)} \tag{61}$$

where

$$p_1 = -p_4 = \frac{\omega_0}{2}\sqrt{\frac{L}{C}}\frac{1}{R_0}\left[-1 + \sqrt{1 - \frac{4R_0^2 C}{L}}\right]$$

$$p_3 = -p_2 = \frac{\omega_0}{2}\sqrt{\frac{L}{C}}\frac{1}{R_0}\left[-1 - \sqrt{1 - \frac{4R_0^2 C}{L}}\right]$$

and

$$\omega_0 = \frac{1}{\sqrt{LC}}$$

When $4R_0^2C/L \leqq 1.0$ the zeros and poles are real. The zeros occur in the left half of the p plane, and the poles are in the right half-plane. The network is, therefore, equivalent to two of the simple types in tandem.

When $4R_0^2C/L > 1.0$ the zeros and poles are complex. Again the zeros are in the left half-plane and are conjugate complex numbers. The poles are again in the right half-plane and are symmetrically disposed about the origin. As would be expected a wide variety of phase characteristics can be obtained. Some typical curves are shown in Fig. 22 plotted against ω/ω_0. Note that, when $4R_0^2C/L = 1.0$, the phase shift is exactly twice that of Type I.

Increasing the complexity of the reactances in the lattice arms merely introduces additional zeros and poles in the expression for ϵ^θ. If the network is to continue to be an all-pass network, the zeros and poles must occur in pairs having characteristics similar to

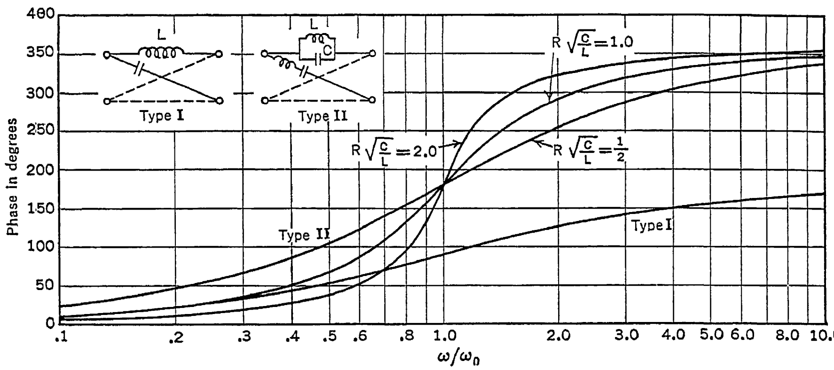

FIG. 22. Typical Phase Characteristics of All-pass Networks

those noted above. Consequently, it is possible to break down a more extensive set of zeros and poles into groups, each group corresponding to a physical network of either Type I or Type II. A number of these simpler networks in tandem will provide characteristics exactly similar to those of the more complicated lattice.

RECURRENT NETWORKS

By P. H. Richardson

Early work on transmission networks was from the viewpoint of wave propagation in uniform media. Later work introduced the methods of particle dynamics, and networks were treated as vibrating systems. In treating the problem of *recurrent networks*, that is, the problem of a number of similar networks in tandem, the terminology of the earlier method is most useful. As might be expected, the problem is readily handled in terms of equivalent line parameters such as the image parameters previously defined.*

* Solutions of the general problem in terms of both image and iterative parameters are given by E. A. Guillemin, *Communication Networks*, Vol. II, pp. 163–175. In the case of symmetrical networks the two sets of parameters are identical.

11. SYMMETRICAL NETWORKS

CURRENT AND VOLTAGE RELATIONS. Consider the tandem combination of two symmetrical networks shown in Fig. 1. The image impedance is assumed to be the same for both structures, while the transfer constants θ_1 and θ_2 are different. To find the voltage

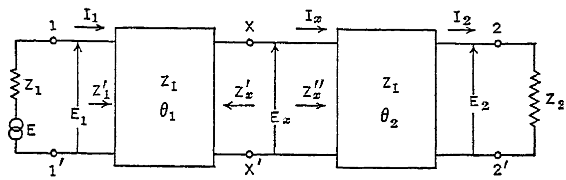

FIG. 1. Tandem Combination of Symmetrical Networks

at the junction x–x' replace the generator and network to the left of the junction by an equivalent Thévenin generator. Then the open circuit voltage at x–x'

$$E_{ocx} = \frac{EZ_I}{\left(Z_1 + \dfrac{Z_I}{\tanh\theta}\right)\sinh\theta} \tag{1}$$

The voltages E_x and E_1 are evidently given by

$$E_x = \frac{E_{ocx}}{1 + (Z_x'/Z_x'')} \quad \text{and} \quad E_1 = \frac{E}{1 + (Z_1/Z_1')} \tag{2}$$

The impedances Z_1', Z_x', and Z_x'' are given by the relations

$$Z_1' = Z_I\left[\frac{1 + \rho_2\epsilon^{-2(\theta_1+\theta_2)}}{1 - \rho_2\epsilon^{-2(\theta_1+\theta_2)}}\right] \tag{3a}$$

$$Z_x' = Z_I\left[\frac{1 + \rho_1\epsilon^{-2\theta_1}}{1 - \rho_1\epsilon^{-2\theta_1}}\right] \tag{3b}$$

$$Z_x'' = Z_I\left[\frac{1 + \rho_2\epsilon^{-2\theta_2}}{1 - \rho_2\epsilon^{-2\theta_2}}\right] \tag{3c}$$

where $\rho_1 = \dfrac{Z_1 - Z_I}{Z_1 + Z_I}$ and $\rho_2 = \dfrac{Z_2 - Z_I}{Z_2 + Z_I}$ are the *reflection coefficients* at junctions 1–1′ and 2–2′ respectively.

Substituting in eq. (2) it can be demonstrated that

$$E_x = E_1(A_1\epsilon^{-\theta_1} + B_1\epsilon^{\theta_1}) \tag{4}$$

$$I_x = \frac{E_x}{Z_x''} = \frac{E_1}{Z_I}(A_1\epsilon^{-\theta_1} - B_1\epsilon^{+\theta_1}) \tag{5}$$

where

$$A_1 = \frac{1}{1 + \rho_2\epsilon^{-2(\theta_1+\theta_2)}} \quad \text{and} \quad B_1 = \frac{\rho_2\epsilon^{-2(\theta_1+\theta_2)}}{1 + \rho_2\epsilon^{-2(\theta_1+\theta_2)}} \tag{6}$$

Note that A_1 and B_1 depend only on the sum of the two transfer constants and the reflection coefficient at the output junction.

INCIDENT AND REFLECTED WAVES. The term $E_1A_1\epsilon^{-\theta_1}$ is called the *incident component* of the voltage, and $E_1B_1\epsilon^{\theta_1}$ is called the *reflected component* of the voltage. Likewise the terms $(E_1/Z_I)A_1\epsilon^{-\theta_1}$ and $-(E_1/Z_I)B_1\epsilon^{\theta_1}$ are called the incident and reflected components respectively of the current at the junction x–x'. Note that if $Z_2 = Z_I$, that is, if the impedances are *matched* at the output, there is no reflected component since $B_1 = 0$. Also, if $\theta_1 + \theta_2$ has a large positive real part, B_1 becomes very small, and again the reflected component vanishes. The voltage ratio and the current ratio are both equal to $\epsilon^{-\theta_1}$, when the reflected "wave" is zero.

IMPEDANCE RELATIONS. The pair of networks having like image impedances behave as regards the input and output meshes as though they together constituted one network of image impedance Z_I and transfer constant $\theta_1 + \theta_2$. When the output impedance matches Z_I, $\rho_2 = 0$ and the impedances Z_1' and Z_x'' are both equal to Z_I. Note also, if the real part of $\theta_1 + \theta_2$ is large, the input impedance again is equal to Z_I.

A relation which is frequently useful in design problems can be obtained from eq. (3). The reflection coefficient at the input terminals

$$\rho_1' = \frac{Z_1' - Z_I}{Z_1' + Z_I} = \rho_2 \epsilon^{-2(\theta_1+\theta_2)} \tag{7}$$

Thus the reflection coefficient at the input terminals, ρ_1', is simply related to the reflection coefficient at the output terminals. If $\theta_1 + \theta_2$ is a pure imaginary, then $|\rho_1'| = |\rho_2|$. Also, if α is the real part of $\theta_1 + \theta_2$, then $|\rho_1'| = |\rho_2|\epsilon^{-2\alpha}$.

12. UNIFORM LINES—NETWORKS WITH DISTRIBUTED CONSTANTS

When the physical dimensions of a network are comparable to the wavelength of the electric current flowing in it, account must be taken of the fact that the series resistance and inductance of each wire, and the shunt capacitance and leakage between wires, are "distributed." Such networks are usually termed transmission lines (see also Section 14 in volume on Electric Power), but in the case of very high-frequency currents (5 meters or less) a network contained within an ordinary room may have to be similarly treated.

The usual transmission line in communication circuits consists of two similar parallel wires, or a single wire enclosed in a conducting cylindrical sheath. At every point on the line, some current flows from one wire to the other, or to the sheath, owing to capacitance and leakage conductance resulting from the imperfect dielectric between them. In consequence of this, the current in each conductor varies along the line. This is illustrated in Fig. 2, which shows an elementary section of a balanced line, or of a completely unbalanced

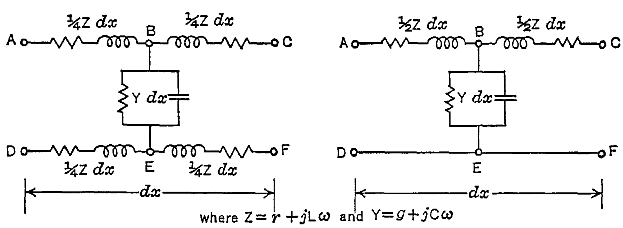

FIG. 2. Elementary Section of a Transmission Line

line equivalent to the coaxial type of construction. The current entering at A is not the same as that leaving at C, owing to the capacitance and conductance shunted between B and E. Hence the total drop due to the total resistance of the line is not this resistance multiplied by the current at any point on the line. Simple impedance equations cannot be written; simple differential equations can be given (for this solution see Section 14 in volume on Electric Power), and these offer one method of attack.

An alternative method is based on the assumption that such a uniform transmission line may be considered to be composed of an infinite number of symmetrical networks, each of which corresponds to an infinitesimal length of line. If r is the resistance and L the inductance per unit length (for two wires, sometimes called a loop-mile when the unit of length is a mile), and g the conductance and C the capacitance between the wires, or from the central conductor to the sheath, per unit of length, then, in a section of length dx, there will be a resistance $r\,dx$, an inductance $L\,dx$, conductance $g\,dx$, and capacitance $C\,dx$. As dx approaches zero the sections become smaller, and a line of these sections approaches a line with uniformly distributed constants.

VOLTAGE AND CURRENT RELATIONS. Let $Z = r + jL\omega = |Z| \underline{/\theta_z}$ be the series impedance per unit length, and let $Y = g + jC\omega = |Y| \underline{/\theta_y}$ be the shunt admittance per unit length of line. Then for the T network equivalent to an infinitesimal length of line (see Fig. 3) for which $\theta = d\theta$

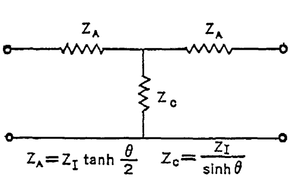

FIG. 3. T Network Equivalent to Smooth Line

$$Z_A = Z_I \frac{d\theta}{2} = \frac{Z}{2}\,dx \tag{8a}$$

$$Z_c = \frac{Z_I}{d\theta} = \frac{1}{Y\,dx} \tag{8b}$$

Thus

$$Z_I = \sqrt{\frac{Z}{Y}} = \sqrt{\frac{(r + jL\omega)}{(g + jC\omega)}} \tag{9a}$$

$$= \sqrt[4]{\frac{r^2 + L^2\omega^2}{g^2 + C^2\omega^2}} \Bigg/ \frac{1}{2}\left(\tan^{-1}\frac{L\omega}{r} - \tan^{-1}\frac{C\omega}{g}\right) \tag{9b}$$

This impedance is frequently called the *characteristic impedance* of the uniform line; the terms image impedance and iterative impedance which are also used are somewhat more clearly defined. They are, of course, identical to one another for the symmetrical line.

From eqs. (8) it follows that $d\theta = \sqrt{ZY}\,dx$, whence

$$\theta = \sqrt{ZY}\,x = \gamma x; \qquad \gamma = \sqrt{ZY} \tag{10}$$

where x represents the distance to a point on the line from the sending end. The quantity γ is called the *propagation constant* of the line and is evaluated *per unit length of line.* For a given length of line the total propagation constant is seen to be identical to the image transfer constant of the equivalent symmetrical network. γ is a complex number and can be expressed as $\gamma = \alpha + j\beta$, where α and β are real. Expanding eq. (10) and separating reals and imaginaries

$$\alpha = \sqrt{{}^1\!/_2[\sqrt{(r^2 + L^2\omega^2)(g^2 + C^2\omega^2)} + (rg - LC\omega^2)]} \tag{11a}$$

$$\beta = \sqrt{{}^1\!/_2[\sqrt{(r^2 + L^2\omega^2)(g^2 + C^2\omega^2)} - (rg - LC\omega^2)]} \tag{11b}$$

The parameters α and β are called the *attenuation constant* and *phase shift constant*, respectively, of the line. Note that they are both functions of frequency.

The relations given by eqs. (9) and (10) indicate the similarity between the behavior of networks having lumped constants and the behavior of uniform lines. At some point a distance x from the sending end of a line of length l the voltage E_x and current I_x are given by eqs. (4), (5), and (6) of article 1, where $\theta_1 = \gamma x$ and $\theta_2 = \gamma(l - x)$. Similarly the input impedance of the line is given by eq. (3a).

INCIDENT AND REFLECTED WAVES. The instantaneous voltage at any point on the wire is

$$e_x = \text{Real part } [E_1\epsilon^{j\omega t}(A_1\epsilon^{-\gamma x} + B_1\epsilon^{\gamma x})]$$

$$= |E_1|\,[|A_1|\,\epsilon^{-\alpha x}\cos(\omega t - \beta x + \delta_A) + |B_1|\,\epsilon^{\alpha x}\cos(\omega t + \beta x + \delta_B)] \tag{12}$$

and

$$i_x = \text{Real part}\left[\frac{E_1}{Z_I}\epsilon^{j\omega t}(A_1\epsilon^{-\gamma x} - B_1\epsilon^{\gamma x})\right]$$

$$= \left|\frac{E_1}{Z_I}\right|[|A_1|\,\epsilon^{-\alpha x}\cos(\omega t - \beta x + \delta_A - \phi) - |B_1|\,\epsilon^{\alpha x}\cos(\omega t + \beta x + \delta_B - \phi)] \tag{13}$$

where $A_1 = |A_1|\,\underline{/\delta_A}$, $B_1 = |B_1|\,\underline{/\delta_B}$, $Z_I = |Z_I|\,\underline{/\phi}$ and E_1 is real.

Each of these expressions is composed of two components, the *incident "wave"* which *decreases* in magnitude as x *increases*, and the *reflected "wave"* which *increases* as x *increases*. These components are called "waves" because they appear to travel along the wire with a velocity $v = \omega/\beta$. The distance between two consecutive points on the line at which $\cos(\omega t - \beta x + \delta_A)$ and its derivative have the same algebraic values for a fixed value of t is called a wavelength (λ), so that $\beta\lambda = 2\pi$. The time elapsing during a complete cycle of values is called the *period* (T), so that $T = 1/f$. In terms of these values the *velocity of phase propagation* of the waves is $v = \omega/\beta = \lambda/T$.

STANDING WAVES. The combination of the incident and reflected waves, adding sometimes in and sometimes out of phase, causes variation in the value of the voltage and current with position along the line. The expression for the amplitude of the voltage is

$$|E_x| = |E_1|\sqrt{|A_1|^2\epsilon^{-2\alpha x} + |B_1|^2\epsilon^{2\alpha x} + 2|A_1||B_1|\cos(2\beta x + \delta_B - \delta_A)} \tag{14}$$

and for the current,

$$|I_x| = \left|\frac{E_1}{Z_I}\right|\sqrt{|A_1|^2\epsilon^{-2\alpha x} + |B_1|^2\epsilon^{2\alpha x} - 2|A_1||B_1|\cos(2\beta x + \delta_B - \delta_A)} \tag{15}$$

each of which will have maximum and minimum values along the line whenever $|B_1| \neq 0$, since $\cos(2\beta x + \delta_B - \delta_A)$ changes more rapidly than $\epsilon^{2\alpha x}$. When attenuation is negligible and $|A_1| = |B_1|$

$$|E_x| = |E_1||A_1|\sqrt{2[1 + \cos(2\beta x + \delta_B - \delta_A)]} \tag{16}$$

From this it is evident that there are positions where $|E_x| = 2|E_1||A_1|$ called *voltage loops*, and others where $|E_x| = 0$ called *voltage nodes*. Similarly there are current loops and nodes, the current nodes corresponding to voltage loops, and vice versa.

It should be noted that the condition that $|A_1| = |B_1|$ requires that $\rho_2\epsilon^{-j2\beta l} = \pm 1.0$. Thus true *standing waves* occur only when the line is a multiple of a quarter wavelength and when $\rho_2 = \pm 1.0$, that is, when Z_2 is either zero or infinite.

INPUT IMPEDANCE. The input impedance of a uniform line terminated in an impedance Z_2 at a distance x from the sending end is given by

$$Z_i = Z_I \left[\frac{1 + \rho_2\epsilon^{-2\alpha x}\epsilon^{-j2\beta x}}{1 - \rho_2\epsilon^{-2\alpha x}\epsilon^{-j2\beta x}} \right] \tag{17}$$

where $\rho_2 = \dfrac{Z_2 - Z_I}{Z_2 + Z_I}$. If $Z_2 = Z_I$, then $\rho_2 = 0$ and $Z_i = Z_I$. The variation of Z_i with frequency is a smooth wave which approaches the value $\sqrt{L/C}$ as f increases.

When $Z_2 \neq Z_I$ the Z_i vs. f curve has maxima and minima which can be approximately located. If it be assumed that Z_I and Z_2 are pure resistances, which together with α are independent of frequency, then the locus of Z_i in the Z_i plane is a circle of radius

$$Z_I \left(\frac{2\rho_2\epsilon^{-2\alpha x}}{1 - \rho_2^2\epsilon^{-4\alpha x}} \right) \tag{18a}$$

with its center at

$$\left[Z_I \left(\frac{1 + \rho_2^2\epsilon^{-4\alpha x}}{1 - \rho_2^2\epsilon^{-4\alpha x}} \right), 0 \right] \tag{18b}$$

If ρ_2 is positive ($Z_2 > Z_I$), Z_i will have its maximum or minimum value when $\epsilon^{-j2\beta x}$ is $+1$ or -1. This requires that $2\beta x = 2n\pi$, or $(2n - 1)\pi$, where n is any integer. Since $\beta = \omega/v$ the frequency at which the maximum or minimum occurs is given by

$$f_{\text{max.}} = \frac{nv}{2x} \quad \text{or} \quad f_{\text{min.}} = \frac{(2n-1)v}{4x}$$

If $f = f_1$ when $n = n_1$ and $f = f_2$ when $n = n_1 + 1$, then

$$x = \frac{v}{2(f_2 - f_1)}$$

But since $f_2 - f_1$ is the frequency interval between two successive maxima, or two successive minima, the distance x to the point on the line at which there is an impedance discontinuity can be determined approximately. It should be noted that the expressions for the frequencies at which maxima and minima occur will be interchanged if ρ_2 is negative ($Z_2 < Z_I$).

DISTORTIONLESS LINES. In communication systems many frequency components are usually present, and it is desirable to have uniform attenuation with frequency. This condition exists on a line if $r/L = g/C$, in which case

$$\alpha = \sqrt{rg} \quad \text{and} \quad Z_I = \sqrt{\frac{L}{C}} = \sqrt{\frac{r}{g}}$$

both of which are independent of frequency. Similarly, $\beta = \omega\sqrt{LC}$, which is the condition for linear phase shift and no delay distortion. In this case also

$$v = \frac{\omega}{\beta} = \frac{1}{\sqrt{LC}}$$

which states that all waves are propagated with the same velocity.

TRANSIENTS IN NETWORKS

By Harold A. Wheeler

13. TRANSIENT DISTURBANCES

PROPERTIES OF TRANSIENTS. A transient disturbance, in its simplest concept, is one that occurs in a time interval separated from other disturbances. In general, a transient may be superimposed on other transients or continuous waves, according to the superposition theorem, while otherwise retaining its own characteristics. A single transient cannot be a periodic wave in the strict sense, although it may be a damped oscillation of a definite period. A borderline case is the "periodic transient," which is a periodic non-overlapping series of transients; each transient retains the properties of a transient while the series has the properties of a periodic wave.

Any periodic wave can be analyzed into a "Fourier series" which is a sum of sinusoidal components of frequencies in harmonic relation. The corresponding representation of a transient disturbance is possible by the "Fourier integral," which does not give a number of distinct components but rather the distribution of energy over the frequency spectrum. The Fourier series and the Fourier integral are analogous to the line spectrum and the band spectrum in light waves.

In general, an exact representation by a Fourier series requires an infinite number of components extending over the entire frequency spectrum, but a practical approximation requires only a limited number of components within a limited bandwidth. The same is true with respect to the limited bandwidth required for the practical reproduction of a transient. It is essential to consider the degree of approximation required or attained in any particular case, and to realize that both the duration of the transient and the frequency bandwidth are theoretically unlimited although practically limited by the sensitivity of the system.

Refer to Section 9, Pulse Techniques, for much information on transients as exemplified by pulses, with emphasis on their application in practical systems.

TYPES OF TRANSIENTS. It is convenient to define transient disturbances of several idealized types. An actual transient may be classified by its similarity to one of these types, or as the response of a certain network to one of these types.

The unit step is one of the elementary transients, shown in Fig. 1(a) and (b). It may be caused by switching or keying a current or voltage of unit amplitude. The form of Fig. 1(a) is also called the "Heaviside unit function," with a jump from zero to one. The form (b) has a jump from $-1/2$ to $+1/2$; it is preferred for some analytical purposes because it has zero d-c component. Campbell and Foster (references 7 and 8) designate the unit step as S_{-1}, called the singularity function of -1 order.

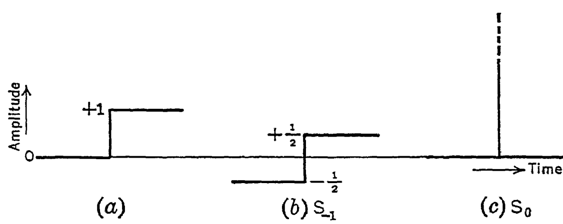

Fig. 1. Unit Step and Unit Impulse

The unit impulse, shown in Fig. 1(c), is unique among transients in that it has a uniform frequency spectrum. It is defined as the derivative or slope of the unit step; therefore it has unit area as the product of very large amplitude and very small duration. It is also called by Hansen the "delta function" (reference 38). Campbell and Foster (references 7 and 8) designate the unit impulse as S_0, called the singularity function of zero order.

In practice, the step is easier to generate because of its limited amplitude, and the transient response thereto has limited amplitude. The impulse may be approximated with limited amplitude if its duration is reduced until its frequency spectrum is substantially uniform over a frequency bandwidth sufficient for any particular tests. Most networks have some integrating action, so their response, even to an ideal impulse, would have limited amplitude.

Some oscillatory transients are illustrated in Fig. 2. In general, there are reversals of polarity, which may or may not be periodic in time. The transient response of a practical network is usually oscillatory in some degree. Figure 2(a) shows a damped oscillation which is a common occurrence; Fig. 2(b) shows a pulse-modulated wave including several cycles of a carrier wave, while (c) shows a carrier wave with a step in its modulation envelope. A carrier wave cannot be conceived as modulated by the ideal impulse, because the duration is insufficient to retain the identity of the carrier frequency.

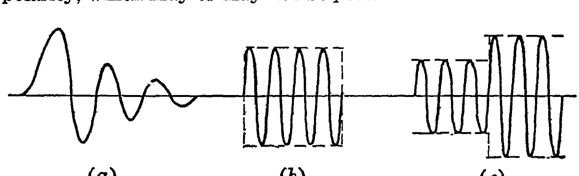

Fig. 2. Oscillatory Transients

Practical steps have finite slope, and practical pulses have finite duration and amplitude.

For test purposes, however, both can be made to approach the ideal as closely as required, so the transient response of a network to the ideal types can be tested.

A pulse to be used for modulating a carrier wave is sometimes denoted a "d-c" pulse to distinguish it from the modulated carrier of pulse envelope. The essential difference is in the frequency spectrum, the former having most of its energy concentrated in a band including zero frequency, and the latter in a band including the relatively high carrier frequency. The direct and carrier pulses are distinct concepts if their respective frequency bands are separate.

Amplitude modulation of a carrier wave generates symmetrical sidebands, and pulse modulation follows this rule. The carrier and both sidebands are needed for exact reproduction of the modulation. A small modulation superimposed on a continuous carrier, as illustrated in Fig. 2(*c*), can be approximately reproduced in a system responsive to one sideband and one-half the relative carrier amplitude, as employed in television (references 5, 11, 12, 16–19, 21, 24, 25, and Section 20).

FREQUENCY SPECTRUM. Figure 3 shows the frequency spectrum of several kinds of disturbances. The pure sine wave has a single frequency component (*a*). A periodic wave in general, such as a repeating short pulse, has a series of frequency components of relative amplitude indicated by an envelope of the lines (*b*). A transient has a continuous frequency spectrum (*c*). If the transient has the same shape as a single cycle of the periodic wave, the continuous spectrum (*c*) has the same frequency distribution as the envelope of lines (*b*).

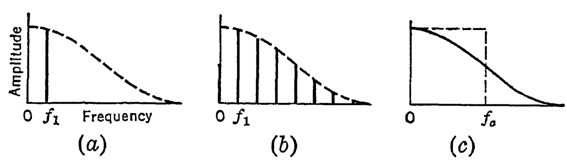

FIG. 3. The Frequency Spectrum of Periodic Waves and Aperiodic Disturbances

Periodic disturbances have a fundamental frequency, denoted f_1 in Fig. 3, and all components are harmonically related on integral multiples of this frequency. A transient lacks a fundamental frequency but, like the periodic wave, still requires frequency components over a certain band width for its reproduction with sufficient approximation. In Fig. 3(*c*), a nominal cutoff frequency f_c may be defined in such a way as to include most of the energy of the frequency spectrum. For pulse operation, the nominal cutoff frequency on the frequency spectrum of amplitude may be defined as the boundary of a rectangle (drawn as shown in dotted lines) having the same area as the amplitude spectrum (reference 11).

In the line spectrum of a periodic wave, each component has a definite amplitude which may be expressed in terms of current or voltage (or analogous linear quantities). In the band spectrum of a transient, however, the amplitude is expressed per unit of frequency bandwidth, in units such as the volt per cycle per second or volt-second. This concept is elusive, but the shape of the spectrum indicates clearly the relative importance of the various frequency components.

As an alternative, the frequency spectrum may be presented in terms of relative energy instead of amplitude. It is then expressed in terms of energy per unit of frequency bandwidth, in units such as the joule per cycle per second or joule-second. The area under the curve is the total energy of the transient.

The frequency spectrum of Fig. 3 shows the relative response of a receiver of very narrow and constant bandwidth as it is tuned over the frequency range. Spectrum analyzers are operated on this principle, some of which show the spectrum directly on an oscilloscope (Section 9).

SPEED OF INFORMATION. In communication of any kind, the available frequency bandwidth is limited, and this may restrict the speed of transmission (references 2, 4–6, 9–11, and Section 9). This is one of the principal limitations in picture transmission.

As a simple example, Fig. 4 shows the code pulses for the word "as." The pulse pattern (*a*) contains dots and dashes in the form of short and long pulses. It is necessary to distinguish the presence or absence of a pulse at intervals of one pulse width.

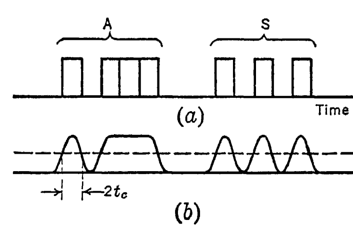

FIG. 4. Speed of Information by Pulses

Increasing the speed or decreasing the frequency bandwidth up to a certain limit has the effect of rounding the pulses (*b*) but not filling in the space between pulses. This much distortion is permissible and economical in practice.

The rounded pulses in Fig. 4(*b*) have a frequency spectrum similar to that in Fig. (3*c*) if the dots have a width $2t_c$ related to the nominal cutoff frequency f_c as follows (reference 11):

$$2t_c = \frac{1}{2f_c} \tag{1}$$

This means that the shortest pulse or space has a duration of 1/2 cycle at the nominal cutoff frequency. The speed of information is proportional to the number of pulses in a given interval which is proportional to the frequency bandwidth.

A completely modulated carrier requires twice the bandwidth because double-sideband operation is essential. A partially modulated carrier, with single-sideband operation as in television, requires only slightly more bandwidth than the modulating pulses but also requires more power to surmount background noise and interference.

14. BEHAVIOR OF NETWORKS

DIFFERENTIATION AND INTEGRATION. A linear network operates only on the amplitude and phase of a sine wave, retaining the wave form. Though the same is true of each component of a transient, the operation on all components may greatly change its shape. The simplest distorting operations of networks are differentiation and integration.

The two basic differentiating networks are shown in Fig. 5. In each case, the input and output are denoted by subscripts 1 and 2. In (*a*) and (*b*), the series capacitor C and the shunt inductor L are so connected that each gives an output proportional to the time derivative of the input;

$$\text{Fig. 5}(a) \quad \frac{dE_1}{dt} C = I_2; \qquad (b) \quad \frac{dI_1}{dt} L = E_2 \tag{2}$$

The instantaneous voltage and current are here denoted E and I.

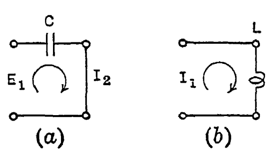

FIG. 5. Basic Differentiating Networks

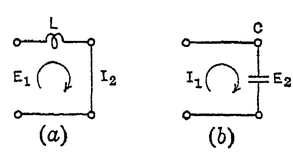

FIG. 6. Basic Integrating Networks

If instead the amplitudes of the frequency components are denoted E and I, the corresponding relations for any particular frequency may be written:

$$\text{Fig. 5}(a) \quad E_1 j\omega C = I_2; \qquad (b) \quad I_1 j\omega L = E_2 \tag{3}$$

Here j is the quadrature factor $\sqrt{-1}$ and $\omega = 2\pi f$ is the radian frequency. The two sets of equations are alike in form except that d/dt is replaced by $j\omega$; this explains why $j\omega$ is sometimes called a differential operator. It includes the inseparable two essentials of differentiation, namely, an amplitude ratio directly proportional to frequency and a leading phase shift of one quadrant.

An example of differentiation is the conversion of a unit step to a unit impulse. The former has frequency components of amplitude inversely proportional to frequency, while differentiation changes it to the impulse having frequency components of uniform amplitude.

The two basic integrating networks are shown in Fig. 6. In (*a*) and (*b*), the series inductor L and the shunt capacitor C are so connected that each gives an output proportional to the time integral of the input:

$$\text{Fig. 6}(a) \quad \left(\int E_1\,dt\right)\frac{1}{L} = I_2; \qquad (b) \quad \left(\int I_1\,dt\right)\frac{1}{C} = E_2 \tag{4}$$

Changing the significance of voltage and current, E and I, from the instantaneous values above to the amplitudes of the frequency components:

$$\text{Fig. 6}(a) \quad E_1 \frac{1}{j\omega L} = I_2; \qquad (b) \quad I_1 \frac{1}{j\omega C} = E_2 \tag{5}$$

Since $\int dt$ is replaced by $1/j\omega$, the latter is sometimes called an integral operator. It includes the inseparable two essentials of integration, namely, an amplitude ratio inversely proportional to frequency and a lagging phase shift of one quadrant. An example of integration is the conversion of a unit impulse to a unit step.

The basic networks of Figs. 5 and 6 rely on simple admittance or impedance coupling, so the input and output are voltage and current in one order or the other. Approximate differentiation and integration can be obtained by voltage-ratio or current-ratio coupling, the former being shown in Figs. 7 and 8. Each of these networks includes a resistor R in

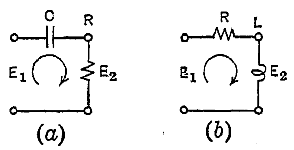

FIG. 7. Voltage-ratio Differentiating Networks

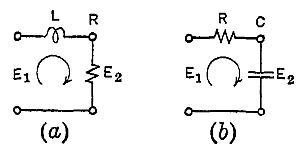

FIG. 8. Voltage-ratio Integrating Networks

addition to a reactor C or L. The required approximation to the ideal operation in each case places certain requirements on the time constant of the network, which is L/R or CR.

Figure 9 shows the meaning of the time constant in a charging or discharging operation (*a*) or (*b*). In each case the transient has an exponential variation with time, and the time constant t_1 is the length of time required to approach completion of the operation. Quantitatively, it is the time to go to $(1 - 1/\epsilon)$ or 0.63 of completion ($\epsilon = 2.72$, the base of natural logarithms).

Though the concept of charging and discharging is commonly associated with energy storage by the voltage on a capacitor, it is equally applicable to energy storage by the current in an inductor.

A charging operation shown in Fig. 9(*a*) is exemplified by a voltage step applied to an integrating network of Fig. 8. The integrating operation continues only for a duration less than the time constant, so the time constant must be longer than the required period of approximate integration. This is a general rule for such integrating networks.

A discharging operation shown in Fig. 9(*b*) is exemplified by a voltage step applied to a differentiating network of Fig. 7. The differentiating operation is prolonged for a duration exceeding the time constant, so the time constant must be shorter than the permissible duration. This is a general rule for such differentiating networks.

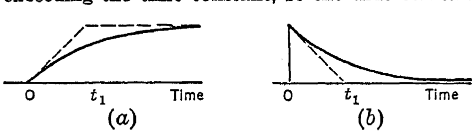

FIG. 9. Time Constants of Charging and Discharging

Meeting these conditions in Figs. 7 and 8 is promoted by a large value of series resistance or a small value of shunt resistance, so the voltage ratio is small for the frequency components of major importance.

Figure 10 is a chart of the charging and discharging operations obtained from the networks of Figs. 7 and 8 in response to steps and impulses.

OSCILLATIONS. If differentiation and integration are mixed in a network by combining CLR, the result is resonance. The transient response to a step or impulse may then be a damped oscillation. Figure 11 shows examples of voltage-ratio resonant networks and the response of each to certain input transients. A resonant network is one having maximum response at the frequency of resonance; an antiresonant network is one having minimum response at that frequency. Either one exhibits damped oscillations after a transient disturbance. The time constant of damping in the series-resonant circuit is $2L/R$, while that in the parallel-resonant circuit (with parallel R) is $2CR$.

REPEATING NETWORKS. There are many kinds of networks which respond to a step or impulse with interesting and significant output transients. One of the simplest is the integrating network of Fig. 8(*b*) repeated in successive stages of a vacuum-tube amplifier (No. 524.2 in references 7 and 8, also reference 38). Figure 12 shows the response of n such networks to an impulse. The integrating action, denoted by the time constant t_1, both delays and widens the pulse by virtue of the energy storage in each capacitor and its subsequent discharge (by repeater action) into the next capacitor. The delay of the pulse exceeds the widening, so this system is a crude delay network. The pulse peak is delayed by $(n - 1)t_1$. For large values of n it is widened to $\sqrt{2\pi}\sqrt{n-1}\,t_1$, and it approaches the symmetrical shape of a probability curve.

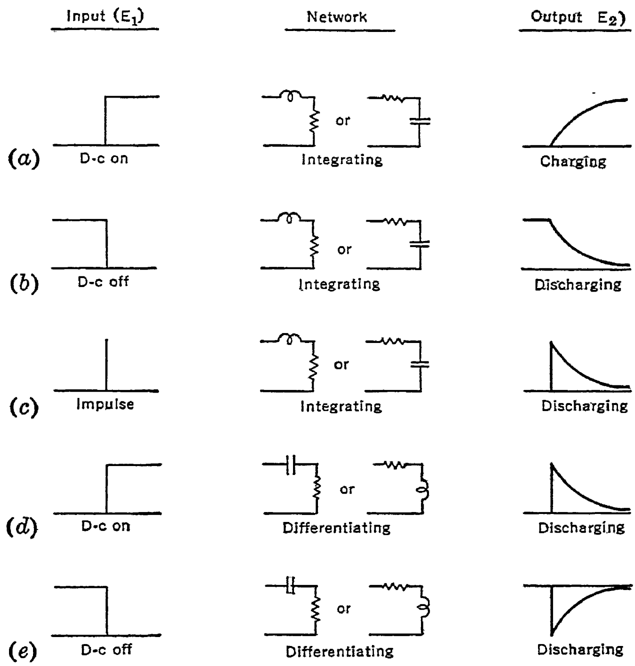

FIG. 10. Transient Response of Simple Networks

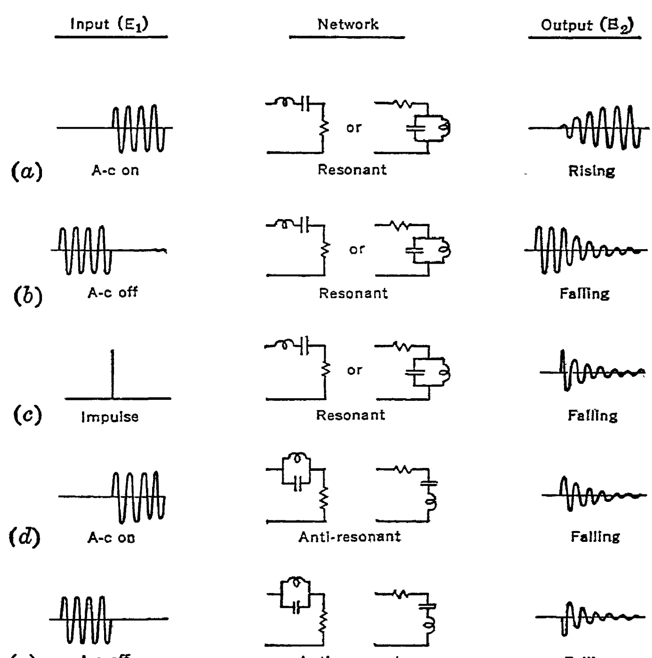

FIG. 11. Transient Response of Oscillatory Networks

The response of a resonant circuit to an impulse, as exemplified in Fig. 11(c) for a single network, may be extended to repeating networks. The envelope of the resulting transient oscillation then assumes the form of Fig. 12.

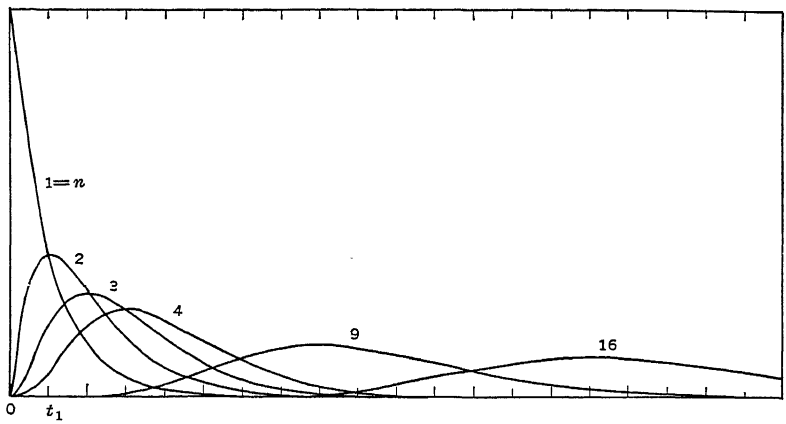

FIG. 12. The Delay and Widening of a Pulse by Repeating Integrating Networks

BANDWIDTH. The integrating action of a shunt capacitor limits the speed of information by restricting the frequency bandwidth. This is a major factor in a wide-band amplifier for such uses as television and radar, because each interstage coupling from one tube to the next has inherent shunt capacitance. Figure 13 shows a resistance-coupled amplifier stage subject to inherent shunt capacitance C across the coupling resistor R.

The frequency variation of the response of such an amplifier is shown in Fig. 14, in which f_1 is the frequency at which the reactance of the capacitor ($1/[2\pi fC]$) is equal to the shunt resistance (R). Figure 14(a) shows the amplitude variation for several conditions, starting with (1) simply R and C. The bandwidth is increased (2) by adding inductance L to build up the impedance by a tendency to resonance. A more complicated network,

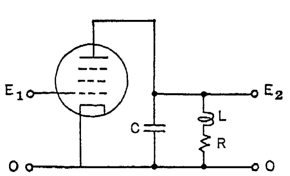

FIG. 13. Amplifier with Shunt Capacitance Limiting the Bandwidth

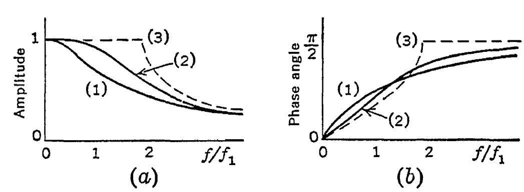

FIG. 14. The Limitation of Bandwidth by Shunt Capacitance

termed the "dead-end filter" (reference 15), can be used to extend the bandwidth as far as curve (3) but no further. The maximum bandwidth over which a uniform amplitude ratio can be obtained is theoretically

$$2f_1 = \frac{1}{\pi CR} \tag{6}$$

In practice, about half this bandwidth is obtained in simple circuits with a sufficient approximation to uniformity.

If many stages of wide-band amplification are needed, the phase distortion shown in Fig. 14(b) may be a limiting factor more severe than amplitude distortion. The ideal phase variation is a linear proportionality to the frequency. Condition (1), with simply R and C, yields a convex phase curvature, but in this case the amplitude distortion is more severe. (See Fig. 12, which applies to this case.) Condition (2), with L added, yields a concave phase curvature which happens to be more detrimental than the residual amplitude distortion. There are cases (notably in radar pulse receivers) where a compromise between (1) and (2) may be optimum (reference 38). The extreme condition (3) yields abrupt changes in amplitude and phase at cutoff, which cause transient damped oscillations.

AMPLITUDE AND PHASE DISTORTION. The transient response of linear networks is related uniquely with their steady-state characteristics, so a knowledge of the latter makes it possible to estimate the transient response. This is the province of the Fourier integral and other concepts such as "paired echoes" for evaluating distortion (references 14 and 20). Examples of amplitude and phase distortion are shown in Fig. 14 for the simple case of Fig. 13 described above.

Amplitude distortion may be simply the limitation of the bandwidth or may also include irregularities within the bandwidth. It is generally expressed in terms of attenuation, since this is a logarithmic quantity which can simply be added for cumulative stages (p. 1-37).

Phase distortion is any departure from linear proportionality between the lagging phase angle and the frequency. It is expressed in angular measure, which is additive for cumulative stages. The absolute unit of angle is the radian, which is $1/2\pi$ circle or 57.3°. The radian is quantitatively comparable with the napier, so 6.6° is comparable with 1 db. The inherent properties of passive linear networks determine certain relations between attenuation and phase angle (references 36 and 41). For any pattern of variation of the attenuation over the entire frequency range, there is a corresponding pattern of minimum phase angle obtainable in networks. Those networks which provide selective attenuation with minimum phase angle are termed "minimum-phase" networks and others "excess-phase" networks. Minimum-phase networks include self-impedance couplings, simple ladder networks, and any other network whose response can be expressed as a product of physically realizable self-impedance factors. Excess-phase networks include transmission lines, all-pass phase-correcting networks (lattice or bridged-tee), and networks with negative mutual inductance.

Phase-correcting networks are theoretically possible free of attenuation, but not attenuation-correcting networks free of phase distortion. Therefore it is customary, in the design of a practical network, first to obtain the required attenuation, and then if necessary to add phase-correcting networks for obtaining linear phase. Usually the phase correction need be effective only over the band width of nearly maximum response. Phase correction (free of attenuation) always increases the phase angle, never the reverse.

Amplitude distortion, free of phase distortion, cannot destroy the symmetry of a symmetrical input pulse. Therefore any asymmetrical distortion is a symptom of departure from phase linearity.

A sharp cutoff at the edge of the useful bandwidth causes a damped oscillation or "overshoot" in the transient response to an impulse or, in less degree, to a step. If this result is not permissible, a gradual cutoff is required, as shown in Fig. 3(*c*) (reference 11).

15. GENERAL PRINCIPLES

THE FOURIER INTEGRAL. In the study and design of networks to handle transient disturbances, the most powerful concept is the Fourier integral. It is an extension of the more familiar Fourier series, which is restricted to periodic waves but still serves as an introduction to the integral. Each is essentially a relationship between a disturbance over a period of time and its frequency components; or, conversely, a set of components can be synthesized into the form of disturbance.

The following presentation of the Fourier series is in a form well adapted for extension to the integral and useful for direct application.

A wave form (of voltage or current, for example) is denoted $T(t)$ and is completed in the time interval between $-t_1/2$ and $+t_1/2$. The same wave form is repeated in successive intervals of the same period t_1, as a periodic wave. This wave can be expressed as a sum of sine-wave components of harmonic frequencies and the proper phase:

$$T(t) = \sum_{n=-\infty}^{\infty} F_n \exp\,(j2\pi n f_1 t) \tag{7}$$

The fundamental frequency is $f_1 = 1/t_1$. Each harmonic component has a frequency nf_1 which is an integral multiple of the fundamental frequency. Its amplitude is F_n, which is generally complex to include the phase angle. Obviously the dimensional units of $T(t)$ and F_n are the same.

The sine-wave nature of each component is indicated by the unit vector rotating at a frequency nf_1:

$$\exp\,(j2\pi n f_1 t) = \text{cis}\,(2\pi n f_1 t) = \cos\,(2\pi n f_1 t) + j \sin\,(2\pi n f_1 t) \tag{8}$$

Since $T(t)$ is real, it is apparent that the imaginary parts of each component in the summation must cancel out. This cancellation occurs between the amplitudes F_n of the components of equal positive and negative values of n. The zero-frequency (direct) component ($n = 0$) always has a real amplitude F_0.

The (complex) amplitude of each component is formulated as

$$F_n = \int_{-t_1/2}^{t_1/2} T(t) \exp(-j2\pi n f_1 t)\, dt \tag{9}$$

This integral selects and evaluates each harmonic of frequency nf_1. A tabular or graphical or formal integration can be used to compute F_n, which in general will be complex.

The extension of the series to the integral requires two more concepts. First, since a transient is presumed to occur only once, the period t_1 is made very large and the corresponding fundamental frequency f_1 very small. Secondly, the harmonic amplitude F_n is changed to the frequency spectrum $F(f)$ which represents the "amplitude-frequency density" or "amplitude per unit of frequency" in the vicinity of the frequency f (instead of nf_1). The density does not have the same dimensional units as $T(t)$ but rather the same units multiplied by "time." For example, if $T(t)$ is in volts, $F(f)$ is in volts per cycle per second, or volt-seconds.

With these steps, there follows the Fourier integral for expressing the wave form of a transient in terms of its frequency spectrum $F(f)$:

$$T(t) = \int_{-\infty}^{\infty} F(f) \exp(j2\pi ft)\, df \tag{10}$$

The other form expresses the frequency spectrum in terms of the transient:

$$F(f) = \int_{-\infty}^{\infty} T(t) \exp(-j2\pi ft)\, dt \tag{11}$$

Following Campbell and Foster (references 7 and 8), the above forms are symmetrical in that $F(f)$ and $T(t)$ are interchangeable merely by reversing the sign of j. This is accomplished by integrating from $-\infty$ to $+\infty$, and expressing in terms of the variables f (instead of $\omega = 2\pi f$) and t, which are mutually reciprocal. These forms include $j2\pi$ under the exponential function, which is logical since $j2\pi$ is the natural logarithm of a unit vector rotated by one cycle, and $\exp(j2\pi)$ symbolizes that vector.

In electrical networks, the interchangeability of $F(f)$ and $T(t)$ has reality only if F is real, since T is real. This is true only in idealized networks, which may be instructive examples. In such cases, both F and T are symmetrical in form.

The direct significance of $F(f)$ and $T(t)$ is simple. It is based on the unique fact that an impulse has a uniform amplitude density over the spectrum. If a unit impulse is applied to a network which modifies its frequency spectrum to the form $F(f)$, the output is a transient of the form $T(t)$.

If a transient T_1 of any shape is applied to any network, the output transient T can be expressed and often evaluated simply by the following procedure: (1) compute F_1, the spectrum of the input transient T_1; (2) formulate F_2, the frequency response of the network; (3) note that the frequency spectrum of the output transient is $F = F_1F_2$; (4) from the knowledge of F, use the Fourier integral to express the output transient T. If the input is a unit step instead of a unit impulse, $F_1 = 1/j2\pi f$.

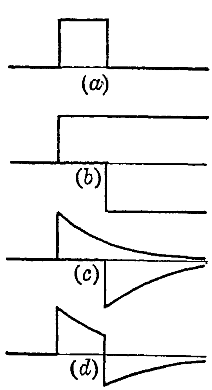

FIG. 15. An Example of Superposition

Closely related methods of transient analysis and synthesis are the Laplace transformation and the Heaviside operational calculus. The Fourier integral is a restricted case of the Laplace transform, but actually the one which is most simply adapted to the study of transients in electrical networks. The operational calculus is merely a process for deriving, explaining, and applying some of the ideas inherent in the Fourier integral. The present state of the literature places the Fourier integral in a position to be of the greatest aid in solving network problems.

THE SUPERPOSITION THEOREM. Any transient can be regarded as built up of a number of steps or pulses, a large number for smooth wave forms. This is the basis of the superposition theorem. A simple example, and probably the first to be discovered, is shown in Fig. 15. A square pulse (*a*) of any width is the resultant of two superimposed steps (*b*), the first one positive and the second negative. The transient response of a network to the square pulse is obtained by first evaluating its response to each step (*c*) and superimposing these transients (*d*).

The F_1F_2 procedure described above has an alternative in the superposition theorem of the operational calculus. This theorem is encompassed in a single Fourier integral (No. 202 in references 7 and 8). As above, T_1 is the input transient (whose frequency spectrum is F_1) and F_2 is the response of the network; T_2 is the transient which would be obtained from the network in response to a unit impulse. The output transient is then expressed in terms of T_1 and T_2 as follows:

$$T(t) = \int_{-\infty}^{\infty} F_1(f)F_2(f) \exp(j2\pi ft)\, df \tag{12}$$

$$= \int_{-\infty}^{\infty} T_1(t')T_2(t - t')\, dt' = \int_{-\infty}^{\infty} T_1(t - t')T_2(t')\, dt' \tag{13}$$

The symbol t' denotes the variable of integration, as distinct from t, the time variable in the transient.

THE ENERGY INTEGRAL. One of the most useful corollaries of the Fourier integral is the "energy integral":

$$\int_{-\infty}^{\infty} |F|^2\, df = \int_{-\infty}^{\infty} T^2\, dt \tag{14}$$

It states that the energy of the transient is proportional to the area under the energy-distribution curve over the frequency range, this curve being plotted in terms of $|F|^2$. This concept has the widest use for the evaluation of the power associated with random noise, which behaves as a great number of impulses occurring at random. It is noted that the total energy is determined by the amplitude (squared) independent of phase.

IDEALIZED FILTERS. Idealized examples of filters and transients are instructive as to the basic limitations. The most common such example is shown in Fig. 16 (references

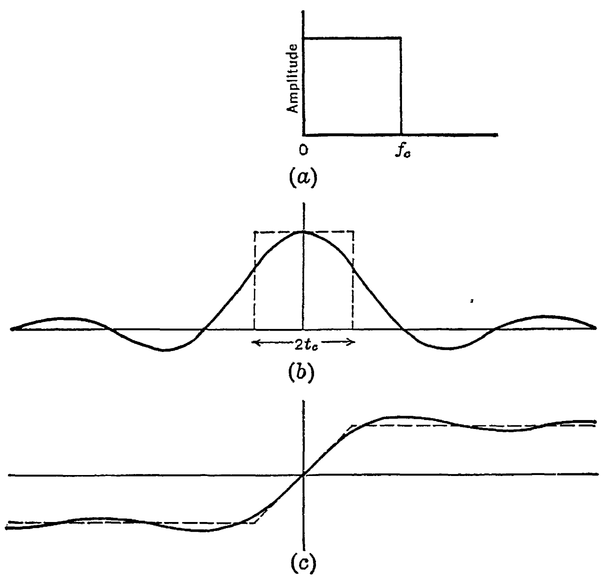

FIG. 16. An Idealized Filter and Its Transient Response

9 and 10). A network (*a*) has uniform response (with zero phase angle) up to a cutoff frequency f_c, and no response above this frequency. If an impulse is applied to this network, the output transient (*b*) is symmetrical and is accompanied by transient oscillations at the cutoff frequency. If this response is approximated in a real network, the phase slope is rather great and delays the main pulse so much that the earliest perceptible oscillations (preceding the pulse) occur at a time later than the applied impulse. Incidentally, this requires an "excess-phase" network as defined above.

In the transient of Fig. 16(*b*), the nominal pulse duration may be defined as $2t_c$, determined by the dotted rectangle of equal net area. If a step (instead of an impulse) is applied to the same network, the output (*c*) has a slope of the same nominal duration (called the "slope time" or "time of rise" or "build-up time").

The ideal filter of Fig. 16(*a*) has a perfectly sharp cutoff, which causes transient oscillations in the output (*b*) and (*c*). The opposite extreme is a response having gradual cutoff of the form of a probability curve, somewhat similar to Fig. 3(*c*) (reference 11). In response to an impulse, such a filter yields a rounded symmetrical pulse of the same shape, free of overshoot and transient oscillations. This performance is approximated by a large number of networks like Fig. 8, with output transients shown in Fig. 12. This case has been found ideal in radar receivers, to assure the prompt damping of one echo pulse in readiness for another.

DELAY. A lagging phase angle is characteristic of filters passing a limited band width (low-pass and band-pass), and also of transmission lines. The result is a delay of the signal, and perhaps also a distortion of its wave form.

The delay is defined in different ways, as a function of frequency. If β is the lagging phase angle (in radians) at a frequency ω (in radians per second), the "intercept delay" or "phase delay" (in seconds) is merely β/ω. It signifies the delay of each sine-wave component along the time axis. If the delay is the same for all components, it is free of distortion. This result requires "linear phase," that is, a phase angle directly proportional to the frequency.

The more general concept is the "envelope delay," defined as the "phase slope" $d\beta/d\omega$. This definition is free of the ambiguity of multiples of 2π in determining the phase angle. It derives its name from its significance as the delay of the envelope of a transient oscillation of many cycles, as distinguished from the delay of the individual cycles. The delay of the cycles is inconsequential if the transient is to be rectified, in which event the envelope delay uniquely determines the effect of the phase angle on the output of the rectifier.

These two definitions of delay correspond with those of the wave velocity in a transmission line or other wave medium. The intercept delay or phase delay determines the "phase velocity" or "steady-state velocity," with its ambiguities. The envelope delay uniquely determines the "group velocity," which, from one point to another, cannot exceed the speed of light.

NON-LINEAR ELECTRIC CIRCUITS

By Knox McIlwain

In solving the fundamental electric circuit equation

$$e = ri + L\frac{di}{dt} + \frac{1}{C}\int i\,dt \tag{1}$$

the assumption is often made that r, L, and C are constants. Circuits in which these conditions exist are called "linear circuits" and have been treated above. If any one or more of these circuit parameters vary with the current through it or the voltage across it, the solution of eq. (1) in general takes the form of an infinite series, so that the current wave form is not a replica of the voltage wave form. Such circuits are called "non-linear circuits."

NON-LINEAR DISTORTION. When it is desired that the wave form of the current through a particular circuit element be the same as the wave form of the original voltage, and when the response of the element is not directly proportional to the driving force (non-linear circuit), the element is said to introduce *non-linear distortion.* When the input voltage is a simple sine wave, the output current will contain components of double and higher multiples of the impressed frequency, the amplitudes being determined by the series solution mentioned above.

Non-linear distortion is most serious in sound reproduction since the spurious sound harmonics are readily noted by the ear and produce a very unpleasant sensation for the fastidious listener. If the rms value of the introduced harmonics is kept below 5 per cent of the rms value of the fundamental, the non-linear distortion will not be objectionable (sometimes even 10 per cent is allowed).

One important characteristic of this type of distortion is that, once introduced, it is difficult if not impossible to correct for it, so that the component parts of the circuit must be separately designed so as to have linear voltage versus current characteristics (except for modulators and detectors, see Section 7).

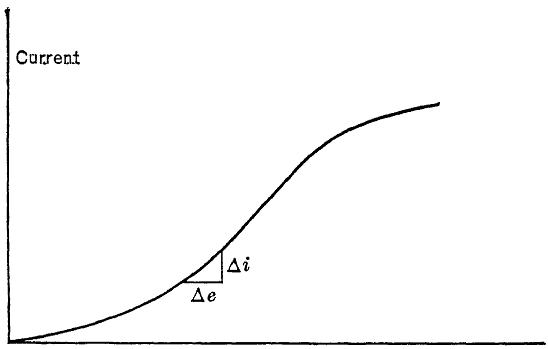

FIG. 1. Non-linear Current-voltage Characteristic

SOLUTION OF NON-LINEAR CIRCUITS. The change in inductance due to the non-linear B-H curve of iron, the varying resistance of an electric arc or of the thermionic vacuum tube, or the varying capacitance of the condenser microphone, all introduce non-linear effects. The simplest case is where the *resistance* is some function of voltage or current. Frequently this functional relationship is given as a curve of current against voltage, as in Fig. 1. The first step is to fit an analytic expression to the curve. Two methods have been widely used in communication practice:

(*a*) a power series of the form

$$i = A_0 + A_1 e + A_2 e^2 + A_3 e^3 + \cdots \tag{2}$$

(*b*) a trigonometric series

$$i = A_0 + A_1 \sin (e + \theta_1) + A_2 \sin (2e + \theta_2) + \cdots \tag{3}$$

16. POWER SERIES SOLUTION

Such devices as thermionic vacuum tubes, electric arcs, some surface contacts (such as copper oxide and lead), and certain crystalline structures have a current-voltage characteristic similar to that shown in Fig. 1. Since the instantaneous value of the electric resistance to an increment of current is $\Delta e/\Delta i$, the resistance varies with the applied voltage, or $r = F(e)$.

The coefficients of the power series of eq. (2) may be evaluated as follows: If four terms of the power series are of interest, choose four separated points on the current-voltage curve and use the four sets of values of e and i in eq. (2). Solve the four resulting algebraic equations by any of the standard methods for A_1, A_2, etc. This method may always be used no matter how irregular the curve and will always give correct results for the points chosen; unless the curve is smooth it may give quite incorrect results for intermediate points. The characteristic must be plotted including all resistance in the circuit whether variable or invariable. It is extremely difficult to include the effect of reactance in the circuit. The application of the method is thus limited, but it is useful in certain special cases.

TAYLOR'S SERIES. If the equation of the current-voltage characteristic is known, or if it can be found (it is frequently of the form $i = Ke^{\eta}$ for at least portions of the curve, in which case the constants can be evaluated by plotting on logarithmic cross-section paper), the solution by Taylor's series is useful in evaluating the coefficients of eq. (2).

The current at any point (e) in terms of the current at a particular point (E_0) can be written.

$$i = F(E_0) + (e - E_0)\left.\frac{\partial i}{\partial e}\right]_0 + \frac{(e - E_0)^2}{2!}\left.\frac{\partial^2 i}{\partial e^2}\right]_0 + \cdots \tag{4}$$

where the derivatives are all evaluated at the operating point (E_0). Care must be exercised in using this formula that the voltage is confined to the region wherein the curve follows the assumed law and within the limits of convergence of the series. A detailed treatment of this method is given in article 20.

17. TRIGONOMETRIC SERIES

In some applications of devices such as vacuum tubes and gas-filled tubes, the devices operate over a range large compared with the part of the characteristic shown in Fig. 1. The application of a power series would usually, under such conditions, require an unreasonable number of terms in order to obtain even a fair approximation. On the other hand, a trigonometric series with a properly chosen fundamental period permits the expansion of such a curve using only a few terms for a fair approximation.

The trigonometric series is periodic by nature and so does not represent the characteristic outside of the interval over which the harmonic analysis was taken. When the curve is of the form abc in Fig. 2 and the voltage varies only over the interval dbe, the curve can be arbitrarily replaced by any other curve outside of this interval. If the curve outside of this interval is replaced by a curve as shown by the broken line in Fig. 2, such that the resulting curve is skew-symmetric about the point e and symmetrical about the vertical axis through d, eq. (3) reduces to

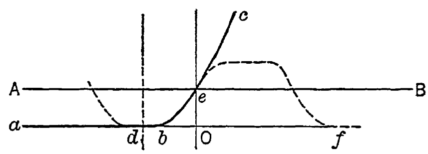

FIG. 2. Construction for Use of Trigonometric Series

$$i = A_0 + A_1 \sin e + A_3 \sin 3e + \cdots \tag{5}$$

Because of the symmetrical properties of the resulting curve both the even harmonics and the phase angles become zero. The choice of curve outside of the operating interval so that the resulting curve has these properties of symmetry is always possible. The convergence of the series is usually greatly increased by using this built-up curve (with a fundamental period four times the distance from d to 0). However, other choices of the curve outside of the working interval are even better in particular cases.

A fundamental period having been chosen and the curve having been completed throughout this period, the coefficients of the harmonic sine functions can be determined by means of one of the several available schemes for harmonic analysis (see article 24).

In most electrical engineering the e has the form of a constant voltage plus a series of sine-wave voltages. When voltages of this form are substituted in eq. (5) and the successive terms expanded by means of the trigonometric formulas for the sine and cosine of the sum of two angles, the series consists of terms of the form cos (x sin d) and sin (x sin d) which can be expanded by the formulas of Jacobi

$$\cos (x \sin d) = J_0(x) + 2\sum_{k=1}^{\infty} J_{2k}(x) \cos 2Rd$$

and

$$\sin (x \sin d) = 2\sum_{R=1}^{\infty} J_{2R-1}(x) \sin (2R - 1)d$$

where $J_n(x)$ is a Bessel function of the first kind, of order n and modulus x. These functions can be found in tables of Bessel functions. See p. 1-37.

By means of this expansion the amplitudes of the sinusoidal components of the current flowing in any circuit can be calculated from the current-voltage characteristic of the circuit, provided that the circuit contains no reactive elements. No general analytic method has yet been devised for the direct application of the trigonometric series in a circuit containing reactive impedance analogous to that treated in article 20. However, eq. (3) or (5) having been obtained, the differential coefficients of eq. (4) can be obtained simply by differentiation.

This solution can be extended to the case of two or more independent variables as in the application to the three-electrode vacuum tube with variable amplification factor and with independent voltages applied in both the grid and plate circuits. However, the work is so voluminous that it is practicable only in very special cases.

18. INDUCTANCE VARIATION

When the variation of inductance is of importance the magnetization curve (locus of the tips of the hysteresis loops) of the iron forming the (closed) magnetic circuit of the reactor is required. This is usually similar in form to the curve in Fig. 1 with flux density (B) as ordinates and magnetizing force (H) as abscissas. This curve must be replotted in the form of i (the exciting current) as a function of ϕ (the total flux). Then by Taylor's formula

$$i = F(\phi_0) + (\phi - \phi_0) \left.\frac{\partial i}{\partial \phi}\right]_0 + \frac{(\phi - \phi_0)^2}{2!} \left.\frac{\partial^2 i}{\partial \phi^2}\right]_0 + \cdots \tag{6}$$

in which the derivatives are evaluated at the operating point. Define

$$\left.\frac{\partial i}{\partial \phi}\right]_0 \equiv \frac{1}{L_0}$$

where L_0 is the usual incremental inductance (apparent inductance to a *change* in current) at the operating point. Then (see article 20)

$$\left.\frac{\partial^2 i}{\partial \phi^2}\right]_0 \equiv - \frac{1}{L_0^2} \left.\frac{\partial L}{\partial \phi}\right]_0$$

and so forth. Also $e = -d\phi/dt$ so that $\int e\, dt = -\phi$. If increments are considered

$$\phi - \phi_0 = \phi_a = -\int e_a\, dt$$

If $e_a = \Sigma E_n \cos(\omega_n t + \theta_n)$ as is usual (see article 21), then

$$\phi_a = -e_a \left[\times \frac{1}{j\omega} \right]$$

where the symbol $[\times]$ indicates that the maximum value of each first-degree cosine term of different frequency in the e immediately preceding is to be multiplied by the modulus of the complex quantity within $[\times]$, and the phase angle of the complex (in this case $\pi/2$) is to be added to the phase of the cosine, both modulus and phase being evaluated at the frequency of the given cosine term (see article 20).

Substituting these expressions in eq. (6)

$$i_a = \frac{-e_a\left[\times \frac{1}{j\omega}\right]}{L_0} - \frac{\left\{e_a\left[\times \frac{1}{j\omega}\right]\right\}^2}{2L_0^2} \left.\frac{\partial L}{\partial \phi}\right]_0 + \cdots \tag{7}$$

Hence if the B-H curve were a straight line $\partial L/\partial \phi = 0$ and

$$i_a = -\sum \frac{E_n \cos(\omega_{nt} + \theta_n - \pi/2)}{\omega_n L_0}$$

To obtain i in terms of the applied voltage E'_a in the circuit containing the variable inductance and a constant impedance z the same process employed in introducing impedance load in the case of a varying resistance must be employed (see article 21)

There results

$$i = e'[\times c_1] + e'^2[\times c_2] + \cdots \tag{8}$$

where

$$c_1 = \frac{1}{z + j\omega L_0} \equiv \frac{1}{z'}$$

$$c_2 = -\frac{L_0}{2} \left.\frac{\partial L}{\partial \phi}\right]_0 \frac{(c_1)^2}{z}$$

which is to be so interpreted that

$$c_{2(m+n)} = -\frac{L_0 c_{1m} c_{1n}}{2z_{(m+n)}} \left.\frac{\partial L}{\partial \phi}\right]_0$$

and

$$c_3 = \frac{c_1(c_2 z)}{z'} \left.\frac{\partial L}{\partial \phi}\right]_0 + \frac{L_0 (c_1)^3}{3! z} \left\{ 2 \left(\left.\frac{\partial L}{\partial \phi}\right]_0 \right)^2 - L_0 \left.\frac{\partial^2 L}{\partial \phi^2}\right]_0 \right\}$$

which is to be so interpreted that

$$\mathrm{c}_3 = \frac{\mathrm{c}_{1m}\mathrm{c}_{2(n+q)}\mathrm{z}_{(n+q)} + \mathrm{c}_{1n}\mathrm{c}_{2(m+q)}\mathrm{z}_{(m+q)} + \mathrm{c}_{1q}\mathrm{c}_{2(m+n)}\mathrm{z}_{(m+n)}}{\mathrm{c}'_{(m+n+q)}} \left.\frac{\partial L}{\partial \phi}\right]_0$$

$$+ \frac{L_0 \mathrm{c}_{1m}\mathrm{c}_{1n}\mathrm{c}_{1q}}{3!\,\mathrm{z}'_{(m+n+q)}} \left\{ 2\left(\left.\frac{\partial L}{\partial \phi}\right]_0\right)^2 - L_0 \left.\frac{\partial^2 L}{\partial \phi^2}\right]_0 \right\}$$

19. CAPACITANCE VARIATION

When the variation of capacitance is of importance, as in such devices as the condenser transmitter, eq. (1) may be rewritten as

$$E = \frac{q}{c} + r\frac{dq}{dt} + L\frac{d^2q}{dt^2} \tag{9}$$

and the characteristic of the device plotted as charge against voltage. The same methods of solution used for resistance variation are then available (with the exception that the operator z introduced in the detailed solution of article 21 must be replaced by $j\omega\mathrm{z}$).

20. APPROXIMATE SERIES EXPANSION FOR THE PLATE CURRENT OF A TRIODE (ASSUMES μ CONSTANT)

Circuits containing thermionic vacuum tubes are chosen to exemplify the detailed treatment of non-linear electric circuits because of the commanding importance of the thermionic tube in communication practice. This wide use has occurred largely because the triode, tetrode, etc., combine an amplification or control function with the non-linearity of the current-voltage device; in most tubes it is possible to employ either or both functions by a simple shift in electrode operating voltages (see Section 4 for nomenclature and characteristics).

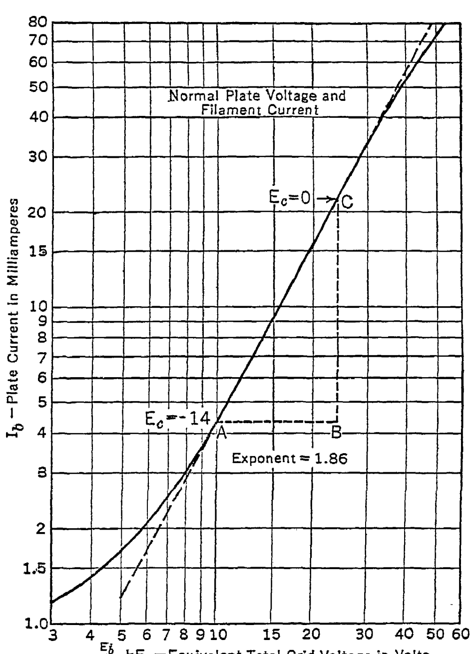

FIG. 3. Mutual Characteristic of a Triode. Normal plate voltage = 130 volts. μ = 5.45.

The triode is generally used in practice with steady voltages applied to both grid and plate, and in addition at least one varying voltage on one of the control electrodes, and frequently with one or more varying voltages impressed in both the plate and grid circuits; these instantaneous currents (i_b, i_c) and voltages (e_b, e_c) may be conveniently split up as follows:

$$i_b = I_b + i_p$$
$$i_c = I_c + i_g$$
$$e_c = E_c + e_g$$
$$e_b = E_b + e_p$$

where the capital letters (E_b, E_c, I_b, I_c) indicate steady values obtaining before the application of any varying voltages in the plate or grid circuits; the lower-case letters with subscript p or g indicate instantaneous values of varying components. All these voltages are specified as actual voltages between electrodes; if the external circuits contain impedance these voltages will differ from the supply voltages.

The plate current of the usual triode is a function of e_c, e_b, and the amplification factor

$\mu(\equiv -\partial e_b \cdot \partial e_c$ when i_b is held constant) such that for at least portions of the operating range

$$i_b = K\left(\frac{e_b}{\mu} + e_c\right)^\eta \tag{10}$$

where K and η are constants. The values may be found for any tube by plotting the plate current of the tube against equivalent grid voltage $\left(\frac{e_b}{\mu} + e_c\right)$ on logarithmic cross-section paper as shown in Fig. 3. The value of η in most triodes usually lies between 1.5 and 2.5; since it varies around 2.0 the triode is sometimes said to follow a square law. This may be sufficiently accurate for rough calculations but is not satisfactory in an exact analysis.

Expanding by Taylor's series

$$i_b = F(E_b, E_c) + (e_p + \mu e_g)\left.\frac{\partial i_b}{\partial e_b}\right]_0 + \frac{(e_p + \mu e_g)^2}{2!}\left.\frac{\partial^2 i_b}{\partial e_b^2}\right]_0 + \frac{(e_p + \mu e_g)^3}{3!}\left.\frac{\partial^3 i_b}{\partial e_b^3}\right]_0 + \cdots \tag{11}$$

where the subscript 0 after a bracket indicates that the derivatives are to be evaluated for $e_b = E_b$ and $e_c = E_c$. Note that $I_b = F(E_b, E_c)$ and may be subtracted from each side of eq. (11). Also define the *static plate resistance* as

$$\frac{1}{r_p} \equiv \left.\frac{\partial i_b}{\partial e_b}\right]_0 \tag{12a}$$

then

$$\left.\frac{\partial^2 i_b}{\partial e_b^2}\right]_0 = -\frac{1}{r_p^2}\left.\frac{\partial r_p}{\partial e_b}\right]_0 \tag{12b}$$

and

$$\left.\frac{\partial^3 i_b}{\partial e_b^3}\right]_0 = \frac{2}{r_p^3}\left(\left.\frac{\partial r_p}{\partial e_b}\right]_0\right)^2 - \frac{1}{r_p^2}\left.\frac{\partial^2 r_p}{\partial e_b^2}\right]_0 \tag{12c}$$

Making these substitutions, eq. (11) becomes

$$i_p = \frac{(e_p + \mu e_g)}{r_p} - \frac{(e_p + \mu e_g)^2}{2r_p^2}\left.\frac{\partial r_p}{\partial e_b}\right]_0 + \frac{2(e_p + \mu e_g)^3}{3!r_p^3}\left(\left.\frac{\partial r_p}{\partial e_b}\right]_0\right)^2$$
$$- \frac{(e_p + \mu e_g)^3}{3!r_p^2}\left.\frac{\partial^2 r_p}{\partial e_b^2}\right]_0 + \cdots \tag{13}$$

If, as is usual in amplifiers, $e_p = 0$, then the factor $\mu/r_p(\equiv \partial i_b/\partial e_c)$ frequently appears in this equation. It is designated g_m and called the *grid-plate transconductance* (mutual conductance). Expansions in terms of transconductance are particularly useful when μ is variable or when the plate resistance of the tube is so high that external resistances are negligible (see article 22).

21. CHARACTERISTICS OF TRIODE WITH LOAD

When the triode is used with external impedance there are voltage drops in these impedances so that the electrode voltages are the differences between the applied voltages and these impedance drops. Since eq. (13) applies to the voltages *between the electrodes,* account must be taken of the impedance drops.

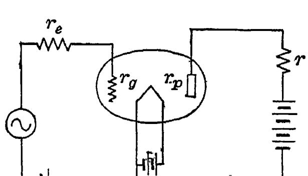

Fig. 4. Triode with Resistance Load

RESISTANCE LOADS. When the external loads are pure resistances the electrode currents and voltages may be split up as follows (see Fig. 4).

$$i_b = I_b + i_p$$
$$i_c = I_c + i_g$$
$$e_c = E_c + e_g = E'_c - r_e I_c + e'_g - r_e i_g$$
$$e_b = E_b + e_p = E'_b - rI_b + e'_p - ri_p$$

where e_p is the sum of the externally impressed voltage and the load resistance drop in the plate circuit, e_g is similar, and r and r_e are the external resistances in the plate and grid circuit. The voltages e'_g and e'_p are the driving voltages introduced in the grid and plate circuits.

If the assumption is made that the plate-grid transconductance $g_n(\equiv \partial i_c/\partial e_b)$ is zero, as is usual for small grid voltages, then the grid current (r_g is the internal grid resistance) is

$$i_g = \frac{e'_g}{r_g + r_e} - \frac{e'^2_g r_g}{2(r_g + r_e)^3}\frac{\partial r_g}{\partial e_c} + \cdots \tag{14}$$

and the varying voltage between grid and cathode is

$$e_g = \frac{e'_g r_g}{r_g + r_e} + \frac{e'^2_g r_e r_g}{2(r_g + r_e)^3}\frac{\partial r_g}{\partial e_c} + \cdots \tag{15}$$

The varying component of the plate current (let $e = e_g + e'_p/\mu$) is

$$i_p = \frac{\mu e}{r_p + r} - \frac{\mu^2 e^2 r_p}{2!(r_p + r)^3}\left.\frac{\partial r_p}{\partial e_b}\right]_0 + \frac{\mu^3 e^3 r_p(2r_p - r)}{3!(r_p + r)^5}\left(\left.\frac{\partial r_p}{\partial e_b}\right]_0\right)^2 - \frac{\mu^3 e^3 r_p^2}{3!(r_p + r)^4}\left.\frac{\partial^2 r_p}{\partial e_b^2}\right]_0 + \cdots \tag{16}$$

Usually the higher-order derivatives rapidly decrease in value, and, since in the higher-order coefficients the power of $(r_p + r)$ in the denominator rises rapidly, all terms beyond the third may be neglected for most practical applications of the tube.

IMPEDANCE LOADS. When impedances are connected in the external circuits of the tube (instead of the resistances of Fig. 4) it is impossible to write the external impedance drop in vector form until the plate circuit is specified. Use may be made of the *operational* impedance $\left(z \equiv r + L\dfrac{d}{dt} + \dfrac{1}{C}\int dt\right)$ which is such that zi *represents* the impedance drop regardless of the form of i. Of course it is impossible to evaluate zi until i is known. The plate current may be written in terms of an operator denoting a delayed multiplication, called the *square cross bracket*, as

$$i_p = e[\times \mathrm{c}_1] + e^2[\times \mathrm{c}_2] + e^3[\times \mathrm{c}_3] + \cdots \tag{17}$$

where

$$\mathrm{c}_1 = \frac{\mu}{r_p + \mathrm{z}} = \frac{\mu}{\mathrm{z}'} \tag{18}$$

in which z is to be separately evaluated for each component frequency of interest. Note that z′ is the total impedance of the plate circuit at the particular frequency. Likewise

$$\mathrm{c}_2 = -\frac{r_p}{2}\left.\frac{\partial r_p}{\partial e_b}\right]_0 \frac{(\mathrm{c}_1)^2}{\mathrm{z}'} \tag{19}$$

in which each of the c's is to be evaluated at the frequency of one of the original frequencies beating together and z′ is to be evaluated at the beat frequency. For instance, to find the size of the current component of periodicity $(\omega_m + \omega_n)$ caused by the beating of two terms of periodicity ω_m and ω_n, evaluate

$$\mathrm{E}_m\mathrm{E}_n\mathrm{c}_{2(m+n)} = -\frac{r_p \mathrm{E}_m \mathrm{E}_n \mu^2}{2!\,\mathrm{z}'_m \mathrm{z}'_n \mathrm{z}'_{(m+n)}}\left.\frac{\partial r_p}{\partial e_b}\right]_0 \tag{19a}$$

Similarly c_3, which embraces terms caused by three of the originally impressed components beating together (these are very important in calculating the amount of interference introduced in a radio receiver by neighboring carriers), is

$$\mathrm{c}_3 = \frac{\mathrm{c}_1(\mathrm{c}_2\mathrm{z})}{\mathrm{z}'}\left.\frac{\partial r_p}{\partial e_b}\right]_0 + \frac{r_p(\mathrm{c}_1)^3}{3!\,\mathrm{z}'}\left\{2\left(\left.\frac{\partial r_p}{\partial e_b}\right]_0\right)^2 - r_p\left.\frac{\partial^2 r_p}{\partial e_b^2}\right]_0\right\} \tag{20}$$

which is to be so interpreted that

$$\mathrm{c}_{3(m+n+q)} = \frac{\mathrm{c}_{1m}\mathrm{c}_{2(n+q)}\mathrm{z}_{(n+q)} + \mathrm{c}_{1n}\mathrm{c}_{2(m+q)}\mathrm{z}_{(m+q)} + \mathrm{c}_{1q}\mathrm{c}_{2(m+n)}\mathrm{z}_{(m+n)}}{\mathrm{z}'_{(m+n+q)}}\left.\frac{\partial r_p}{\partial e_b}\right]_0 + \frac{r_p\mathrm{c}_{1m}\mathrm{c}_{1n}\mathrm{c}_{1q}}{3!\,\mathrm{z}'_{(m+n+q)}}\left\{2\left(\left.\frac{\partial r_p}{\partial e_b}\right]_0\right)^2 - r_p\left.\frac{\partial^2 r_p}{\partial e_b^2}\right]_0\right\} \tag{20a}$$

Table 1. Plate Currents of a Triode

1. No load and resistance load; μ assumed constant.

$$i_p = c_1e + c_2e^2 + c_3e^3 + \text{etc.} \left(e = e_g + \frac{e'_p}{\mu}\right)$$

	c_1	c_2	c_3
No load, eq. (11)	$\frac{\mu}{r_p}$	$-\frac{\mu^2}{2r^2_p}\frac{\partial r_p}{\partial e_b}\Big]_0$	$\frac{\mu^3}{3r^3_p}\left\{\left(\frac{\partial r_p}{\partial e_b}\Big]_0\right)^2 - \frac{r_p}{2}\frac{\partial^2 r_p}{\partial e_b^2}\Big]_0\right\}$
Resistance load, eq. (16)	$\frac{\mu}{r_p + r}$	$-\frac{\mu^2 r_p}{2!(r_p + r)^3}\frac{\partial r_p}{\partial e_b}\Big]_0$	$\frac{\mu^3 r_p}{3!(r_p + r)^5}\left\{(2r_p - r)\left(\frac{\partial r_p}{\partial e_b}\Big]_0\right)^2 - r_p(r_p + r)\frac{\partial^2 r_p}{\partial e_b^2}\Big]_0\right\}$

2. Impedance load; μ assumed constant.

$$i_p = e[\times \mathrm{c}_1] + e^2[\times \mathrm{c}_2] + e^3[\times \mathrm{c}_3] + \text{etc.}$$

c_1	c_2	c_3
$\frac{\mu}{r_p + \mathrm{z}} = \frac{\mu}{\mathrm{z}'}$ eq. (18)	$-\frac{r_p}{2}\frac{\partial r_p}{\partial e_b}\Big]_0 \frac{(\mathrm{c}_1)^2}{\mathrm{z}'}$ eq. (19)	$\frac{\mathrm{c}_1(\mathrm{c}_2\mathrm{z})}{\mathrm{z}'}\frac{\partial r_p}{\partial e_b}\Big]_0 + \frac{r_p}{3}\frac{(\mathrm{c}_1)^3}{\mathrm{z}'}\left\{\left(\frac{\partial r_p}{\partial e_b}\Big]_0\right)^2 - \frac{r_p}{2}\frac{\partial^2 r_p}{\partial e_b^2}\Big]_0\right\}$ eq. (20)

The expression $e^2[\times c_2]$ means that e^2 is to be reduced to *first-degree* cosine terms, after which each cosine term is to be multiplied by the modulus of c_2, evaluated at the frequency or frequencies contained in that term, and the phase angle of c_2 is to be added to the phase of the cosine term. For the method of assigning frequencies in c_2 and c_3 see eqs. (19*a*) and (20*a*).

As in the case of resistance load the grid voltage e_g does not equal the voltage introduced into the grid circuit (e'_g), but can be obtained therefrom, as

$$e_g = e'_g\left[\times \frac{1}{\mathrm{z}''}\right]r_g + e'^2_g\left[\times \frac{\mathrm{z}_e}{(\mathrm{z}'')^2\mathrm{z}''}\right]\frac{r_g}{2}\frac{\partial r_g}{\partial e_c}\Big]_0 + \cdots \tag{21}$$

in which z'' is the total impedance of the grid circuit. In the second term $(\mathrm{z}'')^2$ is to be treated like the term $(\mathrm{c})^2$ in eq. (19), that is evaluated at the separate frequencies which are beating together.

For example, assume a pure cosine voltage $e'_p = E'_{ps}\cos(\omega_s t + \theta_s)$ impressed in the plate circuit, and a similar voltage $e_g = E_{gn}\cos(\omega_n t + \theta_n)$ between grid and filament (or anywhere in the grid circuit if the grid is held negative). Then as far as c_1 and c_2 are concerned

$$\begin{aligned} i_{pa} = {} & \frac{\mu E_{gn}\cos(\omega_n t + \theta'_n)}{\mathrm{z}'_n} + \frac{E'_{ps}\cos(\omega_s t + \theta'_s)}{\mathrm{z}'_s} \\ & - \frac{r_p}{4}\frac{\partial r_p}{\partial e_b}\Big]_0\left[\frac{\mu^2 E_{gn}^2}{z'^2_n(r_p + r)} + \frac{E'^2_{ps}}{z'^2_s(r_p + r)} + \frac{\mu^2 E_{gn}^2\cos(2\omega_n t + \beta_{2n})}{z'^2_n z'_{(2n)}}\right. \\ & + \frac{E'^2_{ps}\cos(2\omega_s t + \beta_{3s})}{z'^2_s z'_{(2s)}} + \frac{2\mu E_{gn}E'_{ps}\cos(\omega_s t + \omega_n t + \beta_{4n})}{z'_s z'_n z'_{(s+n)}} \\ & \left. + \frac{2\mu E_{gn}E'_{ps}\cos(\omega_s t - \omega_n t + \beta_{5n})}{z'_s z'_n z'_{(s-n)}}\right] \end{aligned} \tag{22}$$

where *

$$\theta'_n = \theta_n - \tan^{-1}\frac{x_n}{r_p + r} \text{ and } \theta'_s \text{ is similar}$$

$$\beta_{2n} = 2\theta'_n - \tan^{-1}\frac{x_{(2n)}}{r_p + r} \text{ and } \beta_{3s} \text{ is similar}$$

$$\beta_{4n} = \theta'_n + \theta'_s = \tan^{-1}\frac{x_{(s+n)}}{r_p + r}$$

and

$$\beta_{5n} = \theta'_s - \theta'_n = \tan^{-1}\frac{x_{(s-n)}}{r_p + r}$$

* Note carefully the positive sign associated with $\tan^{-1}\frac{x_n}{r_p + r}$ in β_{5n}. This occurs through the subtraction of θ'_n from θ'_s, even though z_n is in the denominator. The importance of this difference in sign of this term in β_{4n} and β_{5n} is brought out in Section 7, article 18.

A comparison of the expressions for c_1 and c_2 given by eqs. (18) and (19), respectively, shows the effect of the impedance load, which appears in the denominator of c_2 to a higher power, in decreasing the percentage value of the harmonic terms, or in straightening the plate and mutual characteristics. From this it may be seen that an impedance load acts similarly to a resistance load in tending to decrease the relative size of the harmonics introduced by the non-linear shape of these characteristics. The impedance load of course introduces frequency distortion.

DYNAMIC PLATE RESISTANCE. When the steady voltages applied to a triode are such as to cause the static operating point to be within a curved region of the mutual (or other) characteristic, or so near to a curved portion that the applied alternating voltage causes the triode to work on a curved portion for a part of a cycle, more accurate results will be obtained from the series expansion by evaluating the derivatives at the average values of voltages obtaining during the cycle. These may be quite different from the static values. The plate resistance so defined $\left(\frac{1}{r_p} \equiv \frac{\partial i_b}{de_b}\Big]_{\text{average}}\right)$ is called the *dynamic plate resistance*; see eq. (12). All other derivatives should likewise be evaluated at the dynamic operating point, if there is considerable change in the direct, or average, current when the signal is impressed.

The dynamic parameters are quite tedious to compute but their values may be approximately measured on an impedance bridge if the amplitude of the applied voltage is the same as that of the signal voltage. The resistance measured on the bridge is called the *effective plate resistance* and for small or medium voltages is equal to the dynamic plate resistance. When they are not equal the dynamic resistance is the value to be used in evaluating the series; the effective value must be used if it is desired to express all the fundamental current in one term.

VARIATION OF AMPLIFICATION FACTOR. If the variation of μ must be considered (it always should be in pentodes) the first term (c_1), Table 1, is unchanged but the second term (c_2) is

$$c_2 = \frac{-\mu^2 r_p \frac{\partial r_p}{\partial e_b} + r_p(z'_m + z'_n)\frac{\partial \mu}{\partial e_c}}{2z'_m z'_n z'_{(m+n)}}$$

which shows the increased distortion arising from the variation of μ.

22. ANALYSIS FOR MULTI-ELECTRODE TUBES

The above method of analysis can be extended to tetrodes, pentodes, etc. If voltage is introduced into only one control circuit, and if the other grids have low impedance, the analysis as given is sufficient for any case. If, however, there are impedance drops in several of the electrode circuits each must be analyzed in the same manner. The equations are very complicated and not of sufficiently general interest to be included here (see *High-Frequency Alternating Currents*, McIlwain and Brainerd, John Wiley & Sons, Appendix A, for complete development).

23. METHOD OF SUCCESSIVE APPROXIMATIONS *

The calculation of the coefficients in the power series expansion of a vacuum tube and its associated circuit becomes extremely complicated for terms higher than the third term and for analyses of multi-electrode tubes. Thus the analysis of circuits containing vacuum tubes by means of the Taylor's series expansion of the tube characteristics, although theoretically applicable to all circuits, is applicable in practice only to those circuits for which the series converges very rapidly. The factors affecting the convergence are (1) the amplitude of the applied voltages and (2) the sharpness of the curvature of the characteristic in the operating range, that is, the magnitude of the higher derivatives of the characteristic. Thus for high level voltage amplifiers, power amplifiers, large signal detectors (including linear detectors), and most oscillators, the treatment by Taylor's series is practically useless except possibly for qualitative analysis.

In such cases the method of successive approximations is sometimes useful. Equations of the form

$$i_1 = F_1(e_1, e_2) \tag{23a}$$

$$i_2 = F_2(e_1, e_2) \tag{23b}$$

are written for the total number of currents and voltages involved.†

---

* Articles 23 and 24 were contributed by Dr. Carl C. Chambers.

† This method is applicable to certain types of discontinuous functions such as those found in dealing with gas-filled tubes.

For the triode with voltages in both the plate and grid the equations become

$$i_p = F_1(\{e'_g - i_g[\times z_g]\}, \quad \{e'_p - i_p[\times z_p]\}) \tag{24a}$$

$$i_g = F_2(\{e'_g - i_g[\times z_g]\}, \quad \{e'_p - i_p[\times z_p]\}) \tag{24b}$$

where the symbols have the same meaning as in the previous section on the Taylor's series expansion of vacuum tubes.

The values of the resulting currents are estimated and called i_{p0} and i_{g0}. These can be obtained from oscillograms of a similar vacuum tube, from the approximate solution by means of the Taylor's series expansion, or simply from an intuitive guess. Although the accuracy of the estimate of the value of i_{p0} and i_{g0} is not theoretically important, the labor involved is directly dependent upon this accuracy.

Having i_{p0} and i_{g0}, the first approximation is calculated by substitution of these values in the right-hand members of (24*a*) and (24*b*), giving

$$i_{p1} = F_1(\{e'_g - i_{g0}[\times z_g]\}, \quad \{e'_p - i_{p0}[\times z_p]\})$$

$$i_{g1} = F_1(\{e'_g - i_{g0}[\times z_g]\}, \quad \{e'_p - i_{p0}[\times z_p]\})$$

The second and higher order approximations are obtained by substituting the preceding approximation in the right-hand members of eqs. (24).

In making these successive substitutions it is necessary to write the preceding approximation in separate sine-wave terms in order to evaluate $i_{gr}[\times z_g]$ and $i_{pr}[\times z_p]$. This can be done by any of the various methods for harmonic analysis (see Fisher-Hinnen, *Method and Wave Analysis*, article 1). When z_p and z_g are selective impedances, the only harmonic components of the current of importance for purposes of substitution are those for which z_p and z_g are not essentially zero. For this reason this method of analysis is especially applicable to class B and class C r-f amplifiers, oscillators, and frequency multipliers, where the plate impedances are highly selective.

The functions F_1 and F_2 can be in any form in which they are completely specified over the entire operating range of the applied voltages. Thus any analytical expression for the tube currents or any complete set of curves is sufficient for use in the above method of analysis.

24. HARMONIC ANALYSIS OF THE CURRENT FOR A SINUSOIDAL APPLIED VOLTAGE

In many cases the performance of a non-linear circuit can be predicted from a knowledge of the harmonic content of the current when a sinusoidal voltage is impressed in the circuit. The usual discussion of the merit of a non-selective amplifier assumes a sine-wave excitation, to avoid the complexity introduced by the presence of the many beat terms otherwise present.

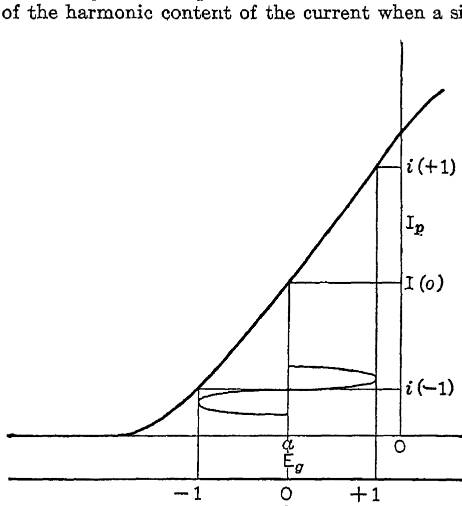

FIG. 5. Tube Characteristic and Sine-wave Input

When the relation between the instantaneous impressed voltage and the instantaneous current is given it is of course possible to plot the wave form of the current. This may then be analyzed by any of the usual methods of wave analysis.

When the input voltage varies sinusoidally, the output current will be periodic, having a fundamental periodicity equal to that of the input voltage. In resistive circuits the relation between the input voltage and the output current is independent of time, so that the output current will pass from maximum to minimum and from minimum to maximum over the same path, in fact, over the characteristic curve. (The term characteristic is applied in its original sense to the instantaneous relation between input voltage and output current). It follows that, if a complete period of the plate current is T seconds, $i(t)$

$= i(T - t)$ when the origin of time is chosen at the instant when the current is a maximum. This form of symmetry insures that when the output current due to a sinusoidal input voltage is written in the form

$$i = I_0 + I_1 \cos(\omega t + \beta_1) + I_2 \cos(2\omega t + \beta_2) + \qquad (25)$$

the phase angles β_1, β_2, etc., will be zero.

Several methods of analysis are used to obtain the values I_0, I_1, etc. The one of broadest application is the variation of the Fisher-Hinnen method applicable to such a characteristic curve instead of to the wave itself. The analysis by this method can be stated as follows: consider the zero point of the sinusoidal input voltage variation to be the zero of the base line of the characteristic, and consider the scale along this base line to be such that the peak value of the input voltage is unity. Then $i(e)$ is the relation given by the mutual characteristic where e is the input voltage which on this scale varies from -1 to $+1$ and i is the corresponding output current (see Fig. 5). Then the I's to the second approximation in the Fisher-Hinnen method of analysis are given by

$$I_1 = {}^1/_2\,[i(1) - i(-1)]$$
$$I_2 = {}^1/_4\,[i(1) - 2i(0) + i(-1)]$$
$$I_3 = {}^1/_6\,[i(1) - 2i(0.5) + 2i(-0.5) - i(-1)]$$
$$I_4 = {}^1/_8\,[i(1) - 2i(0.707) + 2i(0) - 2i(-0.707) + i(-1)]$$
$$\cdots\cdots\cdots\cdots$$
$$I_n = \frac{1}{2n}\left[i(1) - 2i\left(\cos\frac{\pi}{n}\right) + 2i\left(\cos\frac{2\pi}{n}\right) - 2i\left(\cos\frac{3\pi}{n}\right)\cdots \pm 2i\left(\cos\frac{(n-1)\pi}{n}\right) \mp i(-1)\right]$$

The I's to the fourth approximation in the Fisher-Hinnen method are then given by

$$I'_n = I_n - I_{2n} - I_{3n}$$

The d-c component I_0 is given to the second approximation by

$$I_0 = {}^1/_3\left[i(0) + \frac{i(1) + i(-1)}{2} + \frac{i(0.707) + i(-0.707)}{2}\right]$$

Another method (see D. C. Espley, *Proc. I.R.E.*, Vol. 21, 1439 [1933]) has the advantage that the points along the input voltage axis of the mutual characteristic, at which the current is evaluated, are equally spaced. This analysis using three points gives results identically the same as the values for I_1 and I_2 given by the Fisher-Hinnen method. When five points are used the I's become

$$I_0 = {}^1/_6\,[i(1) + 2i(0.5) + 2i(-0.5) + i(-1)]$$
$$I_1 = {}^1/_3\,[i(1) + i(0.5) - i(-0.5) - i(-1)]$$
$$I_2 = {}^1/_4\,[i(1) - 2i(0) + i(-1)]$$
$$I_3 = {}^1/_6\,[i(1) - 2i(0.5) + 2i(-0.5) - i(-1)]$$
$$I_4 = {}^1/_{12}\,[i(1) - 4i(0.5) + 6i(0) - 4i(-0.5) + i(-1)]$$

For the values of the I's using seven equally spaced points see the original paper referred to above.

In the special case when the even harmonics are balanced out as in "back to back" amplifiers (pushpull class A, class B audio, and class AB amplifiers, see Amplifiers, Section 7) the mutual characteristic becomes like that shown in Fig. 6. I_0 is balanced out of the output current as well as the even harmonics so that $i(e) = -i(-e)$. For such amplifiers the analysis by the Fisher-Hinnen method gives for the remaining I's

$$I_1 = i(1)$$
$$I_3 = {}^1/_3\,[i(1) - 2i(0.5)]$$
$$I_5 = {}^1/_5\,[i(1) - 2i(0.809) + 2i(0.309)]$$
$$I_7 = {}^1/_7\,[i(1) - 2i(0.901) + 2i(0.624) - 2i(0.222)]$$
$$\cdots\cdots\cdots\cdots$$
$$I_n = \frac{1}{n}\left[i(1) - 2i\left(\cos\frac{\pi}{n}\right) + 2i\left(\cos\frac{2\pi}{n}\right) - \cdots \pm 2i\left(\cos\frac{(n-1)\pi}{2n}\right)\right]$$

As before, a better approximation for I_n is obtained by subtracting I_{3n} from the calculated I_n.

When this symmetry exists the method of Espley described above reduces to the Fisher-Hinnen method when the measurements are made at only five points (for this special case only two points need actually be measured), and the seven measured point analysis of Espley reduces to

$$I_1 = {}^1/_{320}\,[167i(1) + 252i(0.667) - 45i(0.333)]$$
$$I_3 = {}^1/_{128}\,[45i(1) - 36i(0.667) - 63i(0.333)]$$
$$I_5 = {}^{81}/_{640}\,[i(1) - 4i(0.667) + 5i(0.333)]$$

Here because of the symmetrical character of the curve only three points actually need be measured.

Mouromtseff and Kozanowski (*Proc. I.R.E.*, Vol. 22, 1090 [1934]) give a somewhat simpler method to calculate up to the eleventh harmonic in the case of a symmetrical curve such as Fig. 6. The straight line *aob* is drawn intersecting the curve at the point of maximum input voltage, that is, $e = 1$ in the notation used above. Then, instead of measuring $i(e)$, $\Delta i(e)$ is measured where $\Delta i(e)$ is the difference in current between the curve and the line *aob* and is taken positive when the line *aob* is above the curve. This gives for the I's in the order in which they are to be calculated

$$I_5 = 0.4[\Delta i(0.309) - \Delta i(0.809)]$$
$$I_3 = 0.4475[\Delta i(0.309) + \Delta i(0.809)] + 0.333\Delta i(0.5) - 0.578\Delta i(0.866) - 0.5I_5$$
$$I_7 = 0.4475[\Delta i(0.309) + \Delta i(0.809)] - I_3 + 0.5I_5$$
$$I_9 = I_3 - 0.667\Delta i(0.5)$$
$$I_{11} = 0.707\Delta i(0.707) - I_3 + I_5$$
$$I_1 = i(1) - I_3 + I_5 - I_7 + I_9 - I_{11}$$

Any of the above methods can be used for the calculation of the I's in eq. (25) when the input voltage is sinusoidal. The per cent amplitude for any given harmonic is then I_n/I_1 for an input voltage, the peak value of which is taken $e = 1$. The complete equation of the curve from $e = -1$ to $e = +1$ can be written in the form

$$i(e) = I_0 + I_1 e + I_2 \cos 2(\cos^{-1} e) + I_3 \cos 3(\cos^{-1} e) + \cdots$$

This expression for the output current is unique; that is, for each value of e between -1 and $+1$ this equation gives the corresponding instantaneous plate current provided that the conditions prescribed at the beginning of this section are fulfilled, chiefly, that the load is essentially a constant resistance over the operating frequencies and voltages. This expression can be used in several ways although calculations of the operation for input voltages other than a simple sinusoid of amplitude unity on the scale of e are extremely complex analytically.

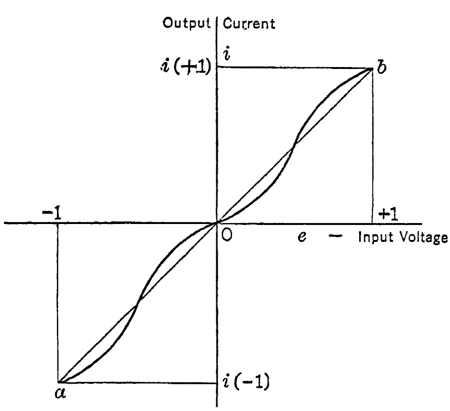

FIG. 6. Mutual Characteristics of Two Tubes "Back to Back"

The calculation of the distortion and output by any of the above methods for a sinusoidal input voltage having an amplitude of a fixed fraction of e can be made by means of this expression for $i(e)$ without again using the curve. Formulas can be developed for this purpose using any of the above methods of analysis as a basis giving the I's corresponding to an input voltage of fractional amplitude.

This method of analysis can generally be used when the resistive load is coupled into the non-linear circuit by a transformer. For if the transformer is "perfect" the relation between voltage and current is the same as for a resistance load (see Transformers, Section 6); in other words the transformer offers a resistive impedance to the circuit. Practical transformers are nearly perfect enough to assume that their only effect is to multiply (or divide) the load resistance by the square of the turn ratio.

25. INPUT IMPEDANCE OF A TRIODE

Neglecting the leakage resistances between electrodes the equivalent circuit of a triode with grid negative is shown in Fig. 7. The equivalent input resistance is

$$r_i = \frac{r_pC_3\left[(r^2+x^2)(\mu C_2 + C_3 + \mu C_3) + r_p r C_3 - \dfrac{\mu x}{\omega}\right]}{(\omega^2 r_p^2 A^2 + B^2)(r^2+x^2) + r_p(C_1+C_3)[2rB - 2\omega r_p x A + r_p(C_1+C_3)]} \tag{26a}$$

the equivalent input reactance by

$$x_i = -\frac{\left\{\begin{array}{l}\omega^2 r_p^2 (C_2+C_3)(r^2+x^2)A + B(r^2+x^2+rr_p)\\ +(C_1+C_3)(r_p^2+rr_p) - \omega r_p^2 x(2A + C_3^2)\end{array}\right\}}{\left\{\begin{array}{l}\omega\{(\omega^2 r_p^2 A^2 + B^2)(r^2+x^2)\\ +r_p(C_1+C_3)[2rB - 2\omega r_p x A + r_p(C_1+C_3)]\}\end{array}\right\}} \tag{26b}$$

where $A = C_1C_2 + C_1C_3 + C_2C_3$, and $B = C_1 + C_2 + \mu C_3$.

Both the numerator and denominator of each of these expressions contain negative terms; thus either can be positive or negative depending on the circuit parameters. If the value of the reactance becomes positive it indicates that the equivalent input reactance is inductive. If the value of the expression for resistance becomes negative, it indicates that the real part of the input impedance of the tube is an *equivalent negative resistance* and is supplying instead of absorbing power. The input resistance will become negative only for certain values of *inductive load;* cf. eq. (26*a*). When this condition exists, the tube will always supply a greater plate current than it would for the same grid voltage and a non-reactive load. When this occurs the tube is said to be *regenerating* (see Section 8). If the negative input resistance exactly equals the external resistance the total resistance of the circuit is zero and current can flow without a driving voltage; in such a case the tube is said to *oscillate* (see Section 7, oscillators).

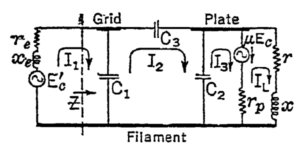

FIG. 7. Simplified Equivalent Circuit of a Triode

When the grid voltage is positive, grid current flows and the grid resistance is defined by $1/r_g = \partial i_g/\partial e_g$. This is practically infinite when the grid is negative but may be quite small when the grid is positive; in this latter case the interelectrode impedances are usually negligible in comparison to it so that the input impedance of the triode is simply r_g.

ELECTROMAGNETIC RADIATION

By Knox McIlwain

All forms of wireless or radio transmission depend on the fact that electromagnetic energy is radiated from any wire in which a varying current flows. The current in the wire sets up magnetic and electric fields, in which it is usually assumed that the energy associated with the current flow is stored; a portion of this energy, however, is not stored, but continually travels away from the wire, or is radiated. Radiation is a phenomenon which is totally negligible at low frequencies.

26. MAXWELL'S EQUATIONS

There are two well-known experimental relations between magnetic and electric fields. The two fields are interdependent, a change in one always being accompanied by a change of the other. The two laws are:

1. Whenever the net magnetic flux linking any closed loop changes, an electromotive force is set up in the loop. If ϕ is the net magnetic flux linking the loop, then (Faraday's law) the electromotive force is

$$e = -\frac{d\phi}{dt} \tag{1}$$

2. The resultant magnetomotive force (in ampere-turns) acting around any closed loop is equal to the rate of flow of electricity through the surface bounded by the loop plus the time rate of change of electric flux through this surface. If $i = dq/dt$ is the rate of flow of electricity (total conduction current in amperes) and ψ the electric flux through the surface then the magnetomotive force is

$$m = i + \frac{d\psi}{dt} \tag{2}$$

Both these relations are such that the force expressed by the left side of the equation bears a right-hand-screw relation to a positive increment of the right-hand side. They apply to any medium whatever, to conductors, dielectrics, ferromagnetic substances, etc.

By applying these equations to an elementary volume in space, Maxwell's laws of electromagnetism are developed. Stated in vector notation these are (all quantities are expressed in mks units)

$$\gamma \boldsymbol{\varepsilon} + K\frac{\partial \boldsymbol{\varepsilon}}{\partial t} = \text{curl } \boldsymbol{H} \tag{3}$$

$$-\mu\frac{\partial \boldsymbol{H}}{\partial t} = \text{curl } \boldsymbol{\varepsilon} \tag{4}$$

From these the continuity equations immediately follow;

$$\text{div } \boldsymbol{u} = 0 \tag{5}$$

$$\text{div } \boldsymbol{B} = 0 \tag{6}$$

where $\boldsymbol{u}$ is the *total* current density in amperes per square meter and $\boldsymbol{B}$ the magnetic flux density in webers per square meter.

Stated in the ordinary component form these equations are:

$$\gamma \varepsilon_x + \frac{K\partial \varepsilon_x}{\partial t} = \frac{\partial H_z}{\partial y} - \frac{\partial H_y}{\partial z} \tag{3a}$$

$$\gamma \varepsilon_y + \frac{K\partial \varepsilon_y}{\partial t} = \frac{\partial H_x}{\partial z} - \frac{\partial H_z}{\partial x} \tag{3b}$$

$$\gamma \varepsilon_z + \frac{K\partial \varepsilon_z}{\partial t} = \frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} \tag{3c}$$

$$-\mu\frac{\partial H_x}{\partial t} = \frac{\partial \varepsilon_z}{\partial y} - \frac{\partial \varepsilon_y}{\partial z} \tag{4a}$$

$$-\mu\frac{\partial H_y}{\partial t} = \frac{\gamma \varepsilon_x}{\partial z} - \frac{\partial \varepsilon_z}{dx} \tag{4b}$$

$$-\mu\frac{\partial H_z}{\partial t} = \frac{\partial \varepsilon_y}{\partial x} - \frac{\partial \varepsilon_x}{\partial y} \tag{4c}$$

$$\frac{\partial}{\partial_x}\left(\sigma_x + \frac{\partial D_x}{\partial t}\right) + \frac{\partial}{\partial y}\left(\sigma_y + \frac{\partial D_y}{\partial t}\right) + \frac{\partial}{\partial z}\left(\sigma_z + \frac{\partial D_z}{\partial t}\right) = 0 \tag{5a}$$

where σ is the conduction current density in amperes per square meter and $\boldsymbol{D}$ the electric flux density in coulombs per square meter, and

$$\frac{\partial B_x}{\partial x} + \frac{\partial B_y}{\partial y} + \frac{\partial B_z}{\partial z} = 0 \tag{6a}$$

Only fields which satisfy these relations are possible, and these equations may be used to determine the necessary form for particular fields.

The energy flow associated with the electromagnetic wave is found by developing Poynting's vector

$$P = \mathcal{E}H \sin(\boldsymbol{\mathcal{E}}, \boldsymbol{H}) \tag{7}$$

which is a vector perpendicular to $\mathcal{E}$ and H, whose magnitude depends on the product of $\mathcal{E}$ and H and the sine of the angle between them (measured counterclockwise from $\boldsymbol{\mathcal{E}}$ to $\boldsymbol{H}$). The integral of Poynting's vector over a surface gives the rate at which energy flows through the surface.

WAVE EQUATION. In an isotropic insulating medium no conduction current can flow, since γ (eq. 3) is zero. Elimination of $\boldsymbol{H}$ between eqs. (3 and 4), and similarly for $\boldsymbol{\mathcal{E}}$, gives the wave equations

$$\frac{\partial^2 \boldsymbol{\mathcal{E}}}{\partial t^2} = \frac{1}{\mu K}\left(\frac{\partial^2 \boldsymbol{\mathcal{E}}}{\partial x^2} + \frac{\partial^2 \boldsymbol{\mathcal{E}}}{\partial y^2} + \frac{\partial^2 \boldsymbol{\mathcal{E}}}{\partial z^2}\right) \equiv \frac{1}{\mu K}\nabla^2 \boldsymbol{\mathcal{E}} \tag{8}$$

$$\frac{\partial^2 \boldsymbol{H}}{\partial t^2} = \frac{1}{\mu K}\left(\frac{\partial^2 \boldsymbol{H}}{\partial x^2} + \frac{\partial^2 \boldsymbol{H}}{\partial y^2} + \frac{\partial^2 \boldsymbol{H}}{\partial z^2}\right) \equiv \frac{1}{\mu K}\nabla^2 \boldsymbol{H} \tag{9}$$

Solution of these equations shows that each component of electric or magnetic field must have the form

$$\mathcal{E}_x = f_1\left(t - \frac{x}{v}\right) + f_2\left(t + \frac{x}{v}\right) \tag{10}$$

where $v = \pm 1/\sqrt{\mu K}$. These functions represent incident and reflected waves (see p. 5-23) traveling at the velocity v ($= 3 \times 10^8$ meters per sec in vacuum and close to that in air). The *wavelength* is defined as the distance traveled in one period.

27. PROGRESSIVE PLANE WAVES

The simplest form of wave mathematically is one which travels along the x axis, say, and in which it is assumed that none of the fields vary with y or z. In such case (by Maxwell's laws)

$$\mathcal{E}_x = 0 \tag{11a}$$

$$\mathcal{E}_y = \bar{\mathcal{E}}_y \cos\left[\omega\left(t - \frac{x}{v}\right)\right] \tag{11b}$$

$$\mathcal{E}_z = \bar{\mathcal{E}}_z \cos\left\{\left[\omega\left(t - \frac{x}{v}\right)\right] + \delta_z\right\} \tag{11c}$$

$$H_x = 0 \tag{11d}$$

$$H_y = -\sqrt{\frac{K}{\mu}}\,\mathcal{E}_z = -\sqrt{\frac{K}{\mu}}\,\bar{\mathcal{E}}_z \cos\left\{\left[\omega\left(t - \frac{x}{v}\right)\right] + \delta_z\right\} \tag{11e}$$

$$H_z = \sqrt{\frac{K}{\mu}}\,\mathcal{E}_y = \sqrt{\frac{K}{\mu}}\,\bar{\mathcal{E}}_y \cos\left[\omega\left(t - \frac{x}{v}\right)\right] \tag{11f}$$

in which $\omega = 2\pi f$. Then $\omega[t - (x/v)] = \omega t - 2\pi x/\lambda$.

In the general form the loci of the vectors $\boldsymbol{\mathcal{E}}$ and $\boldsymbol{H}$ are ellipses, so that the plane wave above is said to be *elliptically polarized.* If $\bar{\mathcal{E}}_y = \bar{\mathcal{E}}_z$ and $\delta_z = \pi/2$ or $3\pi/2$ the ellipse reduces to a circle and the wave is said to be *circularly polarized.*

If either $\bar{\mathcal{E}}_y$ or $\bar{\mathcal{E}}_z$ is zero, or if $\delta_z = 0$ or π, the ellipse reduces to a straight line, in which case the wave is called a plane-polarized wave. The electric energy per meter^3 of such a wave at any point in the field is $K\mathcal{E}^2/2$, and the magnetic energy per meter^3 is $\mu H^2/2$. It follows that for a progressive plane-polarized wave at every point the total energy is always half electric and half magnetic, but its value varies, of course, with position and time. The total energy (W) of the field is

$$W = We + W_m = K\int\int\int \mathcal{E}^2\,dr \tag{12}$$

where dr is an element of volume. The average energy is $W_1 = K\mathcal{E}^2/2$, and the average *rate* at which energy passes through a meter^2 in the YZ plane is

$$P_a = \frac{1}{2}\sqrt{\frac{K}{\mu}}\,\bar{\mathcal{E}}_y{}^2 \tag{13}$$

28. FIELDS DUE TO A CURRENT IN A WIRE

If a current i flows in a short length of wire (see Fig. 1) located in free space and assumed at the origin of coordinates and coincident with the z axis, the fields at any point $P(x, y, z)$ are

$$\varepsilon_x = \frac{1}{K}\frac{\partial^2 w}{\partial x\, \partial z} \tag{14a}$$

$$\varepsilon_y = \frac{1}{K}\frac{\partial^2 w}{\partial y\, \partial z} \tag{14b}$$

$$\varepsilon_z = -\frac{1}{K}\left(\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2}\right) \tag{14c}$$

$$H_x = \frac{\partial^2 w}{\partial y\, \partial t} \tag{14d}$$

$$H_y = -\frac{\partial^2 w}{\partial x\, \partial t} \tag{14e}$$

$$H_z = 0 \tag{14f}$$

where $w \equiv \frac{1}{d} f_1\left(t - \frac{d}{v}\right)$; in this expression d is the distance from the origin to the point, and $F_1(t)$ expresses the distribution of charge in the wire, so that $F(t) = i\delta l$, where δl is the length of the wire (assuming uniform current for the differential length δl).

If the current is assumed sinusoidal, so that $i = \sqrt{2}I \sin(\omega t + 90°)$ amperes, at any point distant from the wire (so that $d \gg \lambda/2\pi$), the fields are

$$\varepsilon = \frac{\pi i\, \delta l}{150\, d\lambda} \cos\theta \cos(\omega t - \beta d) \text{ volts per meter} \tag{15a}$$

$$H = \frac{0.08\pi^2 i\, \delta l}{d\lambda} \cos\theta \cos(\omega t - \beta d) \text{ ampere-turns per meter} \tag{15b}$$

where θ is the angle of elevation of the point P from a plane perpendicular to the wire. All lengths are expressed in meters.

The direction of the electric field is perpendicular to d and in the plane formed by d and the axis of the wire. The magnetic field is perpendicular to d and the electric field.

Such an elementary wire is called an electric doublet. The fields due to a long length of wire l can be obtained by integration of the elementary length (see Antennas, Section 6.)

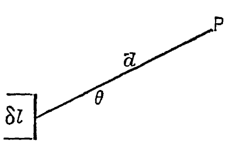

FIG. 1. Elementary Radiator

The average rate of flow of energy per square meter through an area perpendicular to d is (in watts)

$$P_a = \frac{30\pi l^2 I^2}{\lambda^2 r^2} \cos^2\theta \tag{16}$$

and the total power radiated (in watts) is

$$P_T = \frac{80\pi^2 l^2 I^2}{\lambda^2} \tag{17}$$

The radiated power for a given current varies directly as $1/\lambda^2$ or as the square of the frequency. For a given total charge, or a given voltage difference between the ends of the antenna, the radiated power varies as $1/\lambda^4$ or as the fourth power of the frequency.

29. REFLECTION AND REFRACTION

Whenever an electromagnetic wave meets a boundary between two media of different dielectric or magnetic properties, there is a change in the fields and frequently the wave splits into two waves, one of which is *reflected* back into the first medium, the other is *refracted* into the second medium.

CONDITIONS AT THE BOUNDARY. The following proposition is assumed: In two media, the components of the electric (or magnetic) intensity *tangent to the surface separating those media* are equal (in magnitude and direction) at this surface. It follows from this that the normal component (u_N) of the *total* current density is the same on both sides of the surface, that is, $u_N = u_{2N}$, or for insulating media

$$D_N = D_{2N} \tag{18}$$

Similarly

$$B_N = B_{2N} \tag{19}$$

The general expression for a plane wave as far as $\mathbf{\varepsilon}$ is concerned is:

$$\varepsilon_x = \bar{\varepsilon}_x \cos \omega \left(t - \frac{p}{v}\right) \tag{20a}$$

$$\varepsilon_y = \bar{\varepsilon}_y \cos \left[\omega \left(t - \frac{p}{v}\right) + \delta_y\right] \tag{20b}$$

$$\varepsilon_z = \bar{\varepsilon}_z \cos \left[\omega \left(t - \frac{p}{v}\right) + \delta_z\right] \tag{20c}$$

where δ_y and δ_z are constants and $\bar{\varepsilon}_x$ is the maximum value of the X component of $\mathbf{\varepsilon}$.

TWO ISOTROPIC DIELECTRICS. Consider two media separated by a plane surface, and assume that a plane wave in medium 1 impinges on this surface (see Fig. 2). Assume that the total electric intensity $\mathbf{\varepsilon}$ in the first medium is composed of two parts $\mathbf{\varepsilon}_1$ and $\mathbf{\varepsilon}'_1$; then

$$\mathbf{\varepsilon} = \mathbf{\varepsilon}_1 + \mathbf{\varepsilon}'_1 \tag{21}$$

$\mathbf{\varepsilon}_1$ will be called the *incident* wave (see also p. 5-23) and $\mathbf{\varepsilon}'_1$ the *reflected* wave; $\mathbf{\varepsilon}'_1$ will have components similar to those of eq. (20) denoted by primes. Note that, p'_1 being undetermined, what is called the reflected wave is not restricted to travel in a direction directly opposite the incident wave, as is the case on transmission lines.

Assume that the resultant electric intensity in the second medium is $\mathbf{\varepsilon}_2$, called the *refracted* wave, with similar components identified by the subscript 2.

Applying Maxwell's equations at the boundary, $\beta_1 v_1 = \beta'_1 v'_1 = \beta_2 v_2$ or $\omega_1 = \omega'_1 = \omega_2$, so that all waves have the same frequency.

Also the incident, reflected, and refracted waves all have wave normals (perpendiculars to the wave front) in the same plane. Similarly if ϕ is the angle between the wave normal and the normal to the boundary then $\phi_1 = \phi'_1$, or the angle of incidence is equal to the angle of reflection. Also

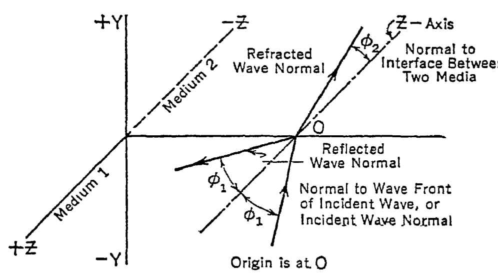

FIG. 2. Wave Normals

$$\frac{\sin \phi_1}{\sin \phi_2} = \frac{v_1}{v_2} = \eta = \frac{\sqrt{\mu_2 K_2}}{\sqrt{\mu_1 K_1}} \tag{22}$$

where η is the relative *index of refraction* of medium 2 with respect to medium 1.

The magnetic intensities of the various waves are, in magnitude (from Maxwell's equations), $H_1 = \sqrt{K_1/\mu_1}\,\varepsilon_1$, $H'_1 = \sqrt{K_1/\mu_1}\,\varepsilon'_1$, and $H_2 = \sqrt{K_2/\mu_2}\,\varepsilon_2$. All these are vectors in the wave fronts such that $\mathbf{\varepsilon}_1$, H_1, and p_1 are mutually perpendicular in such orientation that rotation from $\mathbf{\varepsilon}_1$ to H_1 (through the smaller angle) would move a right-handed screw in the direction of p.

Normal Components. It is convenient to split the electric and magnetic intensities into *two* components, one normal to the *plane of incidence* (not the interface between the media) and one in the plane of incidence. Maxwell's equations apply to each separately, since the equations are assumed linear (there has been some indication, the intermodulation of waves in space, that the equations are not entirely linear). The normal components, at the interface in terms of the incident wave, are

$$\frac{\varepsilon'_{1N}}{\varepsilon_{1N}} = \frac{\bar{\varepsilon}'_{1N}}{\bar{\varepsilon}_{1N}} \underline{/\delta'_{1N}} = \frac{\cos \phi_1 \sqrt{\mu_2 K_1} - \cos \phi_2 \sqrt{\mu_1 K_2}}{\cos \phi_1 \sqrt{\mu_2 K_1} + \cos \phi_2 \sqrt{\mu_1 K_2}} \tag{23a}$$

$$\frac{\varepsilon_{2N}}{\varepsilon_{1N}} = \frac{\bar{\varepsilon}_{2N}}{\bar{\varepsilon}_{1N}} \underline{/\delta_{2N}} = \frac{2 \cos \phi_1 \sqrt{\mu_2 K_1}}{\cos \phi_1 \sqrt{\mu_2 K_1} + \cos \phi_2 \sqrt{\mu_1 K_2}} \tag{23b}$$

Since $\cos\phi_2 = \sqrt{1 - \sin^2\phi_2}$ and since $\sin\phi_1/\sin\phi_2 = \eta$ (the index of refraction), then $\cos\phi_2 = \sqrt{1 - \sin^2\phi_1/\eta}$. Hence, if $\sin\phi_1 > \eta$, $\cos\phi_2$ will be imaginary. This is the case of *total reflection* (see below). The angle of incidence for which $\sin\phi_1 = \eta$ is called the *critical angle.*

Parallel Components. The parallel components at the interface, in terms of the incident wave, are

$$\frac{\mathcal{E}'_{1P}}{\mathcal{E}_{1P}} = \frac{\bar{\mathcal{E}}'_{1P}}{\bar{\mathcal{E}}_{1P}} \underline{/\delta'_{1P}} = \frac{\cos\phi_1\sqrt{\mu_1 K_2} - \cos\phi_2\sqrt{\mu_2 K_1}}{\cos\phi_1\sqrt{\mu_1 K_2} + \cos\phi_2\sqrt{\mu_2 K_1}} \tag{24a}$$

$$\frac{\mathcal{E}_{2P}}{\mathcal{E}_{1P}} = \frac{\bar{\mathcal{E}}_{2P}}{\bar{\mathcal{E}}_{1P}} \underline{/\delta_{2P}} = \frac{2\cos\phi_1\sqrt{\mu_2 K_1}}{\cos\phi_1\sqrt{\mu_1 K_2} + \cos\phi_2\sqrt{\mu_2 K_1}} \tag{24b}$$

Case of Total Reflection. If $\cos\phi_2$ is imaginary let $\cos\phi_2 = jn_2$, where n_2 is the absolute value of the imaginary. Substituting this in eqs. (23) and (24), the normal components are

$$\frac{\mathcal{E}'_{1N}}{\mathcal{E}_{1N}} = \frac{\bar{\mathcal{E}}'_{1N}}{\bar{\mathcal{E}}_{1N}} \underline{/\delta'_{1N}} = \frac{\cos\phi_1\sqrt{\mu_2 K_1} - jn_2\sqrt{\mu_1 K_2}}{\cos\phi_1\sqrt{\mu_2 K_1} + jn_2\sqrt{\mu_1 K_2}}$$

$$= 1 \underline{/2\tan^{-1} - \frac{-n_2\sqrt{\mu_1 K_2}}{\cos\phi_1\sqrt{\mu_2 K_1}}} \tag{25}$$

and the parallel components are

$$\frac{\mathcal{E}'_{1P}}{\mathcal{E}_{1P}} = \frac{\bar{\mathcal{E}}'_{1P}}{\bar{\mathcal{E}}_{1P}}\, \delta'_{1P} = \frac{\cos\phi_1\sqrt{\mu_1 K_2} - jn_2\sqrt{\mu_2 K_1}}{\cos\phi_1\sqrt{\mu_1 K_2} + jn_2\sqrt{\mu_2 K_1}}$$

$$= 1 \underline{/2\tan^{-1} - \frac{n_2\sqrt{\mu_2 K_1}}{\cos\phi_1\sqrt{\mu_1 K_2}}} \tag{26}$$

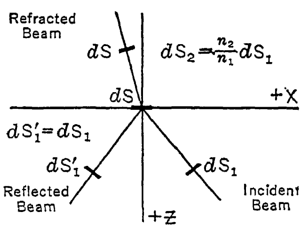

FIG. 3. For Use in Determining Energy Relationships

There is a disturbance in the second medium but no energy is transmitted, so that the wave is said to be totally reflected.

Energy Relations. To compare the energy in the incident, reflected, and refracted waves determine the rate at which energy is delivered by the incident wave to a certain area of the surface separating the two media, and the rates at which it leaves this area in the reflected and refracted waves (see Fig. 3).

The respective energies are

$$\text{Incident beam:}\quad \cos\phi_1\, dS\sqrt{\frac{K_1}{\mu_1}}\,\mathcal{E}_1^2 = \sqrt{\frac{K_1}{\mu_1}}\,\mathcal{E}_1^2 dS_1 \tag{27a}$$

$$\text{Reflected beam:}\quad \cos\phi_1\, dS\sqrt{\frac{K_1}{\mu_1}}\,\mathcal{E}'^2_1 = \sqrt{\frac{K_1}{\mu_1}}\,\mathcal{E}'^2_1 dS_1 \tag{27b}$$

$$\text{Refracted beam:}\quad \cos\phi_2\, dS\sqrt{\frac{K_2}{\mu_2}}\,\mathcal{E}_2^2 = \sqrt{\frac{K_1}{\mu_1}}\frac{\cos\phi_2}{\cos\phi_1}\,\mathcal{E}_2^2 dS_1 \tag{27c}$$

The ratio of reflected to incident energy is $\bar{\mathcal{E}}'^2_1/\bar{\mathcal{E}}_1^2$, and of refracted to the incident energy energy is $\dfrac{\cos\phi_2}{\cos\phi_1}\sqrt{\dfrac{K_2\mu_1}{K_1\mu_2}}\left(\dfrac{\bar{\mathcal{E}}_2}{\bar{\mathcal{E}}_1}\right)^2$, where the $\mathcal{E}$'s are evaluated at the interface.

Rotation of Plane of Polarization. If the incident wave is a plane-polarized wave, and the plane of polarization (which contains H_1 and hence is perpendicular to $\mathbf{\mathcal{E}}_1$) makes an angle θ_1 with the plane of incidence, then the angle between the plane of polarization and the plane of incidence of the reflected wave (θ'_1) is

$$\tan\theta_1 = -\tan\theta_1\frac{\cos(\phi_1 + \phi_2)}{\cos(\phi_1 - \phi_2)} \tag{28}$$

and for the reflected wave

$$\tan\theta_2 = \frac{\tan\theta_1}{\cos(\phi_1 - \phi_2)} \tag{29}$$

When $0 < \theta_1 < \pi/2$, the plane of polarization of the reflected wave is rotated toward the plane of incidence, while that of the refracted wave is rotated away from the plane of incidence.

CASE OF A CONDUCTING MEDIUM. If a medium is conducting, its conductivity is not zero, and by Maxwell's first equation (p. 5-50).

$$\gamma \mathbf{\varepsilon} + \frac{K\partial \mathbf{\varepsilon}}{\partial t} = \text{curl } H \tag{30}$$

where all quantities are in mks units. Assuming $\mathbf{\varepsilon}$ to be a harmonic function, it can be written $\mathbf{\varepsilon} = f\,(xyz)\ \mathbf{\varepsilon}^{j\omega t}$ and $\partial \mathbf{\varepsilon}/\partial t = j\omega \mathbf{\varepsilon}$. Hence eq. (30) becomes

$$\left(\frac{\gamma}{j\omega} + K\right)\frac{\partial \mathbf{\varepsilon}}{\partial t} = \text{curl } H \tag{31}$$

This equation is similar to that for a dielectric, the only difference mathematically being that the coefficient of $\partial \mathbf{\varepsilon}/\partial t$ is the constant K, whereas in eq. (31) it is the constant $K - j\gamma/\omega$. Hence all results obtained for insulating media are applicable to a conducting medium provided the K used in the former case is replaced by $K - j\gamma/\omega$.

If $\varepsilon = \bar{\varepsilon}\epsilon^{-\alpha x}\epsilon^{j(\omega t - \beta x)}$, which is a damped plane wave propagated in the X direction with velocity ω/β and attenuation α per unit length, then for this to be a solution of

$$-\,\omega^2\left(k\mu - j\,\frac{\mu\gamma}{\omega}\right)\varepsilon = \frac{\partial^2 \varepsilon}{\partial x^2} \tag{32}$$

(wave equation, all parameters are those of the conducting medium) it is necessary that $\alpha = 2\mu\gamma v$. For good conductors γ is large, hence α is large and the wave is highly attenuated—good conductors are poor transmitters of electromagnetic waves. Indeed, a perfect conductor ($\gamma = \infty$) will not transmit. These results hold for wavelengths not near the visible-light range when the conductor (called in this case a reflector) is an ordinary metal.

REFLECTION FROM A CONDUCTOR. If a wave traveling through an insulating medium (1) strikes the (plane) interface of an adjacent uniform conducting medium (2) all the results previously obtained for the case of two insulating media are applicable provided K_2 is replaced by $K'_2 - j\gamma/\omega$, where K'_2 now represents the dielectric constant of the conducting medium. Assuming directions shown in Fig. 2, a plane wave in the insulating medium produces in the conducting medium a wave

$$\varepsilon_2 = \bar{\varepsilon}_2\epsilon^{\alpha z}\epsilon^{j[\omega t - \beta'_2(x \sin \phi'_2 - 2 \cos \phi'_2) + \delta_2]} \tag{33}$$

where α is a positive real quantity (z is negative so the wave is damped) and ω, β'_2, ϕ'_2, and δ^2 are all real. The quantity ω is $2\pi f$ where f is the frequency of the incident wave, and v'_2, the velocity of the wave in the conducting medium, is ω/β'_2. Furthermore, $\beta'_2 = 2\pi/\lambda'_2$, where λ'_2 is the wavelength of the wave, and

$$\eta' = \frac{v_1}{v_2} = \frac{\beta'_2}{\beta_1} = \frac{\sin \phi_1}{\sin \phi'_2} \tag{34}$$

is the refractive index of medium 2 with respect to medium 1. The various quantities α, β'_2, $\sin \phi'_2$, $\cos \phi'_2$, v'_2, and η' *are all functions of the angle of incidence* ϕ_1. It is customary, when not otherwise specified, to assume that quoted values of α, β'_2, v'_2, and η' are for normal incidence ($\phi_1 = 0$). To compute these quantities for any angle of incidence, the following procedure may be used (K is written for K'_2 and subscript N refers to normal incidence; T to $2\pi/\omega$). Calculate or measure

$$\eta'_N = \frac{\sqrt{K + \sqrt{K^2 + 4\gamma^2 T^2}}}{\sqrt{2K_1}}$$

$$\alpha_N = \frac{\omega}{\sqrt{2}}\sqrt{\sqrt{K^2 + 4\gamma^2 T^2} - K} \qquad \frac{\alpha_N}{\beta_1} = \frac{\sqrt{\sqrt{K^2 + 4\gamma^2 T^2} - K}}{\sqrt{2K_1}}$$

Then η' can be found from

$$(\eta'^2 - \sin^2 \phi_1)\left(\eta'^2 - \frac{K}{K_1}\right) = \eta^2_N\left(\frac{\alpha_N}{\beta_1}\right)^2$$

and v'_2, β'_2, and ϕ'_2 follow from eq. (34). The following are of importance:

$$\eta_N = \sqrt{K'_2} \text{ only when } \gamma T \text{ is small and } K_1 = 1$$

$$\eta_N = \sqrt{\gamma T/K_1} \text{ when } \gamma T \gg 1$$

$$\alpha_N = \omega\sqrt{\eta_N^2 - K'_2}$$

$$\alpha = \eta'\beta_1 = 2\pi\eta'/\lambda \text{ when } \gamma T \gg 1$$

$$\eta_N \gg 1 \text{ and } \alpha_N = \omega\eta_N \text{ when } \gamma T \gg 1$$

The ratio of energy reflected from to energy incident upon the interface per unit time is

$$\epsilon - (2/\sqrt{\gamma T} \cos \phi_1) \text{ for } \gamma T \text{ large.}$$

As γ approaches ∞, this ratio approaches unity, showing that good conductors are good reflectors. For normal incidence ($\phi_1 = 0$) it becomes

$$1 - 2\sqrt{K_1/\gamma T}$$

and in general, assuming $\mu_1 = \mu_2$, it is

$$\frac{(n_1 - \eta' n_2)^2 + (\alpha/\beta_1)^2}{(n_1 + \eta' n_2)^2 + (\alpha/\beta_1)^2}$$

It may be noted that in a conducting medium neither the electric nor the magnetic vector lies in the wave front.

The preceding discussion has assumed K'_2 a constant, whereas it is sometimes necessary (e.g., in Heaviside layer studies) to consider K'_2 and other quantities as varying.

ELECTROMECHANICAL SYSTEMS

By Knox McIlwain

Vibrations in one dimension occur frequently in systems made up of solid elements, such as a spring suspension, a pendulum, or a rocking lever. They occur occasionally in fluids, an example being the transmission of sound through a long narrow tube. Alternating electric currents in short wires will be shown to be similar analytically to unidimensional mechanical vibrations. Also devices are in common usage (microphones, speakers, etc.) which convert any of these forms of vibration into any other.

Because of the analytical similarity of the three forms of vibration, mathematical results obtained in one field may be used in solving problems in the other fields. The mathematics involved, such as the complex notation, has been applied more generally to the electrical problem than to the others, but once the analytical similarity is established advances in one field are immediately applicable to the others.

As a first approximation all the parameters are considered constants. This is reasonably true in many electrical circuits but is not generally so in mechanical systems. However, the variations for small displacements and velocities such as occur in mechanical systems used in acoustics are usually negligible. The methods of attack available when the variation of parameters must be considered are given in articles 16–24.

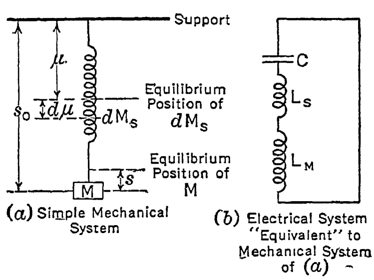

FIG. 1. Electrical and Mechanical Systems of One Degree of Freedom

DEFINITIONS. The number of independent variables required completely to specify the motion of every part of a vibrating system is a measure of the number of *degrees of freedom* of the system. When only one variable is needed the system is said to have one degree of freedom; examples of such systems are (Fig. 1): a piston moving in a cylinder, a weight hanging from a spring, cylinder rolling on a plane surface (no slipping). Systems of two or more degrees of freedom are exemplified by an automobile moving on a plane (two degrees if no skidding, three if skidding occurs), a balloon (three degrees if there is no spinning of the balloon), an airplane (six degrees if rotation is considered), a set of weights connected by springs in series (Fig. 2) which has as many degrees of freedom as there are springs; continuous vibrating systems (waves traveling along a long spring or stretched string) have an infinite number of degrees of freedom.

Consider a system of one degree of freedom (Fig. 1), and let the displacement coordinate be chosen to measure the distance from the center of the mass M to the equilibrium position. Consider that the spring has mass. The velocity of any given elementary mass of the system will then be proportional to $ds/dt(\equiv \dot{s})$, so that the kinetic energy of this elementary mass dm will be $^1/_2\, k_1\dot{s}^2 dm_1$, where k_1 is a constant dependent on the *position* of the mass. Likewise the kinetic energy of any other elementary mass dm_2 will be $^1/_2\, k_2\dot{s}^2 dm_2$, etc., and the total kinetic energy T of the system will be the sum of these, or

$$T = {}^1/_2 \int k_1\dot{s}^2\, dm_1 = {}^1/_2\, \dot{s}^2 \int k_1\, dm_1 \tag{1}$$

where the integration is to extend over the entire mass composing the system. But

$$\int k_1\, dm_1 = m_m \tag{2}$$

where m_m is a constant, called the *generalized mass*. Note that the value of m_m depends on the k's, which in turn depend on the choice of the measure of displacement. This

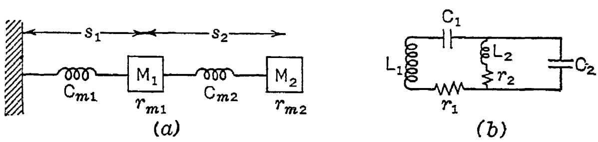

FIG. 2. Mechanical System of Two Degrees of Freedom and Electrical Equivalent

choice is largely arbitrary, and the particular one here chosen may not be the most convenient. The factors entering the problem which depend on this arbitrary choice are termed *generalized*. Thus $\dot{s}$ is a *generalized velocity* of the system; in this case it is the actual velocity of the mass M, but need not be. On the other hand, m_m is not the actual mass of the system but might be made so with a proper choice of s, the *generalized displacement*.

30. ENERGY OF MECHANICAL AND ELECTRICAL SYSTEMS

LINEAR MOTION. The kinetic energy of a mechanical system of one degree of freedom in linear motion is

$$T = {}^1/_2 m_m \dot{s}^2 \tag{3}$$

where m_m is the generalized mass of the system and s is the generalized velocity. The generalized mass can be defined as the quotient of the kinetic energy T of the system divided by the square of the generalized velocity.

The potential energy V of the system is a function of the displacement of the various parts of the system; it is independent of velocity, acceleration, etc., and in a system of one degree of freedom, since the displacements of the various parts are all proportional to the generalized displacement s, the potential energy V is a function of s only, that is

$$V = V(s) \tag{4}$$

This can be expanded in a Taylor's series:

$$V = V_0 + s\frac{\partial V}{\partial s}\bigg]_0 + \frac{s^2}{2}\frac{\partial^2 V}{\partial s^2}\bigg]_0 + \text{etc.} \tag{5}$$

where V_0 is the value of V when $s = 0$, and the subscript 0 indicates that derivatives are to be evaluated at $s = 0$. Since potential energy can be measured from any arbitrary level, V_0 may be taken as zero without loss of generality. Furthermore, in vibrating systems the generalized displacement may be so chosen that $s = 0$ for *equilibrium;* then, since $\partial V/\partial s = 0$ for equilibrium, the second term on the right-hand side of eq. (5) drops out. Making the further assumption that *terms containing higher powers of* s *than the second are negligible* in eq. (5), V reduces to

$$V = \frac{1}{2}\frac{s^2}{C_m} \tag{6}$$

where C_m is a constant $\left(\frac{1}{C_m} = \frac{\partial^2 V}{\partial s^2}\bigg]_0\right)$. C_m is called the compliance; its reciprocal, the stiffness. It will be shown later that eq. (6) is equivalent to assuming that the restoring forces of the system obey Hooke's law.

If there is dissipation (heat) in the mechanical system, *assume* that the *rate* of energy dissipation D is

$$D = r_m \dot{s}^2 \tag{7}$$

where r_m is a constant.

In many mechanical systems, particularly those concerned with the small motions usual in acoustic work, this is practically true; it is equivalent, as shown below, to assuming that the retarding frictional force is proportional to velocity, and for small motions this is approximately true of air friction. r_m is called mechanical resistance. If it is not a constant, that is, if D is not proportional to $\dot{s}^2$, but depends on higher powers of $\dot{s}$ as well, the equations cease to be linear and the methods of articles 16–20 must be used.

ROTATIONAL MOTION. The kinetic energy of a mechanical system of one degree of freedom in rotational motion is

$$T = {}^1/_2 I \dot{\phi}^2 \tag{8}$$

where I is the moment of inertia of the system, ϕ the angular displacement in radians, and $\dot{\phi}$ the angular velocity in radians per second.

The potential energy is

$$V = \frac{1}{2}\frac{\phi^2}{C_r} \tag{9}$$

where the same assumptions regarding higher powers of ϕ are made as in the case of linear motion.

Likewise the dissipation is assumed as

$$D = r_r \dot{\phi}^2 \tag{10}$$

where r_r is a constant.

ELECTRIC CURRENTS. The stored energy in an inductance L in an electrical circuit is (cf. eq. [3])

$$T = {}^1/_2 L i^2 = {}^1/_2 L \dot{q}^2 \tag{11}$$

where $i (= dq/dt \equiv \dot{q})$ is the current in the electric circuit, and q is the charge. This is often called the kinetic energy of the electrical circuit.

The energy in a condenser C is (cf. eq. [6])

$$V = \frac{1}{2}\frac{q^2}{C} \tag{12}$$

The rate of energy dissipation in an electrical circuit is (cf. eq. [7])

$$D = ri^2 \tag{13}$$

where r is the resistance of the circuit.

31. VIBRATIONS OF A SYSTEM OF ONE DEGREE OF FREEDOM

LINEAR MOTION. If a mechanical system of one degree of freedom is in a condition of stable vibration its gains and losses of energy must be equal. Hence the increase in kinetic and potential energy added to the energy dissipated must equal the work done, or

$${}^1/_2 m_m \dot{s}^2 + s^2/2C_m + \int r_m \dot{s}^2\, dt = fs \tag{14}$$

where fs, the product of force and distance, is the work done on the system. The rate of change of energy is

$$m_m \ddot{s} + r_m \dot{s} + s/C_m = f \tag{15}$$

Equation (15) is an equation in forces; that is, each term has the dimensions of a force. The first term, $m\ddot{s}$, represents the usual inertial force due to the motion of the system; the second term, $r_m\dot{s}$, represents a retarding force, proportional to the velocity of the system—this for small displacements and velocities represents approximately air friction, etc.; the third term, s/C_m, represents a force within the system proportional to the displacement. This last force is usually a restoring force, for example, the restoring force of a spring. Since this force is proportional to the displacement, Hooke's law (that the stress is equal to the strain) applies. Any internal force, such as the restoring force accompanying the straining of any part of the mechanical system, so long as the part is not stretched beyond the elastic limit, that is, so long as the restoring force is proportional to the displacement, contributes a term of the form s/C_m. On the other hand, if, instead of a restoring force, the term s/C_m were to represent a force proportional to the displacement, but tending not to restore the system to its equilibrium position but to displace the system further, then

C_m would be intrinsically negative. There is no simple analog in a passive electric circuit to this negative C_m which sometimes appears in mechanical systems. A "negative condenser" must be used, such as can be obtained in vacuum-tube circuits.

Equation (15) would be the equation of the system of Fig. 1, if the force were applied to the mass M and if s were measured from the equilibrium position. The force f is a function of t; it can be expanded in a Fourier series (see article 2) and each component of Form $F\epsilon^{j\omega t}$ treated separately. If $s = s_\epsilon^{j\omega t}$ then

$$s\left[r_m + j\omega m_m + \frac{1}{j\omega C_m}\right] = \frac{F}{j\omega} \tag{16}$$

and $s = F/j\omega z_m$, where $z_m = r_m + j\omega m_m + 1/j\omega C_m$ is called the *vector mechanical impedance* of the mechanical system. The real part of z_m is the *mechanical resistance;* the imaginary part is the *mechanical reactance.* If $\dot{s}$ were determined instead of s, assuming $\dot{s} = \dot{s}_\epsilon^{j\omega t}$, then $\dot{s} = F/z_m$. This is identical in form with the usual equation for a sine-wave current in an electric circuit.

ROTATIONAL MOTION. The above analysis can be applied to rotational motion if torque is substituted for force. Thus

$$r_r\dot{\phi} + I\frac{d\dot{\phi}}{dt} + \frac{\phi}{C_r} = L \tag{17}$$

so that $\dot{\phi} = L/z$, where $z = r_r + j[\omega I - (1/\omega C_r)]$ is called the vector rotational impedance of the system.

32. COMPARISON OF MECHANICAL AND ELECTRICAL SYSTEMS

UNITS. The analogy developed above between the equations of mechanical systems and electric circuits must not be interpreted to mean that there is any actual similarity or analogy between quantities occupying the same position in their respective equations. The inertia of the electric circuit and the mass of the mechanical system though appearing in the same place in the differential equation are otherwise quite diverse. Perhaps the difference is most convincingly shown by the fact that the analogous quantities *current* and *velocity* have different dimensions, current having the dimensions $M^{1/2}L^{1/2}T^{-1}$ in the practical electric system whereas the dimensions of velocity are LT^{-1}.

If this difference is kept in mind and it is remembered that the analogy is merely a formal one, representing the similarity of the differential equations expressing the behavior of the several systems, it is convenient to draw analogies between all quantities of the several systems. A list of these is given in Table 1. Any system of units may be used in any of the equations; only the cgs mechanical systems and the practical system for the electric circuit are shown in Table 1 on p. 5-60.

When energy equations are written in the two systems the dimensions of the equations must of course be identical, since the dimensions of energy are fixed. The usual current-electromotive force equation, however, does not have the same dimensions as a mechanical force-velocity equation. Nevertheless it is perfectly proper to set up electric circuits which are *equivalent* to mechanical systems, or vice versa, use the ordinary electric mesh equations to obtain a solution, and use this solution to specify the proper constants for either or both systems. The validity of this procedure depends on the fact that the solution of the differential equations is independent of the meaning attached to the symbols.

SYSTEMS OF MANY DEGREES OF FREEDOM. The extension of the analogy between electrical and mechanical systems to more than one degree of freedom, and the analysis of such systems which contain *both* electrical and mechanical portions, are most readily accomplished by the application of Lagrange's principle. In the application of this principle the energy equations for the whole system are first written down, in terms of measurements from an equilibrium position. Lagrange's equation that

$$\frac{d}{dt}\frac{\partial T}{\partial \dot{q}_1} - \frac{\partial(T-V)}{\partial q_1} + \frac{1}{2}\frac{\partial D}{\partial \dot{q}_1} = f_1 \tag{18}$$

is applied for each independent coordinate (each q needed in writing the energy equations).

ELECTRICAL CIRCUITS EQUIVALENT TO MECHANICAL SYSTEMS. If the energy equations of two systems can be thrown into the same form then the solutions of the two systems must be identical. The same applies to the differential equations, or to the resulting mesh equations, but in general the similarity of the systems can be established more readily by use of the energy equations.

Table 1. Analogous Quantities in Linear and Rotational Mechanical Systems and Electric Circuits

The cgs units and practical electrical units are used.

Linear Motion			Rotational Motion			Electric Circuit		
Quantity	Unit	Symbol	Quantity	Unit	Symbol	Quantity	Unit	Symbol

Mechanical impedance.	ohm	z_m	Rotational impedance..	ohm	z_r	Impedance	ohm	z
Power......	$\frac{\text{ergs}}{\text{sec}}$	P_m	Power.......	$\frac{\text{ergs}}{\text{sec}}$	P_r	Power......	watts	P

The rules for establishing the equivalence of an electric circuit with a mechanical system are therefore:

1. Write the equations for the kinetic energy, the potential energy, and the dissipation of the mechanical system.
2. There will be an electric mesh for each independent generalized coordinate.
3. Any parameter which appears in an energy equation multiplied only by the square of one generalized coordinate is a part of the corresponding electric mesh, and is not common to any other mesh.
4. Any parameter which appears multiplied by the difference of two generalized coordinates will be common to the corresponding electric meshes.
5. Any parameter which appears multiplied by the product of two generalized velocities may be represented by a mutual inductance between the corresponding electric meshes.
6. If parameters appear in the energy equations multiplied by any other combinations of the generalized coordinates, new coordinates should be chosen in an attempt to eliminate them. If this is impossible * there is no one-to-one (parameter-to-parameter) equivalent circuit.

To illustrate the method two examples will be worked out.

In the mechanical system shown in Fig. 2(a) assume that the masses M_1 and M_2 are resting on a plane surface whose frictional force is proportional to velocity. Let s_1 and s_2 be the changes in s'_1 and s'_2 from the equilibrium position. Then

$$T = \tfrac{1}{2}M_1\dot{s}_1^2 + \tfrac{1}{2}M_2(\dot{s}_1 + \dot{s}_2)^2$$

$$V = \frac{1}{2}\frac{s_1^2}{C_{m1}} + \frac{1}{2}\frac{s_2^2}{C_m{}^2}$$

and

$$D = r_{m1}\dot{s}_1^2 + r_{m2}(\dot{s}_1 + \dot{s}_2)^2$$

* Such cases will not be frequent. When encountered it is best to write force equations and attempt to obtain circuits which will represent the mechanical system by allowing electrical parameters to represent combinations of mechanical constants; for example, $L_2 = 2m_2 + m_1$ or $C_3 = C_{m1} - C_{m4} + C_{m3}$ might be required. In many such cases the utility of the method is doubtful.

The equations for T and D both contain a parameter multiplied by the *sum* of two generalized velocities squared, for which no electrical equivalent is given in the usual simple rules for independent meshes. These equations may be altered in two ways; first, the direction in which s'_2 (or s'_1) is measured may be changed; or second, new s's may be chosen. If the first alternative is employed

$$T = {}^1/_2 M_1 \dot{s}_1^2 + {}^1/_2 M_2(\dot{s}_1 - \dot{s}_2)^2$$

V is unchanged and

$$D = r_{m1}\dot{s}_1^2 + r_{m2}(\dot{s}_1 - \dot{s}_2)^2$$

The equivalent electrical circuit is shown, in which $L_1 = M_1$, $L_2 = M_2$, $r_1 = r_{m1}$, $r_2 = r_{m2}$, $C_1 = C_{m1}$ and $C_2 = C_{m2}$. That is, in the electrical circuit 1 henry of inductance is specified for each gram of mass in the mechanical system, 1 farad of capacitance for each centimeter/dyne of compliance, etc.

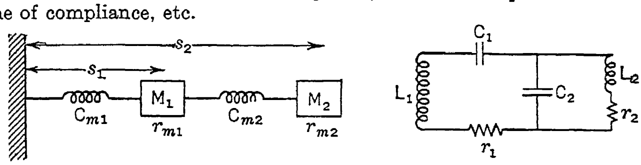

FIG. 3. Same Mechanical System as Fig. 2 and Alternate Electrical Equivalent

If the second alternative is chosen the sketch of Fig. 3 would represent the conditions. Here

$$T = {}^1/_2 M_1 \dot{s}_1^2 + {}^1/_2 M_2 \dot{s}_2^2$$

$$V = \frac{1}{2}\frac{s_1^2}{C_{m1}} + \frac{1}{2}\frac{(s_2 - s_1)^2}{C_{m2}}$$

and

$$D = r_{m1}\dot{s}_1^2 + r_{m2}\dot{s}_2^2$$

The corresponding electric circuit is shown.

It is thus possible to have more than one equivalent electric circuit for a given mechanical system, depending on the choice of independent variables for the mechanical system. Casual examination of the electric circuits reveals them as equivalent, in that although the mesh currents differ the current through any element would be the same.

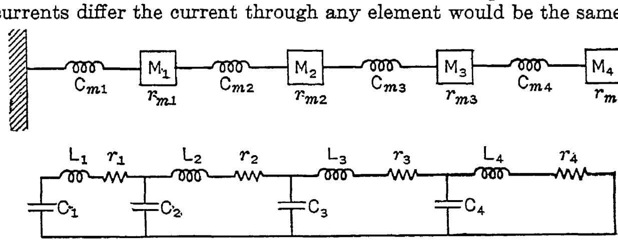

FIG. 4. Mechanical System of Four Degrees of Freedom and Electrical Low-pass Filter

In the mechanical system shown in Fig. 4 first assume that the displacements are measured between masses, as in Fig. 2. The energy equations are

$$T = {}^1/_2 M_1 \dot{s}_1 + {}^1/_2 M_2(\dot{s}_1 + \dot{s}_2)^2 + {}^1/_2 M_3(\dot{s}_1 + \dot{s}_2 + \dot{s}_3)^2 + {}^1/_2 M_4(\dot{s}_1 + \dot{s}_2 + \dot{s}_3 + \dot{s}_4)$$

$$V = \frac{1}{2}\frac{s_1^2}{C_{m1}} + \frac{1}{2}\frac{s_2^2}{C_{m2}} + \frac{1}{2}\frac{s_3^2}{C_{m3}} + \frac{1}{2}\frac{s_4^2}{C_{m4}}.$$

and

$$D = r_{m1}\dot{s}_1^2 + r_{m2}(\dot{s}_1 + \dot{s}_2)^2 + r_{m3}(\dot{s}_1 + \dot{s}_2 + \dot{s}_3)^2 + r_{m4}(\dot{s}_1 + \dot{s}_2 + \dot{s}_3 + \dot{s}_4)^2$$

In this case it is impossible to throw the equations into the usual mesh equation form by changing the direction of measurement of one or more of the variables, so the variables must be changed if the convenience of the mesh equation technique is to be utilized. If the system used in Fig. 3 is assumed

$$T = {}^1/_2 M_1 \dot{s}_1^2 + {}^1/_2 M_2 \dot{s}_2^2 + {}^1/_2 M_3 \dot{s}_3^2 + {}^1/_2 M_4 \dot{s}_4^2$$

$$V = \frac{1}{2}\frac{s_1^2}{C_{m1}} + \frac{1}{2}\frac{(s_2 - s_1)^2}{C_{m2}} + \frac{1}{2}\frac{(s_3 - s_2)^2}{C_{m3}} + \frac{1}{2}\frac{(s_4 - s_3)^2}{C_{m4}}$$

and

$$D = r_{m1}\dot{s}_1^2 + r_{m2}\dot{s}_2^2 + r_{m3}\dot{s}_3^2 + r_{m4}\dot{s}_4^2$$

The equivalent electric circuit is a low-pass filter as shown.

33. ELECTROMECHANICAL-ACOUSTIC SYSTEMS

Many vibrating systems consist of combinations of two or more of the separate energy systems discussed above. Examples of such combinations are electrically controlled vibrating reeds and tuning forks, microphones and speakers of all varieties, fluid-type automobile stabilizers, and almost all musical instruments.

In such systems energy is converted from one form to another within the system. The methods of converting energy are many, so that the forms of the interaction between the different portions of the system are many, but the same general method of determining the force equations that was used for homogeneous systems can be applied.

The energy of each portion of the system should be set up exactly as for a homogeneous system in terms of the constants of the particular portion. Some of these constants will be functions of the velocity or displacement, etc., of some other portion of the system, and these must be so specified. Then the "force" equations may be obtained directly by means of Lagrange's equation, and from these the mesh equations may be written. These mesh equations will not usually be of the same dimensions, but this fact may be disregarded since the interaction factors between the equations will be such that when the equations are solved simultaneously these differences will be automatically compensated. One set of self-consistent units is shown in Table 2. Several particular cases will be developed to show the operation of the method.

ELECTROMECHANICAL SYSTEMS, ELECTROSTATICALLY COUPLED. Consider a system consisting of two metal plates, one fixed and immovable, the other held in position by a spring (cf. Fig. 5) and resting on a rough surface. An electric circuit connected between the two plates contains an inductance, a resistance, and a source of voltage.

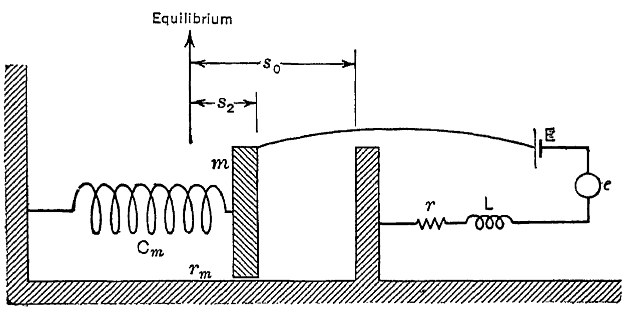

FIG. 5. Electromechanical System, Electrostatically Coupled

The potential energy V_m stored in the spring (measuring energy from its value at the equilibrium position, when the electric charge is zero) is

$$V_m = \frac{1}{2}\frac{s_2^2}{C_m}$$

where C_m is the compliance of the spring and s_2 is the distance the spring is stretched by moving the movable plate toward the fixed plate.

The potential energy V_e stored in the condenser is

$$V_e = \frac{1}{2}\frac{q^2}{C} = \frac{1}{2}\frac{q^2}{C'}(s_0 - s_2)$$

where q is the charge on the condenser and C its capacitance. The value of C is

$$C = \frac{kS}{4\pi(s_0 - s_2)} = \frac{C'}{s_0 - s_2}$$

where k is the dielectric constant, S the cross-section of the plates, and $(s_0 - s)$ the distance between them.

The kinetic energy of the system is

$$T = \frac{m\dot{s}_2^2}{2} + \frac{Li^2}{2}$$

where m is the generalized mass of the movable plate and spring together and L is the inductance of the electrical system. The dissipation of the system is

$$D = r_m\dot{s}_2^2 + ri^2$$

* Based on the practical electrical system and the centimeter. An alternate set of units is given in Olsen and Massa, Applied Acoustics.
† A mechanical, or an acoustical, ohm is one dyne second per centimeter. A rotational ohm is one dyne centimeter second per radian.

The force equations may be obtained by applying Lagrange's equations to these energy equations; they are

$$m\ddot{s}_2 + \frac{s_2}{C_m} - \frac{q^2}{2C'} + r_m\dot{s}_2 = f$$

and

$$L\frac{di}{dt} + \frac{s_0}{C'}q - \frac{q}{C'}s_2 + ri = e$$

Assuming that q can be split into a steady or average part q_0 and a varying part q_1 and that q_1 is considerably smaller than q_0, so that squares of q_1 are negligible,

$$-\frac{q^2}{2C'} = -\frac{(q_0^2 + 2q_0q_1 + q_1^2)}{2C'}$$

The first term on the right-hand side of this equation represents a steady pull or initial set of the plunger accompanying the initial charge on the condenser. The second term reduces to $\frac{q_0}{C'}q_1$, and the third term is negligible by assumption. Neglecting the steady terms the force equations become

$$m\ddot{s}_2 + \frac{s_2}{C_m} - \frac{q_0}{C'}q_1 + r_m\dot{s}_2 = f_2 \tag{19a}$$

$$L\frac{di_1}{dt} + \frac{q_0}{C'}q_1 - \frac{q_0}{C'}s_2 + ri_1 = e_1 \tag{19b}$$

which for steady-state sine waves may be written in the familiar mesh equation form

$$F_2 = z_{22}\dot{S}_2 + z_{12}I_1 \tag{20a}$$

$$E_1 = z_{12}\dot{S}_2 + z_{11}I_1 \tag{20b}$$

where mesh 2 represents the mechanical and mesh 1 the electrical system. z_{11} and z_{22} are the usual mechanical and electrical impedances and F_2 and E_1 the respective "forces." $z_{12} = -q_0/j\omega C' = -1/j\omega C_{12}$ is the interaction factor. The dimensions of $1/C_{12}$ are such that multiplication of it by a charge gives a quantity with the dimensions of a force, while multiplication of it by a distance or length produces a quantity with the dimensions of an electromotive force.* It is energy divided by distance and charge, and its use is valid for any system of electrical units in combination with any system of mechanical units provided those units were used in evaluating z_{12}.

Equations (20) are then in proper form to use for any case of mechanical and electrical systems where the interaction between the two systems depends on varying the capacitance of the electrical circuit by the motion of a part of the mechanical system.

ELECTROMECHANICAL SYSTEMS, MAGNETICALLY COUPLED. When the interaction between the electric and mechanical systems occurs through magnetic attrac-

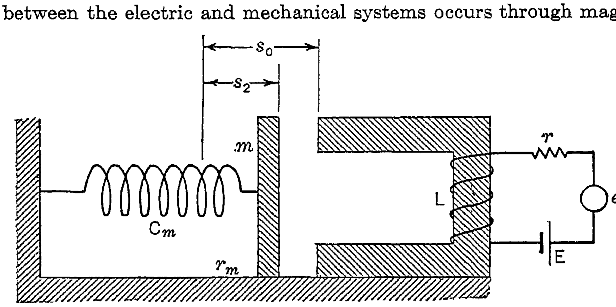

FIG. 6. Electromechanical System, Electromagnetically Coupled

tion the inductance of the electric circuit is varied by the mechanical motion. The energy equations for the system of Fig. 6 are (s_0 is the equilibrium position)

$$V = \frac{\dot{s}_2^2}{2C_m}$$

$$T = \frac{m\dot{s}_2^2}{2} + \frac{Li^2}{2}$$

and

$$D = r_m\dot{s}_2^2 + ri^2$$

* The factor $1/C_{12}$ has the dimensions of an electric field, although it is a rather unusual expression for such a field.

Here L, the self-inductance of the electric circuit, is a function of the displacement s_2. Since most of the reluctance of the magnetic circuit is in the air gap rather than in the iron portions, L can be assumed to vary as the first power of s for small displacements, with little error. Hence

$$L = L_0(1 + bs_2)$$

where b is a constant depending on the configuration of the physical system and on the systems of units used.

Applying Lagrange's equations, the force equations for the system are

$$m\ddot{s}_2 - \frac{bL_0 i^2}{2} + \frac{s_2}{C_m} r_m \dot{s}_2 = f$$

and

$$L\frac{di}{dt} + bL_0 i\dot{s}_2 + \frac{q}{C} + ri = e + E$$

Assuming that i is composed of a steady, or average, value i_0 and a varying part i_1, and that i_1 is considerably smaller than i_0, so that squares of i_1 are negligible,

$$-\frac{bL_0 i^2}{2} = -\frac{bL_0(i_0^2 + 2i_0 i_1 + i_1^2)}{2}$$

The first term on the right-hand side again represents a steady pull or initial set of the plunger accompanying the average or d-c exciting current of the magnet. The second term reduces to $-(bL_0 i_0)i_1$, and the third term is negligible by assumption. Disregarding the steady terms the force equations become

$$m\ddot{s}_2 + \frac{s_2}{C_m} - bL_0 i_0 i_1 + r_m \dot{s}_2 = f_2 \tag{21a}$$

and

$$L\frac{di_1}{dt} + \frac{q_1}{C} + bL_0 i_0 \dot{s}_2 + ri_1 = e_1 \tag{21b}$$

which for steady-state sine waves may be written

$$E_1 = z_{11}I_1 + z_{12}\dot{s}_2 \tag{22a}$$

$$F_2 = z_{21}I_1 + z_{22}\dot{s}_2 = -z_{12}I_1 + z_{22}\dot{s}_2 \tag{22b}$$

where mesh 1 represents the electrical and mesh 2 the mechanical system, E_1 and F_2 represent the respective "forces." *In this case, however, the interaction factors are not equal*, but $z_{12} = -z_{21}$.

The solutions for current and velocity give

$$I_1 = \frac{E_1 z_{22} - F_2 z_{12}}{z_{11}z_{22} + z_{12}^2}$$

and

$$\dot{s}_2 = \frac{F_2 z_{11} + E_1 z_{12}}{z_{11}z_{22} + z_{12}^2}$$

indicating that, when a mechanical force is applied to the plunger in phase with an applied electromotive force, the velocity of the plunger is increased but the electric current is decreased. Analysis of the physical action also indicates this result since increase in the electromotive force attracts the plunger, but the inward motion of the plunger due to an applied force increases the inductance of the electric circuit and so decreases the current flow.

These are the equations of a simple moving-armature telephone receiver such as that shown in Fig. 7, when eddy currents are neglected. The *input impedance* (z_i) of the receiver is the ratio of E_1 to I_1, when there is no externally applied force (that is, when $F_2 = 0$), hence

$$z_i = z_{11} + \frac{z_{12}^2}{z_{22}}$$

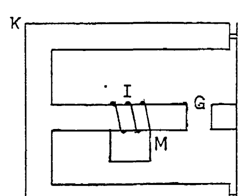

FIG. 7. Simple Telephone Receiver (No Eddy Currents)

The *blocked impedance* of a receiver is defined as the impedance measured when the diaphragm is constrained from moving (diaphragm held at $s = 0$). The *motional impedance* is the difference between z_i and the damped impedance; that is, it is that part of z_i due to the motion of the diaphragm. Evidently for the simple receiver the damped impedance is z_{11} (which is the impedance of the electric circuit considered alone) and the motional impedance $z_{\text{mot.}}$ is

$$z_{\text{mot.}} = \frac{z_{12}^2}{z_{22}} \tag{23}$$

Since z_{12} is a constant, independent of frequency by definition, it follows that, if the real part of $z_{\text{mot.}}$ (the resistance component of $z_{\text{mot.}}$) and corresponding values of the imaginary component (reactance component) be plotted for various frequencies, the resulting graph will be a circle, called the *motional impedance* circle, tangent to the j axis, with center on the positive real axis (see *High-frequency Alternating Currents*, McIlwain and Brainerd, John Wiley & Sons, Chapter XIII).

MECHANICAL-ACOUSTIC SYSTEM. The simplest mechanical-fluid system is that where a plunger moves in a fluid displacing a volume of the fluid (see Fig. 8).

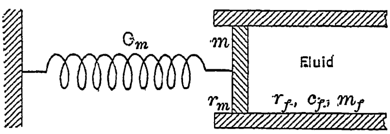

FIG. 8. Simple Mechanical-acoustic System

The potential energy of a volume of fluid moving as a unit is

$$T_f = {}^1/_2 \rho l S \dot{s}^2 = \frac{m_f}{2} \dot{s}^2$$

where ρ is the density, l the length, S the cross-section, and m_f the mass of the fluid, and $\dot{s}$ is the particle velocity. If the fluid is incompressible, $\dot{s}$ for the fluid will equal $\dot{s}$, the velocity of the plunger, and m_f will be the actual mass of the fluid; if the fluid is compressible $\dot{s}$ may still be taken as the velocity of the plunger but the generalized mass of the fluid will be less than the actual mass. The potential energy and dissipation are

$$V_f = \frac{s^2}{2C_f}$$

and

$$D_f = r_f \dot{s}^2$$

The total energy equations of the system are

$$V = \frac{s^2}{2C_m} + \frac{s^2}{2C_f}$$

$$T = \frac{m_m \dot{s}^2}{2} + \frac{m_f s^2}{2}$$

and

$$D = r_m \dot{s}^2 + r_f \dot{s}^2$$

where r_f and C_f as well as m_f are generalized parameters. Operating with Lagrange's equation there results

$$f = \left(\frac{1}{C_m} + \frac{1}{C_f}\right) s + (m_m + m_f)\ddot{s} + (r_m + r_f)\dot{s} \tag{24}$$

Thus this combination of a mechanical and an acoustic system can be represented by one equation with only one coordinate, instead of the two equations which might have been expected. Each parameter of the mechanical system has been altered by the presence of the acoustic chamber, and the resonance frequency has been lowered.

Assuming sine-wave excitation, eq. (24) becomes

$$F_m - F_f = \left[(r_m + r_f) + j\left(\omega m_m + \omega m_f - \frac{1}{\omega C_m} - \omega C_f\right)\right]\dot{s}$$

or

$$F_m - F_f = z_{mf}\dot{s}$$

where

$$z_{mf} = \sqrt{(r_m + r_f)^2 + \left(\omega m_m + \omega m_f - \frac{C_m + C_f}{\omega C_f C_m}\right)^2}$$

and

$$\theta_{mf} = \tan^{-1} \frac{\omega m_m + \omega m_f - \dfrac{C_m + C_f}{\omega C_f C_m}}{r_m + r_f}$$

The net result of the air chamber is thus to increase the resistance and inertial effect of the plunger but to decrease its compliance. In general both the magnitude and phase angle of the impedance are altered.

SECTION 6

PASSIVE CIRCUIT ELEMENTS

PASSIVE CIRCUIT ELEMENTS

SINGLE-MESH AND COUPLED CIRCUITS

By Vernon D. Landon and Knox McIlwain

The individual elements used in communication circuits must be carefully designed to meet certain definite specifications if the circuit as a whole is to function properly. Among the more important factors to be considered are the efficiency and load-carrying capacity of the element, its impedance, its selectivity, and the introduction of the various forms of distortion.

Circuit requirements frequently demand not only that the transmission (ratio of output to input) have a particular value at a given frequency, but also that the variation of transmission with frequency, called the transmission-frequency characteristic, have a definite form.

1. SERIES RESONANT CIRCUITS

Figure 1 represents a series circuit in which the resistance of all the elements of the circuit is lumped into one resistance r, and similarly for the inductance and capacitance. For a given value of impressed voltage the current in this circuit depends on r, L, and C, and the frequency of the impressed voltage. For given values of L and C there will be one frequency, and only one, for which $\omega L = 1/\omega C$. At this frequency (f_r), which is called the *resonant frequency* of the circuit, the current is maximum for any given value of voltage and is in phase with the impressed voltage. The resonant frequency is given by

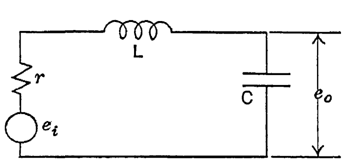

FIG. 1. Simple Series Resonant Circuit

$$f_r = \frac{1}{2\pi\sqrt{LC}} \tag{1}$$

where L is in henrys and C in farads. When L is expressed in millihenrys and C in microfarads eq. (1) becomes:

$$f_r = \frac{5033}{\sqrt{LC}} \tag{1a}$$

The absolute value of the current I_r in the circuit at this frequency is

$$I_r = \frac{E}{z_r} = \frac{E}{r} \tag{2}$$

For frequencies less than f_r, $\omega L < \dfrac{1}{\omega C}$ and the current will lead the impressed voltage (β is negative), whereas for frequencies greater than f_r the current will lag the voltage (β is positive, see Section 5, article 2).

In Fig. 2 are shown graphs of the absolute values of current versus frequency in a simple series circuit for two values of resistance.

VOLTAGE RELATIONS. At the resonant frequency the magnitude of the impressed voltage is given by $E = rI$, and the voltages across the inductor and condenser are $E_L = 2\pi f_r LI$ and $E_c = \dfrac{I}{2\pi f_r C}$. Since the only condition necessary for resonance is that the sum of the reactances is zero, either reactance may be many times as great as the circuit resistance; thus the voltage across the inductor, or the condenser, may be several hundred times the impressed voltage. Figure 3 shows how the voltage components in a circuit vary as the frequency is changed.

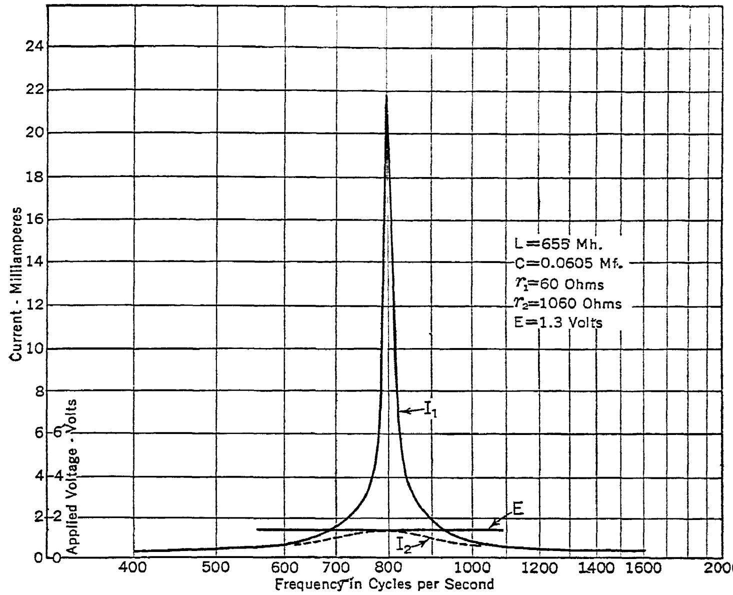

FIG. 2. Variation of Current with Frequency in a Simple Series Circuit (I_1 is for resistance r_1, and I_2 for r_2)

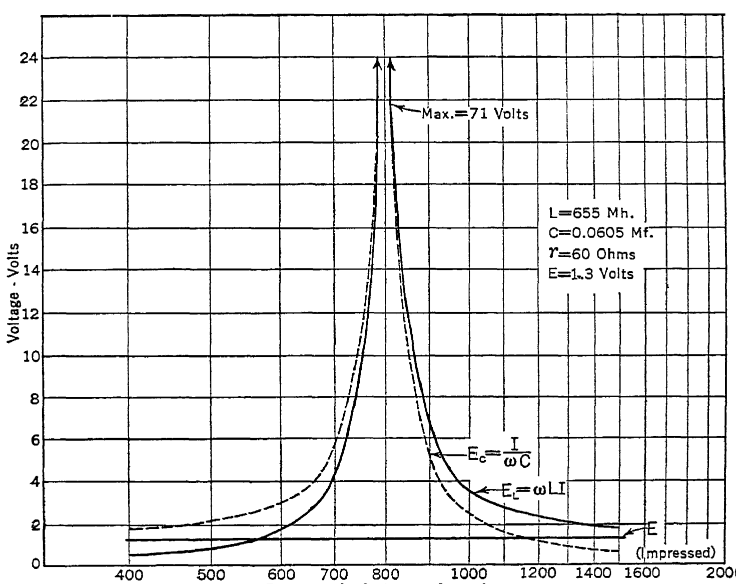

FIG. 3. Variation of Voltage Components with Frequency in a Simple Series Circuit

CIRCUIT Q. The per cent change in current from its maximum value for a given percentage frequency change depends on the relative values of r, L, and C. As a measure of this change a factor Q is defined as $\omega L/r$. From this the voltage across the coil (or condenser) of a simple series circuit at resonance is

$$E_L = \frac{2\pi f_r LE}{r} = EQ \tag{3}$$

For a given value of inductance the circuit having the higher Q will have smaller r, will have higher resonance current in comparison to current off resonance, will be represented by a more sharply peaked current vs. frequency curve, and is said to be more *sharply tuned.*

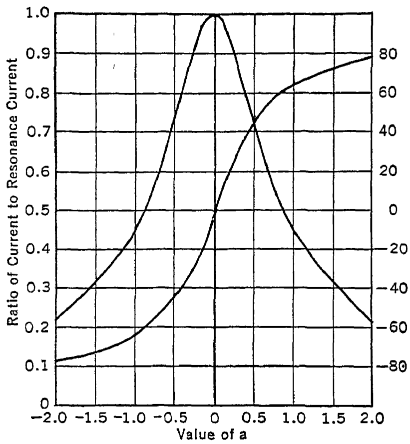

FIG. 4. Values of a Universal Resonance Curve. Calculated from

$$\frac{1}{1 + \frac{a}{Q} + ja\left(\dfrac{2 + \frac{a}{Q}}{1 + \frac{a}{Q}}\right)} \doteq \frac{1}{1 + j2a}$$

since a/Q is quite small. For parallel circuits change ratio of currents to ratios of impedances and leading phase angles to lagging.

Universal Resonance Curve. Terman has shown that, when Q is constant (loss resistance proportional to frequency), the relation of resonant current to current off resonance for any circuit can be plotted in a *universal resonance* curve as shown in Fig. 4. If the ratio of the actual current and the current at resonance are known, the ordinate is established and therefore the two possible values of a. From these the required deviation in frequency is determined from the relation

$$a = Q\,\frac{\text{Cycles off resonance}}{\text{Resonant frequency}} \tag{4}$$

Conversely, if the deviation in frequency is known, a can be readily found and thence the relative response.

2. PARALLEL RESONANT CIRCUITS

It is not so easy to define resonance in a parallel circuit. If the condition $x_1 = \omega L = -x_2 = 1/\omega C$ is used, there results

$$r = \frac{r_1 r_2 + x_1^2}{r_1 + r_2} \tag{5}$$

and

$$x = \frac{r_2 - r_1}{r_1 + r_2}\,x_1 \tag{6}$$

so that as r_1 and r_2 decrease r rises indefinitely and theoretically becomes infinite when the circuit resistance is zero. However, x is not zero at the frequency f_r, so that the current is not in phase with the voltage, nor is z a maximum. Either of these last conditions may be the important one, and the condition of z maximum (I minimum) is certainly the easiest to measure. If $r_1 = r_2$ the three conditions coincide, and are but slightly different when r_1 and r_2 are small.

In the particular important case of a coil and condenser in parallel (Fig. 5) these equations reduce (neglecting the resistance of the condenser) to

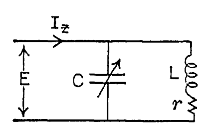

FIG. 5. Simple Parallel Resonant Circuit

$$r = \frac{L}{r_L C} \quad \text{and} \quad x = -\sqrt{\frac{L}{C}} \tag{7}$$

and the frequency for which $x = 0$ is

$$F_{(x=0)} = \frac{1}{2\pi}\sqrt{\frac{1}{LC}\,\frac{(L - r_L^2 C)}{L}} \tag{8}$$

Graphs of r, x, and **Z** for such a circuit are shown in Fig. 6.

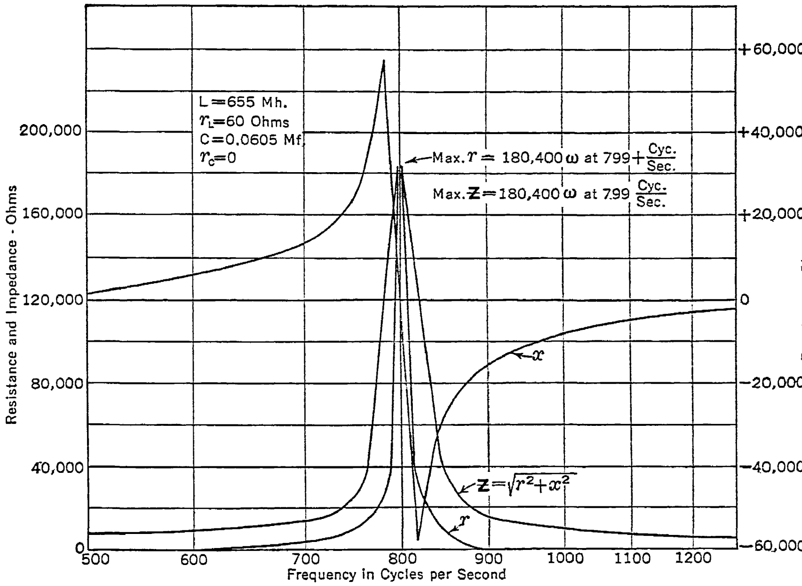

FIG. 6. Variation of the Impedance of a Simple Parallel Circuit with Frequency

Another case of particular interest exists when $r_L = r_C = \sqrt{L/C}$. Then for any frequency

$$r = \sqrt{L/C} = r_L = r_C \quad \text{and} \quad x = 0 \tag{9}$$

Thus the apparent resistance is constant with frequency, and the apparent reactance is zero for all frequencies.

TUNING. Although they are subject to the same limitations as regards controlling selectivity and frequency characteristic as the series resonant meshes, simple parallel tuned circuits are frequently used as coupling elements between vacuum tubes. When the circuit of Fig. 5 is adjusted for unity power factor, $I_c = Ex_L/(r^2 + x_L^2)$, $I_L = E/\sqrt{r^2 + x_L^2}$, $I_z = ErC/L$, and $z = L/rC$. If the capacitance only is varied, unity power factor coincides with the condition of minimum line current and with maximum impedance.

When the circuit is tuned by adjustment of the inductance this is not true, and in this case full output is obtained for a slight detuning from the condition of minimum plate current. If the resistance remains constant the maximum impedance is

$$z = \frac{2x_C r}{\sqrt{4r^2 + x_C^2} - x_C}$$

where

$$x_L = r\sqrt{\frac{2\sqrt{4r^2 + x_C^2}}{\sqrt{4r^2 + x_C^2} - x_C} - 1}$$

whereas if the phase angle (x_L/r) of the inductance remains constant the maximum impedance is $z = \sqrt{r^2 + x_L^2}\, x_L/r$ which occurs when $x_L = x_C$.

(For further details see R. Lee, *Proc. I.R.E.*, Vol. 21, 271.)

3. ATTENUATORS, PADS

Use of the concepts and equations of insertion loss (Section 5, article 7) permits the designs of definite elements (either dipoles or quadripoles) which may be inserted into circuits to produce definite effects at a given frequency. Such elements are called *attenuator sections*, or sometimes *pads;* more complicated sections which aim to provide a desired definite variation of loss with frequency are termed *distortion correctors*, or equalizers.

MATCHED IMPEDANCES. The simplest design occurs when it is desirable to have uniform loss at all frequencies, in which case the image impedances of the network must match those of the circuit into which it is inserted. By Thévenin's theorem (p. 5-12) the circuit, no matter how complicated, can be reduced to a generator in series with a simple impedance on each side of the point of insertion. (See Figs. 7 and 8.)

These impedances are designated by Z and z and their ratio by $Z/z = s^2$. Either T or π type sections may be utilized. The formulas are most useful for resistive networks.

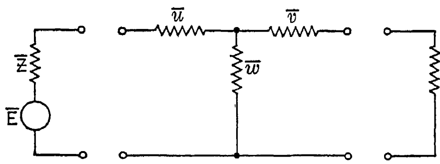

FIG. 7. T Section Attenuator

T SECTIONS. To design a T section (see Fig. 7) which causes a loss of n decibels, read off the current ratio (k) corresponding to such a loss in the decibel table, Section 1. Then the proper values for the arms of the T section are

$$u = \left(\frac{1 + k^2 - 2k/s}{1 - k^2}\right) Z, \quad v = \left(\frac{1 + k^2 - 2ks}{1 - k^2}\right) z, \quad \text{and} \quad w = 2\left(\frac{k}{1 - k^2}\right) sz$$

When the impedances in either direction are equal,

$$Z = z, \quad \text{then} \quad s = 1 \quad \text{and} \quad u = v = \frac{1 - k}{1 + k} z \quad \text{and} \quad w = \frac{2k}{1 - k^2} z$$

For instance, to cause a loss of 3 db in a circuit where $Z = z = 500 \angle 60°$, $k = 0.7080$, $u = v = 85.5 \angle 60°$, and $w = 1420 \angle 60°$.

To design a balanced T or H section simply put $\frac{1}{2}$ u and $\frac{1}{2}$ v in each series leg.

π SECTIONS. The proper values for the arms of the π section of Fig. 8 are

$$u = \left(\frac{1 - k^2}{1 - 2ks + k^2}\right) Z, \quad v = \left(\frac{1 - k^2}{k}\right) \frac{sz}{2}, \quad \text{and} \quad w = \left(\frac{1 - k^2}{1 - \frac{2k}{s} + k^2}\right) z$$

When the impedances in either direction are equal, $Z = z$, then $s = 1$ and $u = w = \left(\frac{1 + k}{1 - k}\right) z$ and $v = \frac{z}{2}\left(\frac{1 - k^2}{k}\right)$

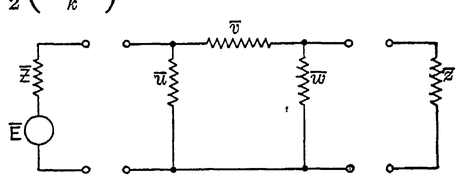

FIG. 8. π Section Attenuator

Tabular aids in computing such sections and rules for other types of sections are given by McElroy (*Proc. I.R.E.*, Vol. 23, 213 [March 1935]).

NON-MATCHED IMPEDANCES. When the impedance variation with frequency of the terminating circuits is such that it cannot be duplicated in a simple network, the insertion loss of the network at any frequency can be obtained by the methods of Section 5, article 8. Exact methods of design of sections to insure a predetermined variation of loss (and phase change) with frequency are given by Mead (*B.S.T.J.*, Vol. 7, 195), Zobel (*B.S.T.J.*, Vol. 7, 438) and Gewertz (*Network Synthesis*, Williams and Wilkins Co. [1933]).

4. COUPLED CIRCUITS

Two electric meshes are said to be coupled to each other when they have an impedance in common, so that a current in one causes a voltage in the other. The common, or *mutual*, impedance is defined as the factor by which the current in one mesh must be multiplied to give the voltage, due to that current, in the second mesh. It may be a pure resistance, or a pure reactance, in which case the meshes are said to have a *pure* coupling; or the common impedance may be complex, in which case the coupling is said to be *complex.*

Figures 9 and 10 illustrate some of the more usual types of coupling, although a complicated intervening network may be considered as simply a coupling impedance if the relation between current in one mesh and resulting voltage in the other is of interest.

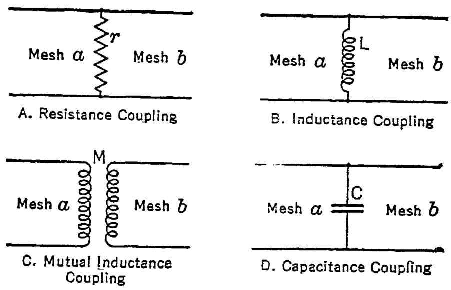

FIG. 9. Simple Types of Coupling

MUTUAL IMPEDANCES. The mutual impedances of the circuits shown in Fig. 9 are $Z_M = r, j\omega L, j\omega M, 1/j\omega C$. In Fig. 10, case E, the mutual impedance is $j\omega(L' + M)$ if the windings are in the same sense and $j\omega(L' - M)$ if they are in opposite sense. In case F, $Z_M = j(\omega L - 1/\omega C)$; in case G, $Z_M = j(\omega L/\omega^2 LC - 1)$. When the middle mesh of case H is considered as a mutual impedance between meshes a and b its value is

$$j\left[\frac{\omega^2 L_1 L_2 - \omega^2 M^2 - (M/C)}{\omega(L_1 + L_2 - 2M) - (1/\omega C)}\right]$$

when the transformer windings are so connected as to have minimum voltage across the coupling condenser. Reversing one winding reverses the sign of M.

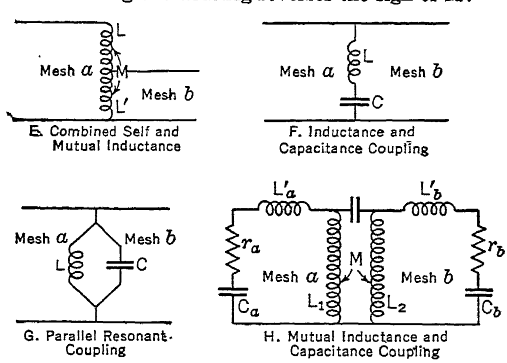

FIG. 10. Common Types of Involved Coupling

5. CURRENTS AND VOLTAGES IN COUPLED CIRCUITS

If two meshes are coupled as shown in Fig. 11 the primary current is

$$\mathbf{I}_a = \mathbf{E}/(r_a' + jx_a') = \mathbf{E}/\mathbf{z}_a' \tag{10}$$

where

$$r_a' = r_{aa} + \frac{x_m^2 r_{bb} - r_m^2 r_{bb} - 2r_m x_m x_{bb}}{z^2_{bb}} \tag{10a}$$

and

$$x_a' = x_{aa} + \frac{r_m^2 x_{bb} - x_m^2 x_{bb} - 2r_m x_m r_{bb}}{z_{bb}^2} \tag{10b}$$

Note that in these equations r_{aa} and r_{bb} are the *self-resistances* of the respective meshes ($r_{aa} = r_{ao} + r_m$), and x_{aa} and x_{bb} are the *self-reactances.* (For a complete discussion of self-impedances and mesh currents see Section 5, article 4. z_a' is called the *equivalent primary impedance* and r_a' and x_a' the *equivalent primary resistance* and *reactance.* The

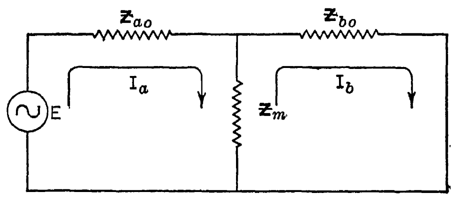

FIG. 11. Two Meshes Coupled through an Impedance $\mathbf{z}_m$

second term on the right of eq. (10*a*) is called the *transferred resistance*, and the corresponding term of eq. (10*b*) the *transferred reactance.*

The secondary current is

$$\mathbf{I}_b = \mathbf{z}_m\mathbf{I}_a/\mathbf{z}_{bb} = \mathbf{z}_m\mathbf{E}/\mathbf{z}_{aa}\mathbf{z}_b' \tag{11}$$

where

$$r_b' = r_{bb} + \frac{x_m^2 r_{aa} - r_m^2 r_{aa} - 2r_m x_m x_{aa}}{z_{aa}^2} \tag{11a}$$

and

$$x_b' = x_{bb} + \frac{r_m^2 x_{aa} - x_m^2 x_{aa} - 2r_m x_m r_{aa}}{z_{aa}^2} \tag{11b}$$

RESISTANCE COUPLING. When the coupling is a pure resistance, eqs. (11*a* and *b*) reduce to

$$r_b' = r_{bb} - r_m^2 r_{aa}/z_{aa}^2 \tag{12a}$$

and

$$x_b' = x_{bb} + r_m^2 x_{aa}/z_{aa}^2 \tag{12b}$$

so that the secondary current is

$$\mathbf{I}_b = \frac{r_m\mathbf{E}}{\mathbf{z}_{aa}\left[r_{bb} - \dfrac{r_m^2 r_{aa}}{\mathbf{z}_{aa}^2} + j\left(x_{bb} + \dfrac{r_m^2 x_{aa}}{z_{aa}^2}\right)\right]} \tag{13}$$

and its absolute value is

$$I_b = \frac{r_m E}{\sqrt{r_{aa}^2 + x_{aa}^2}\sqrt{\left(r_{bb} - \dfrac{r_m^2 r_{aa}}{z_{aa}^2}\right)^2 + \left(x_{bb} + \dfrac{r_m^2 x_{aa}}{z_{aa}^2}\right)^2}} \tag{13a}$$

The maximum value possible for I_b (for optimum tuning arrangements, $x_{aa} = x_{bb} = 0$) is

$$I_{b\,\mathrm{max\,max}} = \frac{r_m E}{r_{aa} r_{bb} - r_m^2} \tag{14}$$

REACTANCE COUPLING. When the coupling is a pure reactance, eqs. (11*a* and *b*) reduce to

$$r_b' = r_{bb} + x_m^2 r_{aa}/z_{aa}^2 \tag{15a}$$

and

$$x_b' = x_{bb} - x_m^2 x_{aa}/z_{aa}^2 \tag{15b}$$

so that the expression for the secondary current becomes

$$\mathbf{I}_b = \frac{jx_m\mathbf{E}}{\mathbf{z}_{aa}\left[r_{bb} + \dfrac{x_m^2 r_{aa}}{\mathbf{z}_{aa}^2} + j\left(x_{bb} - \dfrac{x_m^2 x_{aa}}{z_{aa}^2}\right)\right]} \tag{16}$$

and its absolute value is

$$I_b = \frac{x_m E}{\sqrt{r_{aa}^2 + x_{aa}^2}\sqrt{\left(r_{bb} + \dfrac{x_m^2 r_{aa}}{z_{aa}^2}\right)^2 + \left(x_{bb} - \dfrac{x_m^2 x_{aa}}{z_{aa}^2}\right)^2}} \tag{16a}$$

Since the nature of the curve of secondary current against mesh reactances (Fig. 12) changes completely at the point where $x_m^2 = r_{aa}r_{bb}$ this condition is defined as the condition of *critical coupling.* The condition when $x_m^2 > r_{aa}r_{bb}$ is spoken of as coupling greater than critical, whereas when $x_m^2 < r_{aa}r_{bb}$ the coupling is said to be less than critical.

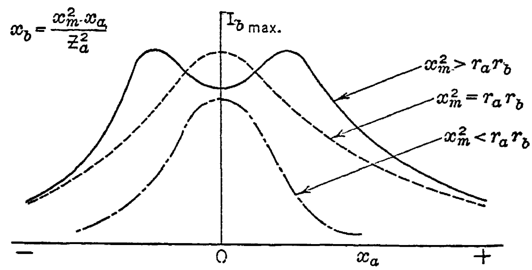

FIG. 12. Variation of I_b max with Primary Reactance for Three Degrees of Coupling

These conditions have been variously named *adequate* and *inadequate* coupling, *sufficient* and *deficient* coupling, *super* and *sub* coupling; there is no general agreement as to terminology.

When the *coupling is less than or equal to critical* there is only one inflection point on the curve of $I_{b\ \max}$ against primary reactance, which gives a maximum value for $x_a = x_b = 0$, or when each mesh is separately tuned to resonance. When the *coupling is greater than critical* the current curve shows a minimum for the condition $x_a = x_b = 0$ with maximum points on either side of zero. The proper adjustments and absolute value of currents obtainable are shown in Table 1.

Table 1. Conditions for and Values of Maximum Secondary Current in Two Mesh Circuits (For Best Possible Tuning)

	Reactance Coupling			Resistance Coupling
	$x_m^2 < r_{aa}r_{bb}$	$x_m^2 = r_{aa}r_{bb}$	$x_m^2 > r_{aa}r_{bb}$	
Optimum value for x_a.......	0	0	$\sqrt{\frac{r_{aa}}{r_{bb}}(x_m^2 - r_{aa}r_{bb})}$	0
Optimum value for x_b.......	0	0	$\sqrt{\frac{r_{bb}}{r_{aa}}(x_m^2 - r_{aa}r_{bb})}$	0
Maximum secondary current	$\frac{Ex_m}{r_{aa}r_{bb} + x_m^2}$	$\frac{E}{2\sqrt{r_{aa}r_{bb}}}$	$\frac{E}{2\sqrt{r_{aa}r_{bb}}}$	$\frac{Er_m}{r_{aa}r_{bb} - r_m^2}$
Corresponding primary current....................	$\frac{Er_{bb}}{r_{aa}r_{bb} + x_m^2}$	$\frac{E}{2r_{aa}}$	$\frac{E}{2r_{aa}}$	$\frac{Er_{bb}}{r_{aa}r_{bb} - r_m^2}$

Coupled circuits are frequently used to match two circuits with dissimilar impedances. The conditions listed in Table 1 for maximum secondary current also give the conditions for maximum power transfer and so for conjugate impedances.

TRANSMISSION-FREQUENCY CHARACTERISTIC. The most-used form of coupled circuit is that of Fig. 10, case *H*. Assuming that the distributed capacitance between windings is negligible, the transmission formula is

$$T = \frac{1}{F^2}\sqrt{\frac{L_2}{L_1}}\frac{K}{\sqrt{[d_1d_2 + K^2 - (1 - 1/F^2)^2]^2 + [(d_1 + d_2)(1 - 1/F^2)]^2}} \tag{17}$$

where $K = M/\sqrt{L_1L_2}$ is called the coefficient of coupling, and d_1 and d_2 are the decrement coefficients at resonance of the two meshes. Near resonance where $F = 1$ approximately

$$T = \sqrt{\frac{L_2}{L_1}}\frac{K}{\sqrt{2(f - f_r)/f_r]^4 + (d_1^2 + d_2^2 - 2K^2)[2(f - f_r)/f_r]^2 + (d_1d_2 + k^2)^2}} \tag{18}$$

The shape of the transmission curve as the frequency varies depends on the coefficients $(d_1^2 + d_2^2 - 2K^2)$ and $(d_1d_2 + K^2)^2$. With three independent variables resulting in two coefficients there are many solutions for a given shape. For a maximum transmission the additional condition may be specified that K is as large as possible.

SELECTIVITY. Comparing eq. (18) with eq. (4) for a single circuit it is seen that for frequencies some distance from resonance the transmission for a coupled circuit varies roughly inversely as the square of the departure from resonance, while for the single circuit the variation is roughly as the inverse first power. The transmission of two single circuits in cascade (and separated by a vacuum tube) is the product of the separate transmissions. For two circuits of decrement coefficients d_1 and d_2 this would be

$$T = \frac{1}{\sqrt{[2(f - f_r)/f_r]^4 + (d_1^2 + d_2^2)[2(f - f_r)/f_r]^2 + d_1^2 d_2^2}} \tag{19}$$

Comparison of this with eq. (18) shows that the selectivity of the coupled circuit approaches that of the cascaded single circuits as K decreases, but the transmission of the coupled circuit is decreased in the process. (For complete discussion see Purington, *Proc. I.R.E.*, Vol. 18, 983 [June 1930], and Aiken, *Proc. I.R.E.*, Vol. 25, 230 [February 1937].) Figure 13 shows the selectivity to be expected with well-designed coupled circuits. Curve C is for critical coupling; curve D for greater than critical coupling; and curves A and B for less than critical coupling.

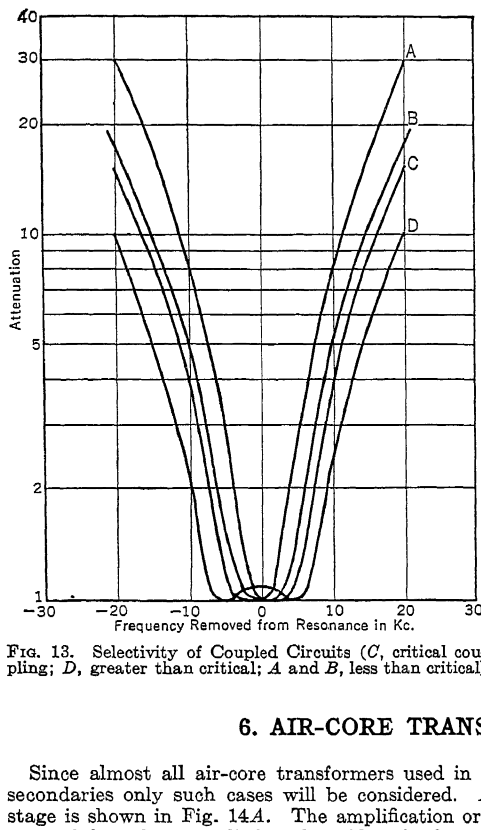

FIG. 13. Selectivity of Coupled Circuits (C, critical coupling; D, greater than critical; A and B, less than critical)

STAGGERED TUNING. The selectivity curve of a pair of coupled resonant circuits may be duplicated by the use of a two-stage amplifier having a single tuned circuit per stage, one circuit being tuned above and the other below the desired mean frequency. Similarly any desired number of single-tuned-circuit stages may be used to obtain an overall selectivity curve with a flat top and steep sides. The tuning points are distributed systematically across the pass bands. The effective Q is highest on the circuits tuned near the cutoff frequency. See Section 7, article 13; also the literature (particularly V. D. Landon, Cascade Amplifiers with Maximal Flatness, *RCA Rev.*, Vol. V, No. 3–4 [January–April 1941]).

6. AIR-CORE TRANSFORMERS

Since almost all air-core transformers used in communication circuits employ tuned secondaries only such cases will be considered. A simple circuit for a tuned amplifier stage is shown in Fig. 14*A*. The amplification or gain of such a stage is defined as the ratio of the voltage applied to the grid of the first tube to the voltage delivered to the grid of the second tube. The value of the gain at resonance is

$$\frac{E_2}{E_1} = \frac{\mu\omega^2 M^2/r_s}{(\omega^2 M^2/r_s) + r_p} \times \frac{L_s}{M} \tag{20}$$

where μ is the amplification factor of the tube.

In this equation $\omega^2 M^2/r_s$ represents the impedance reflected into the primary circuit by the tuned secondary circuit. It is assumed in this equation that the primary reactance is negligible.

This equation may be written in a simpler algebraic form but is most easily remembered and used in the form shown. Keeping in mind that $\omega^2 M^2/r_s$ is the load on the tube it is evident that $\mu E_1 \dfrac{\omega^2 M^2/r_s}{(\omega^2 M^2/r_s) + r_p}$ is the voltage drop across the plate load. Multiplying this voltage by the ratio of transformation L_s/M gives E_2, the output voltage.

As the mutual reactance between the primary and secondary circuits is varied, a maximum of gain is obtained when the value of ω^2M^2/r_s is equal to r_p. This constitutes matching the impedance of the tube.

In modern tubes of the screen-grid or of the pentode type, the plate impedance (r_p) is of such a high magnitude that it is ordinarily impracticable to match its impedance. In fact, ordinarily the load in the plate circuit is so small as to have a negligible effect upon the plate current, in which case the formula for gain becomes $\dfrac{E_2}{E_1} = \dfrac{s_m\omega^2M^2}{r_s}\dfrac{L_s}{M}$, where s_m is the mutual conductance, or transconductance, of the tube. Expressing this equation in words, the gain of a tuned amplifier, employing a tube of very high plate impedance, is equal to the transconductance, multiplied by the load impedance, and by the transformation ratio.

The equation may be written in another form, $\dfrac{E_2}{E_1} = s_m \dfrac{\omega L}{r_s} \omega M$. That is, the gain is equal to the transconductance, divided by the power factor of the secondary, and multiplied by the mutual reactance.

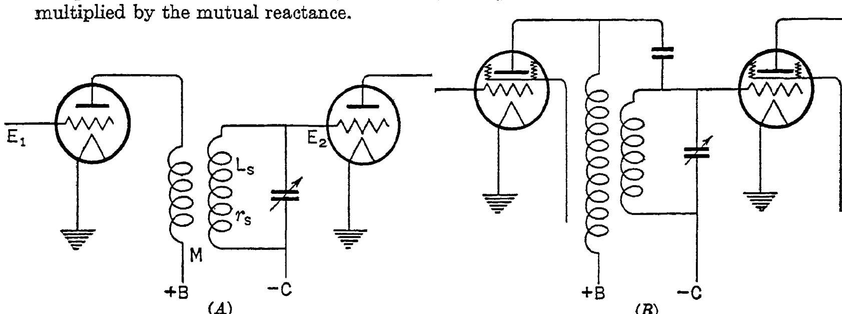

FIG. 14. Tuned Amplifier Circuits

VARIATION OF GAIN WITH FREQUENCY OF RESONANCE. The gain of an amplifier of this type varies considerably with frequency as it is tuned over the frequency band. The frequency squared occurs in the numerator, causing the gain to tend to be larger at the high-frequency end of the tuning range. This tendency is partly counterbalanced by the normal variation of the circuit resistance with frequency. The rate of change of resistance varies considerably from coil to coil, but the resistance varies faster than the first power of the frequency, and slower than the second power. If the resistance varies directly with the frequency the gain is proportional to the frequency of resonance. However, if the resistance is proportional to the square of the frequency the gain is constant. Usually the resistance rises only slightly faster than the frequency, causing the gain to rise with frequency.

EFFECT OF LEAKAGE REACTANCE. With tight coupling it is justifiable to neglect the primary reactance and the tube's plate-filament capacitance, because the value of the reflected impedance exceeds the primary reactance so greatly.

However, when the coupling is only moderate, the plate-filament capacitance and the primary reactance are no longer negligible. The effect is to increase the gain, above that of the formula, especially at high frequencies.

In practice, the transformer is frequently of such a design that the primary reactance is far from negligible. The gain formula then becomes somewhat too complicated for practical use. Cut-and-try methods are the rule for designing such transformers.

TUNED R-F TRANSFORMER EMPLOYING COMPOUND COUPLING. A common design of transformer in broadcast receivers employing screen-grid tubes is that shown in Fig. 14*B*. It employs a primary of such a high inductance that its primary is resonant in conjunction with the output capacitance of the tube, at a frequency below the broadcast frequency spectrum, 450 kc and below. The secondary coil is of the usual type, but the per cent coupling is quite low, usually between 15 and 25 per cent. Sufficient capacitance coupling is used to give the desired high-frequency gain.

The performance of this transformer is an improvement over that of the low-inductance primary type, in that the gain may be made more nearly constant throughout the tuning range.

The average voltage gain in this type of transformer is somewhat less, but the great amplifying ability of screen-grid tubes makes it unnecessary to obtain the greatest possible gain in transformers.

7. THREE-WINDING TRANSFORMERS (HYBRID COILS)

It is frequently desirable in electric circuits that currents in one portion of a circuit shall induce voltage in all branches of the circuit except certain designated ones, in which no voltage is to be introduced. This may be accomplished by means of an *impedance bridge* (Fig. 15) which consists of six adjustable impedances arranged in the form of a Wheatstone bridge. If the impedances are so adjusted that for a certain frequency $z_A/z_B = z_C/z_D$ a voltage of that frequency introduced at E will cause no current in the arm G, and vice versa.

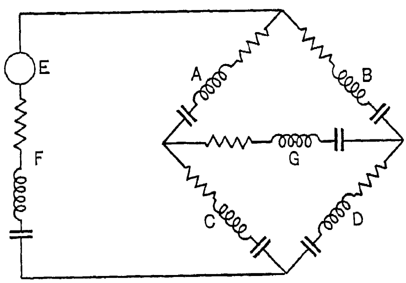

FIG. 15. Impedance Bridge Circuit

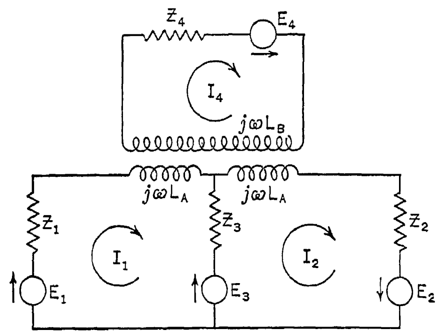

FIG. 16. Schematic Circuit of Three-winding Transformer with Load

A more widely used means of blocking voltages out of a particular branch is a combination of three coils such as that shown in Fig. 16; it is optionally called a *three-winding transformer* or a *hybrid coil.* If the two coils L_a are wound series aiding and the transformer is well made so that the winding resistances may be neglected and the coefficients of coupling are practically unity, then a voltage E_1 will cause no current through E_2 (and vice versa) provided $z_3 = z_4/N^2$, where N is the turn ratio between one of the L_a coils and the L_b coil. Also if $z_1 = z_2$ a voltage E_3 will cause no current through E_4, and vice versa. If all these conditions are fulfilled, then power from E_1 or E_2 will divide equally between z_3 and z_4 and power from E_3 and E_4 will divide equally between z_1 and z_2. Such transformers are extensively used in bidirectional amplifiers (see p. 7-13); also this circuit is the basic circuit for all neutralizing circuits. (See p. 7-29)

TRANSFORMERS WITH IRON CORES

By A. J. Rohner

8. AUDIO-FREQUENCY TRANSFORMERS

The Function of the audio-frequency transformer is to couple various circuits, at audio frequencies, over a considerable range of the audio-frequency band. It may be used as an impedance-matching device, as a means of isolating circuits, or as a means of obtaining phase reversal. When it couples a voltage source, such as a microphone, a phonograph pick-up, or a telephone line, to the grid of a vacuum tube, it is usually called an **input transformer.** If it couples the plate of one tube to the grid of another, it is called an **interstage transformer.** If it couples the plate of a vacuum tube to some sort of load, such as a loudspeaker, indicating meter, or telephone line, it is referred to as an **output transformer.** The **modulation transformer** is a special case of the output transformer, in which the load is the plate of a radio-frequency amplifier tube. If the transformer is used to match telephone lines of unequal impedance, or to isolate lines of equal impedance, it is called a **line transformer.** There are, of course, many variations of the above-mentioned applications.

The audio-frequency transformer is constructed much like a power transformer, but there are two distinct points of difference. Power transformers are usually one-frequency devices, whereas audio transformers must operate over a wide band of frequencies. In high-fidelity systems, for example, a range of from 30 to 15,000 cycles may be required. In systems where intelligibility of speech is all that is necessary, 300 to 3000 cycles may suffice. Then, too, the power transformer works from a voltage source having good regulation; that is, the impedance of the source, or "generator impedance," is negligible as compared with the load impedance. An audio transformer always works from a voltage source having poor regulation, the generator impedance often being equal to the load impedance, and in pentode or Class B power amplifiers, being greater than the load impedance.

These two factors, wide frequency range, and high generator impedance, place severe restrictions on the constants of an audio transformer. Primary inductance must be high; leakage inductance and distributed and other capacitances must be low. See G. Koehler, Design of Transformers for Audio-frequency Amplifiers with Preassigned Characteristics, *Proc. I.R.E.* (December 1928); P. W. Willans, Low-frequency Intervalve Transformers, *I.E.E. J.* (October 1926).

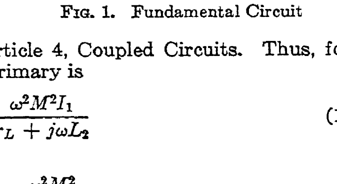

FIG. 1. Fundamental Circuit

COUPLED CIRCUITS. The design of an audio-frequency transformer requires the solution of coupled circuits, of which the transformer is a part, and including the generator and the load impedances. This solution may be carried out by the classical method, using mutual inductance. See article 4, Coupled Circuits. Thus, for the circuit of Fig. 1, the voltage impressed on the primary is

$$E_1 = r_pI_1 + j\omega L_1I_1 + \frac{\omega^2M^2I_1}{r_L + j\omega L_2} \tag{1}$$

The impedance "looking in" to the primary is

$$Z_1 = \frac{E_1}{I_1} = r_p + j\omega L_1 + \frac{\omega^2M^2}{r_L + j\omega L_2} \tag{2}$$

The voltage across the load, r_L, is

$$E_2 = r_LI_2 = \frac{\omega MI_1r_L}{r_L + j\omega L_2} \tag{3}$$

This method becomes quite complicated, however, when all the factors affecting audio transformers are considered: core loss, winding resistances, distributed capacitance, interwinding capacitance, turns ratio, etc. The first step in simplifying the analysis of the audio transformer and its associated circuits is to convert them to an equivalent direct-connected network. See J. H. Morecroft, *Principles of Radio Communication*, 2nd Ed., pp. 95–105.

EQUIVALENT DIRECT-CONNECTED NETWORK. Considering the transformer shown in Fig. 1 as a unity-ratio transformer, $L_1 = L_2$. Then $kL_1 = kL_2$, where k = coefficient of coupling, and $M = k\sqrt{L_1L_2} = kL_1$, where M is the mutual inductance.

The leakage inductance of the primary, or that portion of the primary which is not coupled to the secondary, equals $(1 - k)L_1$. Similarly, the portion of the secondary not coupled to the primary equals $(1 - k)L_2$, which is, of course, equal to $(1 - k)L_1$. The circuit of Fig. 1 can now be replaced by a direct-connected network as shown by Fig. 2. The common impedance is kL_1.

It may be shown that this circuit is the exact equivalent of Fig. 1. For example, the input impedance equals Z_1 and

$$Z_1 = r_p + j\omega L_1 + \frac{\omega^2 k^2 L_1^2}{r_L + j\omega L_1}$$

Substituting M for kL_1, and L_2 for L_1

$$Z_1 = r_p + j\omega L_1 + \frac{\omega^2 M^2}{r_L + j\omega L_2}$$

which is the expression derived for the circuit of Fig. 1.

The equivalent network of an inequality ratio transformer may be referred to either the primary or secondary circuit, provided the correct transformations are made. To reflect the secondary constants to the primary, for example, it is necessary to multiply all the impedances on the secondary side by the ratio L_1/L_2. With iron-core transformers, the ratio L_1/L_2 is for all practical purposes equal to the square of the turns ratio. Voltages are transformed by the turns ratio, currents by the inverse of the turns ratio.

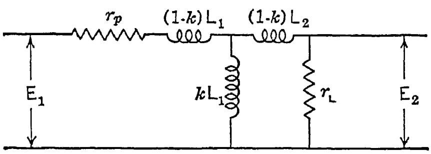

Fig. 2. Equivalent Network

If N_p = primary turns, and N_s = secondary turns, the secondary constants, referred to the primary, are

$$L_2' = \left(\frac{N_p}{N_s}\right)^2 L_2 \qquad r_2' = \left(\frac{N_p}{N_s}\right)^2 r_2 \qquad C_2' = \left(\frac{N_s}{N_p}\right)^2 C_2$$

$$E_2' = \left(\frac{N_p}{N_s}\right) E_2 \qquad I_2' = \left(\frac{N_s}{N_p}\right) I_2 \qquad r_L' = \left(\frac{N_p}{N_s}\right)^2 r_L$$

After these conversions are made, the transformer becomes a unity-ratio transformer and can be replaced by an equivalent direct-connected network.

COMPLETE EQUIVALENT NETWORK. Figure 3 shows the complete equivalent network of an audio-frequency transformer, referred to the primary, in which E_1 is the generator voltage (μEg in the case of a vacuum tube); r_p is the generator resistance; C_1 is the distributed capacitance of the primary winding, plus any additional capacitance across that winding; r_1 is the primary winding resistance; r_c is the core-loss resistance; r_2' is the secondary winding resistance, referred to the primary; C_2' is the distributed capacitance of the secondary winding, plus additional capacitances across that winding within the transformer itself, referred to the primary; and r_L', C_L', and E_2' are the load resistance, load capacitance, and load voltage, all referred to the primary.

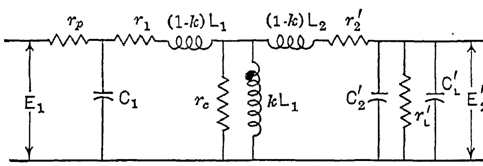

Fig. 3. Equivalent Network of Audio Transformer

The "additional capacitances" spoken of may be capacitances of the windings to ground, or capacitance between windings. For example, a single-ended interstage transformer might have its primary on the inside, next to the core, and secondary on the outside, wound over the primary. If the primary finish is connected to $+B$, and the secondary start is connected to ground, there is no a-c potential between the adjacent surfaces of the two windings, so that capacitance between the two windings has no effect. However, the primary start would go to plate, and the start layer of the winding has capacitance to the core. This capacitance is an additional capacitance across the primary winding. Similarly, the secondary finish would go to grid, and any capacitance existing between the finish layer of the secondary and the core or case would be an additional capacitance across the secondary winding. If the connections to both windings were reversed, making primary start $+B$, and secondary finish ground, those capacitances would have no effect. The capacitance between windings, however, would be of great importance. This would be somewhat equivalent to an additional capacitance across the winding having the most turns. Use of a grounded electrostatic shield between windings will largely eliminate capacitance between windings, but, of course, it adds additional capacitances to ground.

Solution of the circuit of Fig. 3 will give the characteristics of the audio transformer, such as (1) voltage ratio as a function of frequency; (2) primary impedance as a function of frequency; (3) phase shift as a function of frequency; (4) efficiency.

SIMPLIFIED NETWORK AT LOW FREQUENCIES. The network of Fig. 3 can be greatly simplified for practical design purposes by considering, first, the effect of frequency upon the relative importance of the various constants, and second, the particular application in which the transformer is used.

At low frequencies, leakage inductance and all the capacitances can be ignored. Furthermore the coefficient of coupling, k, of most audio transformers is above 0.995, so that kL_1 may be taken as L_1 with an error of less than 1 per cent. The low-frequency characteristics of any audio transformer are determined by the primary inductance and the various resistances of the network, as shown in Fig. 4.

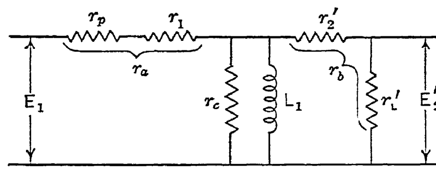

FIG. 4. Network at Low Frequencies

But Fig. 4 can be simplified still further. The resistances can be lumped together into a single resistor, as shown in Figs. 5 and 6. Let $r_a = r_p + r_1$ and let $r_b = r_2' + r_L'$. Then the lumped resistance, R, is equivalent to r_a, r_b, and r_c in parallel, or

$$R = \frac{r_a r_b r_c}{r_a r_b + r_a r_c + r_b r_c} \tag{4}$$

If the input voltage, E_1, is multiplied by the attenuation of the resistance network, the circuit of Fig. 5 becomes identical, in its output voltage and phase shift, with Fig. 4. The new value for the input voltage, of Fig. 5, is

$$E = \frac{r_L' r_c E_1}{r_a r_b + r_a r_c + r_b r_c} \tag{5}$$

Figure 6 is simply a redrawing of Fig. 5, showing the single resistor and the new input voltage. Figure 6 is an exact equivalent of Fig. 4 as far as voltage output and phase shift are concerned. The voltage output and the phase shift, at low frequencies, of *all* audio transformers are given by this simple circuit. Figure 7 shows those characteristics, as a function of $2\pi f L_1/R$.

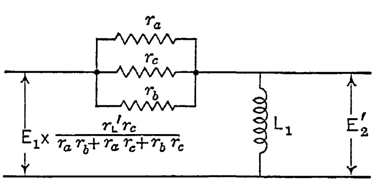

FIG. 5. Method of Combining Resistances

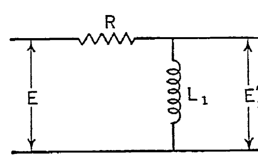

FIG. 6. Circuit of Audio Transformer at Low Frequencies

At some frequency, $2\pi f L_1 = R$, so that $2\pi f L_1/R = 1$. Let this particular frequency be called f_1. This is the low frequency at which the response has dropped 3 db from its value in the middle-frequency range. At twice this frequency, $2\pi f L_1/R = 2$. At three times this frequency, $2\pi f L_1/R = 3$, etc. At any frequency, f, $2\pi f L_1/R = f/f_1$. The curves given in Fig. 7, as a function of $2\pi f L_1/R$, are at the same time frequency characteristics, the frequency being expressed in terms of the reference frequency, f_1.

In order to determine the proper value of primary inductance, it is necessary to know what drop in secondary voltage is permissible, at some specified low frequency, as compared with the voltage in the middle-frequency range. For example, 1-db drop at 100 cycles might be given as the requirement of low-frequency response. From Fig. 7, the ratio of $2\pi f L_1/R$ is found, which gives this particular drop. As a first approximation, the winding and core-loss resistances may be neglected, so

$$R \cong \frac{r_p r_L'}{r_p + rL'} \tag{6}$$

Then

$$L_1 = \frac{2\pi f L_1}{R} \times \frac{R}{2\pi f} \tag{7}$$

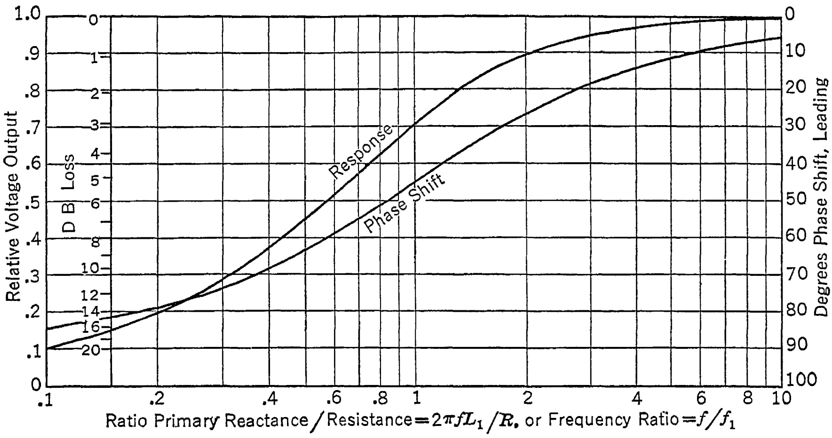

Fig. 7. Response and Phase Shift at Low Frequencies

SIMPLIFIED NETWORK AT MIDDLE FREQUENCIES. In this frequency range, all reactance elements become negligible, and the transformer reduces to a network of resistances, as shown in Fig. 8. In this range, phase shift is practically zero. This is the "flat" portion of the frequency-response characteristic, the secondary voltage being

$$E_2 = \frac{N_s}{N_p} \times E_1 \times \frac{r_L' r_c}{r_a r_b + r_a r_c + r_b r_c} \tag{8}$$

and the efficiency of the transformer being, to a very close approximation,

$$\text{Efficiency} = \frac{r_L'}{r_1 + r_2' + r_L' + (r_L'/r_c)(2r_1 + 2r_2' + r_L')} \tag{9}$$

SIMPLIFIED NETWORK AT HIGH FREQUENCIES. The shunting effect of the primary inductance is negligible at high frequencies. See Fig. 7. If the generator resistance, r_p, or the reflected load resistance, r_L', is less than 20.000 ohms, the primary capacitance, C_1, may be neglected. Most audio transformers fall in this class. Similarly, considering the secondary side of the transformer, if the *reflected* generator resistance, or the load resistance, is less than 20,000 ohms, the secondary capacitance, C_2, may be neglected. Though this is usually true of output transformers, it is seldom true of input or interstage transformers.

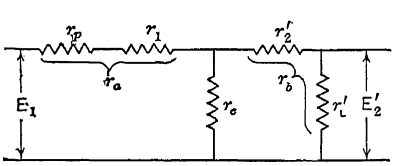

Fig. 8. Equivalent Network at Middle Frequencies

The core-loss resistance, r_c, has little effect at high frequencies beyond reducing the secondary voltage by a few per cent. The per cent voltage drop caused by core loss, using the symbols of Fig. 8, is

$$\text{Core loss drop} = \frac{100}{1 + r_c/r_b + r_c/r_a} \text{ per cent} \tag{10}$$

This usually amounts to 2 or 3 per cent. As far as the shape of the response curve, or the amount of phase shift, is concerned, core loss may be neglected.

Neglecting primary inductance, primary capacitance, and core loss, the equivalent circuit, at high frequencies, becomes as shown in Fig. 9. The term $2(1 - k)L_1$, is called the leakage inductance referred to the primary and is usually designated by L_e.

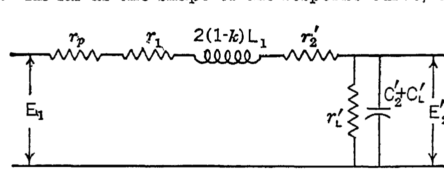

Fig. 9. Equivalent Network at High Frequencies

9. OUTPUT TRANSFORMERS

The function of the output transformer is to transfer power from the plate, or plates, of vacuum tubes to a load, such as a loudspeaker, an indicating meter, or a line. It provides the necessary impedance transformation, and it isolates the load from the d-c potential and current of the plate circuit. Efficiency is usually important, and the transformer must meet a prescribed frequency-response characteristic.

TURNS RATIO is determined by the plate load recommended for the tube, or tubes, by the tube manufacturer, r_L', and the actual load resistance, r_L.

$$\frac{N_p}{N_s} = \sqrt{\frac{r_L'}{r_L}} \tag{11}$$

FREQUENCY RESPONSE is controlled by the amount of primary inductance, at low frequencies, and by the amount of leakage inductance, at high frequencies. The allowable drop at low frequencies fixes a minimum value of primary inductance. See Fig. 7 and eqs. (6) and (7).

The equivalent network of the output transformer at high frequencies is given by Fig. 10, which is the same as Fig. 9 except that all capacitances have been omitted. The

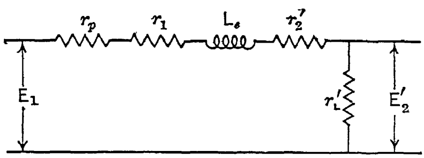

FIG. 10. Output Transformer at High Frequencies

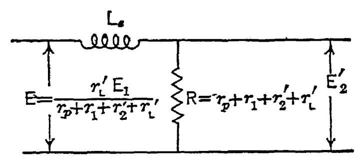

FIG. 11. Circuit Equivalent to Fig. 10

capacitance of an ordinary audio transformer winding will be about 100 $\mu\mu f$, more or less, depending upon the coil construction. At 10,000 cycles, this is 160,000 ohms of capacitive reactance. The load on an output transformer is seldom over a few thousand ohms and may be as low as 3 or 4 ohms. The shunting effect of the secondary capacitance is therefore negligible, even at the highest audio frequencies. The reflected load, looking into the primary, is seldom greater than 20,000 ohms, e.g., pushpull 6F6 tubes require 10,000 ohms. Again, primary capacitance is negligible.

The circuit of Fig. 11 is the exact equivalent of that of Fig. 10, as far as voltage output and phase shift are concerned. The voltage output and the phase shift of *all* output

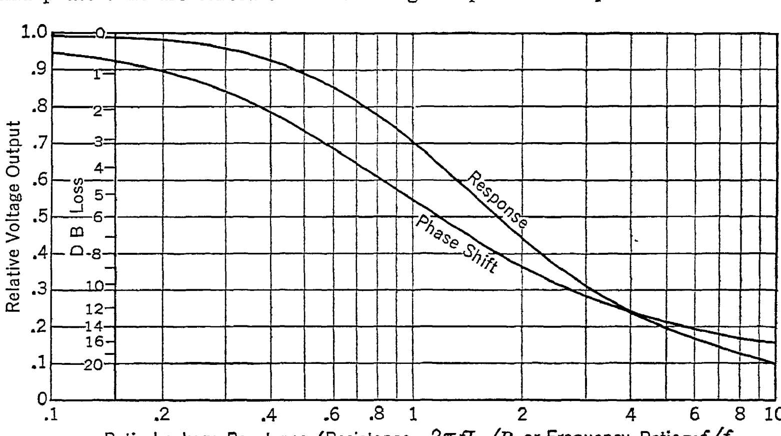

FIG. 12. Response and Phase Shift. Output Transformers at High Frequencies

transformers at high frequencies are given by this simple circuit, provided that the load is resistive and the load and reflected load are less than 20,000 ohms. Figure 12 shows those characteristics as a function of $2\pi fL_e/R$.

At some frequency, $2\pi f L_e = R$, so that $2\pi f L_e/R = 1$. Call this particular frequency f_2. This is the high frequency at which the response has dropped 3 db from its value in the middle-frequency range. At twice this frequency $2\pi f L_e/R = 2$. At three times this frequency, $2\pi f L_e/R = 3$, etc. At any frequency, f, $2\pi f L_e/R = f/f_2$. The curves given in Fig. 12, as a function of $2\pi f L_e/R$, are at the same time frequency characteristics, the frequency being expressed in terms of the reference frequency, f_2.

To determine the allowable amount of leakage inductance, it is necessary to know what drop in secondary voltage is permissible, at some specified high frequency, as compared with the voltage in the middle-frequency range. From Fig. 12, the ratio of $2\pi f L_e/R$ which gives this drop is found.

$$R = r_p + r_1 + r_2' + r_L'$$

Then

$$L_e = \frac{2\pi f L_e}{R} \times \frac{R}{2\pi f} \tag{12}$$

See F. E. Terman, *Radio Engineering*, 2nd Ed., pp. 293–299; L. A. Kelley, Transformer Design, *Rad. Engrg.* (December 1934, February 1935); F. E. Terman and R. E. Ingebretsen, Output Transformer Response, *Electronics*, January 1936; and *Magnetic Circuits and Transformers*, staff of M.I.T., pp. 472–486.

EFFICIENCY of output transformers is usually between 80 and 90 per cent, though it may be as low as 60 per cent for cheap or poorly designed transformers. Maximum efficiency is obtained, for a given physical size and core material, when copper loss = core loss, and when primary copper loss = secondary copper loss. Such a balance of losses is not always possible, however. If the secondary resistance, r_2, is made 5 per cent of the load resistance, r_L; if the primary resistance, r_1, is made 5 per cent of the reflected load resistance, r_L'; and if the core-loss resistance, r_c, is made 10 times the reflected load, r_L', the losses will be very nearly balanced, and the efficiency will be 82 per cent. See eq. (9).

LOUDSPEAKER LOAD. The analysis of output transformers given above has assumed a constant, resistive load. If the load impedance is not constant throughout the frequency range, the frequency-response characteristic will not be flat but will rise and fall where the load impedance rises and falls. This effect is not very pronounced with Class A triode amplifiers. However, with pentode or with Class B triode amplifiers, the output voltage is approximately proportional to the load impedance. When such tubes are used to drive the conventional moving-coil loudspeaker, a flat frequency-response characteristic is no longer obtained.

The impedance-frequency characteristic of a moving-coil loudspeaker is characterized by a low-frequency resonance peak and by a rise in impedance with frequency at the higher audio frequencies. In the neighborhood of 400 cycles, the loudspeaker impedance is the minimum and is resistive. This minimum, resistive impedance should be used as the basis of calculating the turns ratio and the efficiency of the transformer.

Flattening of the frequency-response curve by mismatching, that is, by using a value for r_L perhaps twice the value of the actual minimum, resistive impedance, in order to favor the low and high frequencies at the expense of the middle frequencies, is somewhat effective when used with Class A triode amplifiers. It does not level the voltage characteristic but does tend to level the power output over a wider frequency range. Mismatching is futile, however, when used with pentode or Class B amplifiers.

The rise in impedance at the high frequencies may be offset by connecting a capacitor, or a resistor and capacitor in series, across the primary of the output transformer. The low-frequency peak is best controlled by acoustical damping of the loudspeaker itself.

PUSHPULL OUTPUT TRANSFORMER, CLASS A. No special problems are introduced by pushpull operation of the output transformer if the amplifier is Class A. (See Section 7, Amplifiers.) The generator resistance, r_p, is twice the plate resistance of one tube. The reflected load, r_L', is the recommended tube load, plate-to-plate. In fact, the design of the transformer is simpler, for pushpull operation, because the d-c plate currents of the two tubes flow in opposite directions in the transformer windings, so that d-c magnetization of the core is canceled out. This results in higher primary inductance and a better low-frequency response.

Data are furnished by the tube manufacturers on optimum plate-to-plate load. The method of arriving at this optimum load is discussed by B. J. Thompson, Graphical Determination of Performance of Pushpull Audio Amplifiers, *Proc. I.R.E.*, April 1933.

PUSHPULL OUTPUT TRANSFORMER, CLASS B. Class B operation imposes special requirements on the output transformer, because one half of the primary works during one half-cycle, and the other during the other half-cycle. It is important that the two halves of the primary be closely coupled, so that the cross-over from one to the other may be accomplished smoothly and without introducing transients. It is also important that each half of the primary be coupled equally to the secondary. Otherwise the high-frequency response of the transformer will not be the same for both half-cycles, which will produce even harmonics in the output wave. In general, leakage inductance should be kept to the minimum between the windings of a Class B output transformer, even beyond the requirements of frequency response.

These requirements of low leakage and equal coupling are met by using the coil construction illustrated in Fig. 13.

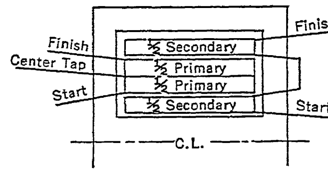

Fig. 13. Arrangement of Windings, Class B Output Transformer

THE MODULATION TRANSFORMER is an output transformer, which has as its load the plate of a Class C radio-frequency amplifier. This load is resistive and is usually of the order of a few thousand ohms. (See Section 7, Modulators.) The audio-frequency generator is usually a Class B amplifier, so that the discussion of Class B output transformers given above applies to modulation transformers.

The secondary often is required to carry the d-c current of the Class C amplifier. This produces a d-c magnetization of the core, which must be considered when designing the transformer, because of its effect upon inductance and low-frequency response as well as upon heating. Core saturation, due to d-c and a-c magnetization, is usually an important factor in modulation transformers. It is most serious at the lowest frequency of the frequency range, since there the a-c flux density is greatest. The effects of d-c magnetization of the core upon inductance and upon saturation are discussed in Section 3, Ferrous-cored Inductors.

Modulation transformers often work at high power levels, of the order of hundreds or thousands of watts. Heating is an important consideration, as with power transformers. Usually, too, high voltages are applied to the modulation transformer. The primary center tap and one end of the secondary winding are connected to the d-c plate supply and must be insulated to withstand its voltage. The ends of the primary and the other end of the secondary, all of which are connected to plates, must withstand twice the d-c plate supply voltage, since they have audio-frequency voltage, additional to the d-c voltage, and of a peak value approximately equal to the d-c voltage.

Since the primary center tap and one end of the secondary are often connected to a common point, the *B* supply, and since the load resistance of the Class C amplifier is of the same order of magnitude as the reflected load on one tube of the Class B amplifier, there is a strong temptation to make the modulation transformer an auto transformer, having one half of the primary common with the secondary. The saving in size, cost, and insulation by such construction is very great. Invariably, however, such construction leads to trouble due to the unequal coupling between the two halves of the primary and the secondary. (See above, Pushpull, Class B.)

For a practical analysis of Class B modulation, and driver, transformers, see J. Kunz, Transformers for Class B Modulators, *Radio Engrg.*, July 1934.

THE LINE TRANSFORMER is not an output transformer, as it does not work out of the plate of a vacuum tube. However, the analysis presented above for the output transformer applies equally well to the line transformer. Turns ratio is determined in the same manner. Frequency response and phase shift are governed by the same factors, viz., primary and leakage inductances.

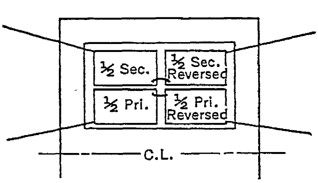

Fig. 14. Balanced Coil Construction

Line transformers usually operate at low power levels, of the order of 6 milliwatts, or less, so that shielding from stray magnetic fields may be necessary.

Often, too, it is necessary to balance the line to ground. This means that the capacitance from one end of the primary to ground shall equal that from the other, and the capacitance from one end of the secondary to ground shall equal that from the other. A symmetrical coil construction, as shown in Fig. 14, accomplishes this purpose.

10. INPUT AND INTERSTAGE TRANSFORMERS

The function of the input transformer is to couple an audio-frequency voltage source, such as a microphone, phonograph pick-up, or telephone line, to the grid of a vacuum tube. That of the interstage transformer is to couple the plate of one tube to the grid of another. Either type must conform to a predetermined frequency-response characteristic and must furnish the greatest possible voltage amplification consistent therewith.

With either type of transformer, the load consists of the grid circuit of a vacuum tube (or tubes), and its impedance is very high, frequently of the order of megohms. It is often no more than the input capacitance of the tube, although sometimes a resistor of 100,000 to 500,000 ohms is placed across the secondary, also. With such a high-impedance load, the secondary winding capacitance is not negligible. The secondary winding capacitance and the load capacitance, together, largely control the high-frequency response and the turns ratio of the transformer.

FREQUENCY CHARACTERISTICS, LOW AND MIDDLE FREQUENCIES. The same analysis applies to input and interstage transformers, at these frequencies, as applies to other audio transformers. See above, Simplified Network at Low Frequencies and Middle Frequencies. If there is no resistance load on the secondary, that is, if $r_L' = \infty$, the equations given become simpler. Thus, eq. (8), for the secondary voltage, becomes

$$E_2 = \frac{N_s}{N_p} \times E_1 \times \frac{r_c}{r_a + r_c} \tag{13}$$

and eq. (9), for efficiency, becomes

$$\text{Efficiency} = 0 \tag{14}$$

FREQUENCY CHARACTERISTIC, HIGH FREQUENCIES. Figure 9 shows the equivalent network at high frequencies. Considering first the case when there is no secondary resistance load, the equivalent circuit becomes that shown in Fig. 15. This is a simple series resonant circuit. It is convenient to express the performance of this circuit by means of a family of curves, plotting voltage ratio vs. frequency, as shown by Fig. 16. It is seen that the shape of the desired frequency-response characteristic determines the value of a constant, N, while the position of the desired characteristic on the frequency band determines the value of the resonant frequency, f_0. Then

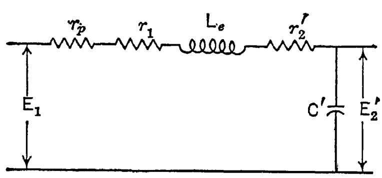

FIG. 15. Input or Interstage Transformer at High Frequencies

$$\sqrt{\frac{L_e}{C'}} = N(r_p + r_1 + r_2') \tag{15}$$

and

$$\sqrt{L_e C'} = \frac{1}{2\pi f_0} \tag{16}$$

From these equations, the value of the leakage inductance, L_e, and of the reflected secondary capacitances, C', which will give the desired frequency response, can be calculated. If the amplification at high frequencies is to be substantially constant, the value of the constant N must lie between 0.75 and 1.0. See F. E. Terman, *Radio Engineering*, 2nd Ed., pp. 188–202; *Gen. Elec. Tech. Report* 19366, Audio Transformer Design (July 1930); and *Magnetic Circuits and Transformers*, staff of M.I.T., pp. 486–494.

Considering the case in which a resistance load is placed across the secondary, in addition to the tube input and secondary winding capacitances, the equivalent network is that of Fig. 9. The resistance load will reduce the leakage resonance peak, at the same time lowering the voltage output in the middle-frequency range in accordance with eq. (8). However, the effect is more pronounced in the region of leakage resonance, so that an overall flattening of the response characteristic results. See Terman, p. 199.

No single family of curves can be drawn which will show the performance of this circuit. However, two methods of attacking the problem have been described. One method uses a master chart showing the response at the leakage-resonance frequency. This chart enables a designer to pick out a value of secondary loading resistance that will give the desired response at resonance. He then computes the response at a few other points, sufficient for plotting the frequency-response characteristic. See P. W. Klipsch, A.F. Amplifier Circuits Using Transformers, *Proc. I.R.E.*, February 1936.

Another method of solving the circuit of Fig. 9 is to draw several families of curves, each family representing some fixed relationship between the various constants. This method, with six such families of curves, is described by J. G. Story, Design of A.F. Input and Intervalve Transformers, *Wireless Engr.*, February 1938.

THE TURNS RATIO, of an input or interstage transformer is determined by the secondary capacitance, that is, by the sum of the secondary winding capacitance, C_2, and the input capacitance of the tube, C_L. Call this total capacitance C, and let its value reflected to the primary be C'. The correct value of C' is found from the frequency-response requirements, as described above. Then

$$\frac{N_s}{N_p} = \sqrt{\frac{C'}{C}} \tag{17}$$

The capacitance, distributed, and to ground, of the secondary winding cannot be calculated accurately until the design of the transformer has been completed. As a first approximation, for finding the turns ratio, a value of 50 $\mu\mu f$ may be used. The input capacitance of the tube is given by the formula

$$C_L = C_{gf} + C_{gp}(1 + \mu)$$

where C_{gf} = static capacitance between grid and filament, C_{gp} = static capacitance between grid and plate, and μ = effective amplification of tube.

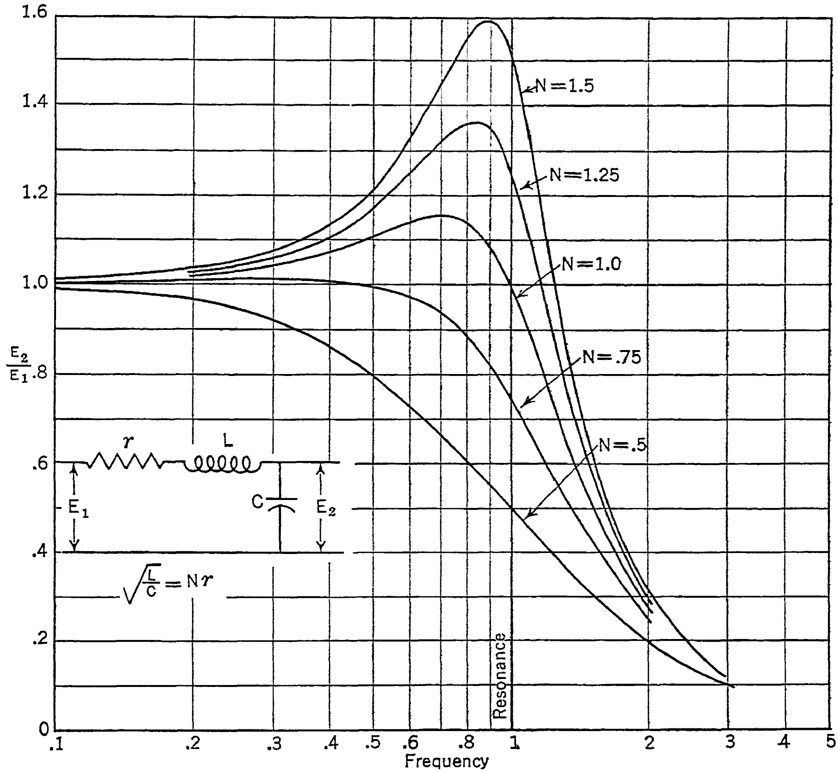

FIG. 16. Leakage Resonance

As an example of what can be expected in the way of turns ratio, assume that all secondary capacitances total 100 $\mu\mu f$ and that the high-frequency response of the transformer is as given by $N = 1$ of Fig. 16, the resonance frequency being chosen as 10,000 cycles. The following step-up ratios are obtainable: with 10,000-ohm generator (triode), 1 to 4; with 500-ohm generator (line), 1 to 17.8; with 100-ohm generator (carbon mike), 1 to 40; with 0.2-ohm generator (ribbon mike), 1 to 890.

PICK-UP AND SHIELDING. Input and interstage transformers often work at very low voltage levels. As a result, voltage induced in the windings by stray magnetic fields may be as large as or larger than the signal voltage. These stray fields are produced by nearby power transformers, rectifier filter reactors, open loops in wires carrying large a-c currents, motor generators, etc. A hum of the frequency of the stray field is introduced into the amplifier.

Correction of hum pick-up should begin at the source, if possible. Reduction of the flux density in power transformers and reactors, by proper design, placing of air gaps of reactors inside of the coils, use of shielding cans around power transformers and reactors, and tight twisting of heavy-current wiring are all helpful.

Removal of the input, or interstage, transformer further from the source of disturbance, and orienting it so that its coil will be at right angles with the coil of the disturbing transformer, are precautions that should be taken when laying out an amplifier.

Input transformers are sometimes made with a two-legged core (see Section 3), half of the primary and half of the secondary being placed on each leg. The two halves of each winding are connected in series, being additive for flux within the core, but subtractive for external fields. Such "hum-bucking" construction is very effective in reducing hum pick-up, if the external field is uniform, so that it acts upon both parts of the transformer equally. A reduction of 40 db in pick-up may be realized.

Shielding of the input, or interstage, transformer is also very effective in reducing pick-up. A drawn nickel-alloy case with a tight-fitting lid will reduce pick-up about 30 db. Two such nickel-alloy shields, one inside the other, separated by a similar copper shield, will reduce pick-up by about 60 db. Three nickel-alloy and two copper shields will give about 90-db reduction of pick-up. Such nested shields are available. See E. B. Harrison, Notes on Transformer Design, *Electronics*, February 1944.

11. DRIVER TRANSFORMER

Function. The Class B operated output stage requires an auxiliary stage of audio amplification called the "driver" stage. The driver transformer couples the plate of the driver tube, usually a triode, to the grids of the Class B amplifier. The function of the driver stage is to supply to the grid circuit of the output stage large positive voltage peaks, which means that the driver stage is required to furnish power. In this respect the driver transformer is similar to the output transformer, but it has additional requirements imposed upon it which make its design more exacting.

TURNS RATIO. The secondary load on a driver transformer varies over a wide range during each half-cycle, from a very high resistance when both grids are negative to a low resistance when either grid is positive. The turns ratio of the transformer must be selected so that the change in load resistance has a negligible effect on driver tube distortion, a condition which is satisfied by using a step-down ratio. The value of the turns ratio is a compromise between distortion and driving power.

FREQUENCY RESPONSE is governed by the same factors as for the output transformer, viz., primary inductance at the low frequencies and leakage inductance at the high frequencies. There is a difference, in that the load on the driver transformer is not a constant resistance but varies during the cycle. Primary inductance should be high enough to give the desired low-frequency response with $r_L = \infty$. Leakage inductance should be low enough to give the desired response when r_L = peak grid voltage swing/peak grid current swing.

LEAKAGE AND DISTORTION. Leakage reactance in the driver transformer is a reactance in series with the grids of the Class B stage. It causes distortion of the grid voltage wave at the higher frequencies. The high-frequency range of a driver transformer is limited by distortion rather than by a falling off of the secondary voltage. Leakage between primary and secondary must therefore be kept to the minimum. It is also important that each half of the secondary be coupled equally to the primary; otherwise the secondary voltage, at high frequencies, will not be the same for both half-cycles, which will produce even harmonics in the grid-voltage wave. The requirements of low leakage and equal coupling are met by using the coil arrangement shown in Fig 17. See T. McLean, An Analysis of Distortion in Class B Audio Amplifiers, *Proc. I.R.E.*, March 1936.

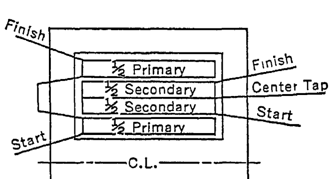

FIG. 17. Winding Arrangement, Class B Driver Transformer

Capacitances of the windings and input capacitance of the tubes have very little effect upon frequency response or distortion. However, they may resonate with the leakage reactance at some superaudible frequency to cause parasitic oscillations of the Class B stage. Such oscillations cannot be suppressed by means of series grid resistors without increasing distortion. It is desirable, therefore, to shunt a small capacitance from each Class B grid to ground.

12. PHYSICAL DESIGN OF AUDIO TRANSFORMERS

Data Required. From the foregoing analyses of various kinds of audio transformers, it is evident that the circuits which the transformer is coupling together must be clearly and completely specified before a design of the transformer is attempted. The first step in designing an audio transformer is to draw a diagram of the circuits, showing the values of generator and load impedance, direct current in any winding, and other pertinent data. Next, the desired constants of the transformer, such as turns ratio, primary inductance, leakage inductance, secondary capacitance, winding resistances, and core-loss resistance are determined from the required performance of the transformer. Methods of finding what constants in the transformer will give desired performance are described above.

DESIGN METHOD. There is no straightforward method of going at the physical design of an audio transformer. The design is carried out by making several trials, each one approaching closer to the desired constants. Procedure is as follows:

1. Assume a core size and a core material. As a starter, a core of EI scrapless laminations (see Section 3, Ferrous-cored Inductors), 1/2 in. to 3/4 in. center leg, stack equal to width of center leg, and silicon-steel material, might be chosen.

2. Calculate the number of primary turns that will give the desired value of primary inductance (Ferrous-cored Inductors).

3. Multiply the number of primary turns by the turns ratio to give the number of secondary turns.

4. Determine the primary and secondary wire sizes, using 500 circular mils per ampere as a first trial, but not using wire smaller than No. 41 AWG. Extremely small and light transformers may employ wire as small as No. 44, but these very small wire sizes should be avoided, if possible, because of breakage when winding. If direct as well as alternating current is present in a winding, the total current rms value will be

$$I_{\text{total}} = \sqrt{I_{\text{dc}}^2 + I_{\text{ac}}^2} \tag{18}$$

5. Lay out the windings. As a rule it is best to calculate the number of turns per layer and the number of layers of each winding rather than to rely on some winding space factor. The arrangement of windings may be fixed by some special requirements of the transformer, as shown in Figs. 13, 14, and 17. Unless there is some reason for doing otherwise, the primary is customarily wound first, with the secondary over it. (See Inductors for details of construction.)

6. If the total calculated build of the coil, including spool, layer insulation, and wrapper, exceeds 90 per cent of the window height, the core is too small, and steps 1, 2, 3, and 5 must be repeated, using either a larger core, a core with a larger window, such as the EE scrapless style, or a core of better magnetic material. If the coil build is far below 90 per cent of the window height, a smaller core should be tried.

7. After working out a core and coil that will fit and will have the desired primary inductance and turns ratio, the other constants should be calculated from the design. These include primary and secondary resistances, core-loss resistance, and leakage inductance. In the case of input and interstage transformers, the distributed capacitance and capacitance to ground of the secondary should also be calculated. In the case of high-level output and modulation transformers, maximum flux density at the lowest frequency (see Inductors), middle-range efficiency, and heating, should also be calculated.

8. Modify the design as required. An inspection of the first trial design will suggest the changes needed. Leakage inductance and secondary capacitance can be varied considerably by changing the arrangement and shape of the windings. Resistance of the windings can be changed by using larger or smaller wire.

LEAKAGE INDUCTANCE depends upon coil geometry. For a two-winding transformer, as shown in Fig. 18, the leakage inductance, referred to the primary, is

$$L_s = \frac{32cN_p^2}{l}\left(a + \frac{d_1 + d_2}{3}\right) \times 10^{-9} \quad \text{henry} \tag{19}$$

in which c = length of a mean turn, a turn halfway between the innermost and outermost layers; l = length of winding, or wire traverse; a = distance between windings, copper to copper; d_1 and d_2 are the build-ups of the two windings, all dimensions being expressed in inches; and N_p is the number of turns of the primary winding. The method of deriving this formula is given by R. R. Lawrence, *Principles of A-C Machinery*. Leakage inductance, referred to the secondary, is given by the same formula, except that N_s^2 is used in place of N_p^2, N_s being the number of turns of the secondary winding.

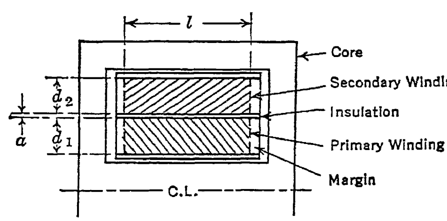

Fig. 18. Cross-section of Transformer Windings

Leakage inductance can be reduced by dividing either the primary or the secondary winding into two sections, placing the other winding between the two sections. One arrangement is shown in Fig. 19*a*, in which the windings are concentrically wound. A second arrangement is shown in Fig. 19*b*, in which the windings are coaxially wound; this construction is termed "pancake" winding. For the two cases:

$$L_e = \frac{8cN_p^2}{l}\left(a_1 + a_2 + \frac{d_1 + d_2 + d_3}{3}\right) \times 10^{-9} \quad \text{henry} \tag{20a}$$

$$L_e = \frac{8cN_p^2}{h}\left(a_1 + a_2 + \frac{d_1 + d_2 + d_3}{3}\right) \times 10^{-9} \quad \text{henry} \tag{20b}$$

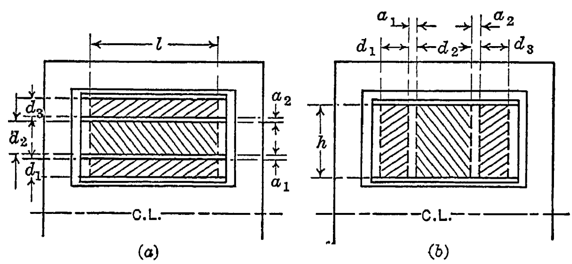

FIG. 19. Interleaved Windings. (*a*) Concentrically Wound. (*b*) Coaxially Wound.

DISTRIBUTED CAPACITANCE of an audio-frequency transformer winding is made up of the layer-to-layer capacitances. The turn-to-turn capacitances are negligible. The equivalent capacitance across a winding is the resultant of the layer-to-layer capacitances, in series. A winding of many layers, therefore, has less distributed capacitance than a winding of few layers. The distributed capacitance, C_d, is

$$C_d = \frac{0.3clk(T-1)}{dT^2} \quad \text{micro-microfarads} \tag{21}$$

in which c = mean length of turn of the winding; l = length of winding, or wire traverse; d = distance between layers, copper to copper, all dimensions expressed in inches; T = number of layers of wire in the winding; and k = average dielectric constant of layer insulation, enamel, and impregnating compounds. For paper-insulated layers, $k = 3$, approximately. See J. H. Morecroft, *Principles of Radio Communication*, 2nd Ed., pp. 233–235.

CAPACITANCE TO GROUND or between windings consists of the capacitances of the inner layer and of the outer layer of a winding to surfaces which are adjacent to them. The capacitances at the ends of a winding are usually negligible. Usually, one winding is wound over another, concentrically, with 10 to 40 mils of insulation between them. Also, the wire traverse is usually the same for both windings. The capacitance between the two windings is the capacitance between two parallel surfaces, of the same area, having a very small separation between them.

It is true that the a-c voltage between the two surfaces is not usually the same at all points, because the a-c voltage across the outer layer of the one winding is usually not the same as that across the inner layer of the other winding. Also, the capacitance calculated between the outer *layer* of the one winding and the inner *layer* of the other is assumed to be from the *finish* of the one winding to the *start* of the other. These are minor errors if the number of layers on each winding is greater than 10.

If the mean circumference of the space between the two windings = c, length of winding = l, and separation of windings = d, all dimensions in inches, and k is the dielectric constant of the insulation between them, the winding-to-winding capacitance, C_w, is

$$C_w = \frac{0.225clk}{d} \quad \text{micro-microfarads} \tag{22}$$

The same formula may be used to compute other capacitances, such as that to core or to shield.

13. AUDIO TRANSFORMER MEASUREMENTS

RESISTANCE. The d-c resistance is usually accurate enough at audio frequencies.

INDUCTANCE AND CAPACITANCE. Most iron-cored transformers for audio and power frequencies resonate at some frequency in the neighborhood of 1000 cycles. This is a parallel resonance of the mutual inductance and the winding capacitances. Measurement of primary or secondary inductance or winding capacitance at 1000 cycles is meaningless. Primary or secondary inductance must be measured at some low frequency, 60 cycles being a convenient one, care being taken to apply an appropriate value of a-c voltage and direct current. Bridges for inductance measurement are described in Section 11.

Capacitance must be measured at some high frequency, such as 4000 cycles or above. Any terminals which are normally at a-c ground potential should be grounded during such measurements. A measurement of capacitance across any winding will include reflected capacitances from other windings. If it is desired to measure the secondary capacitance of an input or interstage transformer, this may be done indirectly by measuring the leakage inductance and the leakage resonance frequency.

LEAKAGE INDUCTANCE is most conveniently measured on a 1000-cycle bridge, short-circuiting one winding and measuring the inductance of the other. This frequency is satisfactory since the mutual inductance and winding capacitances are shorted out, leaving only the leakage inductance and winding resistances as factors in the measurement. If the leakage inductance referred to the primary is to be measured, the secondary is short-circuited and the inductance of the primary is measured. See Fig. 3, in which E_2' would be short-circuited.

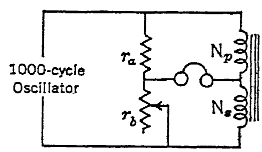

FIG. 20. Turns-ratio Bridge

TURNS RATIO is most accurately and conveniently measured with a bridge as illustrated in Fig. 20. Such a bridge is as accurate as the resistance arms, except when there is a large amount of leakage inductance in the transformer. Polarity is determined at the same time as turns ratio. The windings must be additive in order to obtain a null.

$$\frac{N_s}{N_p} = \frac{r_b}{r_a}$$

CORE-LOSS RESISTANCE, in the middle-frequency range, referred to the primary, is found by measuring the primary impedance, at the self-resonant frequency of the transformer, with no load on the secondary. Figure 21 shows how this impedance may be measured. This impedance is practically equal to the core-loss resistance. Referring to Fig. 3, if kL_1, the primary inductance, is resonant with the total capacitance $C_1 + C_2'$, their combined impedance is infinite, and they have no shunting effect on the circuit. If r_L' and C_L', the load resistance and capacitance, are removed from the transformer, the only shunt left in the circuit is the core-loss resistance r_c. The series elements r_1, the primary winding resistance, and $(1 - k)L_1$, which is half of the leakage inductance, are usually very small as compared with r_c and can be neglected.

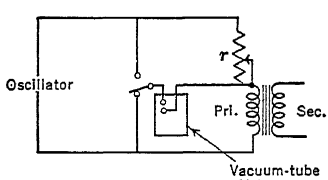

FIG. 21. Measurement of Impedance

FREQUENCY CHARACTERISTIC. An audio oscillator and a suitable voltmeter are required. For measuring input or interstage transformers, the voltmeter must be of the tube type, but for output transformers thermocouple or rectifier-type voltmeters may be used. In any event, the voltmeter should not appreciably load the circuit being measured.

It is essential, when measuring frequency response or phase shift of an audio transformer, that the circuits between which the transformer works, on the primary and secondary sides, be either included in the measurement or that equivalent resistors, capacitors, etc., be used. A measurement of the transformer alone is meaningless. If the actual tube or line on the primary side is not used, an equivalent resistor should be placed in *series* with the primary winding.

Measurements should be made at an a-c voltage level corresponding to actual operating conditions, and with direct current in the windings equal to any unbalanced direct current under actual operating conditions.

14. POWER TRANSFORMER

The function of the power transformer in radio and communication equipment is threefold: to insulate the equipment from the power line, to reduce the line voltage to the voltages required by the tube heater circuits, and to step up the line voltage to energize the anodes of the rectifier that supplies the d-c plate and bias voltages. The secondary windings that supply voltage to heater circuits are usually called "filament" windings, and the secondary winding that supplies voltage to rectifier anodes is termed the "plate" winding. A typical power transformer might have a 115-volt 60-cycle primary, a 600-volt center-tapped plate winding, a 5-volt 2-ampere filament winding for the rectifier heater, and a 6.3-volt 3-ampere filament winding for the other heaters. Variations of this basic pattern are, of course, very numerous, depending upon the voltages and currents needed. Additional secondaries may be required to supply pilot lamps, relays, control motors, etc. In transmitters, separate rectifiers may be used to supply plate and bias voltages, requiring two plate windings. It may be desirable to turn on the heaters of large tubes for a warm-up period before applying the plate voltage, which means that two separate power transformers are required, one to supply the heaters, termed a **filament transformer,** and one to supply the rectifier anodes, termed a **plate transformer.**

Power-line Frequency is 60 cycles per second throughout most of the United States. In some parts of the United States and in many foreign countries 50 cycles is standard. Most power transformers for radio equipment are designed for 50- and 60-cycle operation. In aircraft, 400 or 800 cycles per second is often used.

VOLT-AMPERE RATING. The volt-ampere rating, of any secondary winding is the product of the rms voltage, under load, by the rms current. The total volt-ampere rating of all the secondaries is the sum of the volt-ampere ratings of the individual secondaries. For a filament winding, the volt-ampere rating is simply a-c voltage times a-c current (in amperes). Both voltage and current are of sinusoidal wave form, and the rms value of each is the ordinary a-c effective value. For a plate winding, the rms voltage is the ordinary a-c voltage, since the voltage wave is sinusoidal. However, the current in a plate winding is not sinusoidal. Its rms value depends upon the amount of direct current supplied by the rectifier, the kind of rectifier circuit used, and whether the first element of the rectifier filter is an inductor (choke input) or a capacitor (condenser input). Table 1 gives the ratio of rms current, in the winding, to direct current, for various kinds of rectifier. The factors given for capacitor input are round-number approximations, which are accurate enough for most power-transformer designs. Actually these factors for capacitor input vary widely, depending upon the resistance of the rectifier and the resistance of the d-c load. For analysis of rectifiers see O. H. Schade, Analysis of Rectifier Operation, *Proc. I.R.E.*, July 1943; F. E. Terman, *Radio Engineering*, 2nd Ed., pp. 479–500; R. W. Armstrong, Polyphase Rectification Special Connections, *Proc. I.R.E.*, January 1931.

Table 1. Form Factors for Plate-winding Currents

Type of Rectifier	Heating Current	Volt-drop Current
	I_{rms}/I_{dc}	n
Bridge, inductor input	1.0	1.0
Full-wave, pushpull, inductor input	0.707	0.500
Full-wave, pushpull, capacitor input	1.0	0.707
Bridge, capacitor input	1.5	1.5
Half-wave, capacitor input	2.0	2.0
Voltage-doubler, capacitor input	3.0	3.0

SIZE OF POWER TRANSFORMERS is governed by heating rather than by efficiency in most radio and communications work. Allowable heating limits the flux density in the core and the current density in the windings. If the flux density is fixed, the core cross-section is proportional to the volts per turn. See eq. (26), below. If the current density is fixed, the core window area is proportional to the ampere-turns.

Core cross-section × window area is proportional to volts per turn × ampere-turns.

$$A \times W = p\left(\frac{E}{N} \times NI\right) = p(E \times I) \tag{23}$$

where A is the cross-section of the core, W is the area of the core window, p is a constant of proportionality, N is the number of turns on the secondary of a transformer having but one secondary, E and I are the rms voltage and current of this secondary, and $E \times I$ is the volt-ampere rating of the transformer. When there are several secondaries, the same formula holds, but $E \times I$ is the sum of the volt-ampere ratings of all the secondaries. Applying this formula to the common case of a 60-cycle power transformer, having 40 to 50 deg cent temperature rise, dimensions being in inches,

$$A \times W = 0.024(E \times I) \quad \text{approximately} \tag{24}$$

Power transformers often employ laminations of the EI-scrapless shape (see Section 3, Ferrous-cored Inductors). The core stack is often equal, or nearly so, to the width of the center leg; that is, the center leg has a square cross-section. This core shape has a

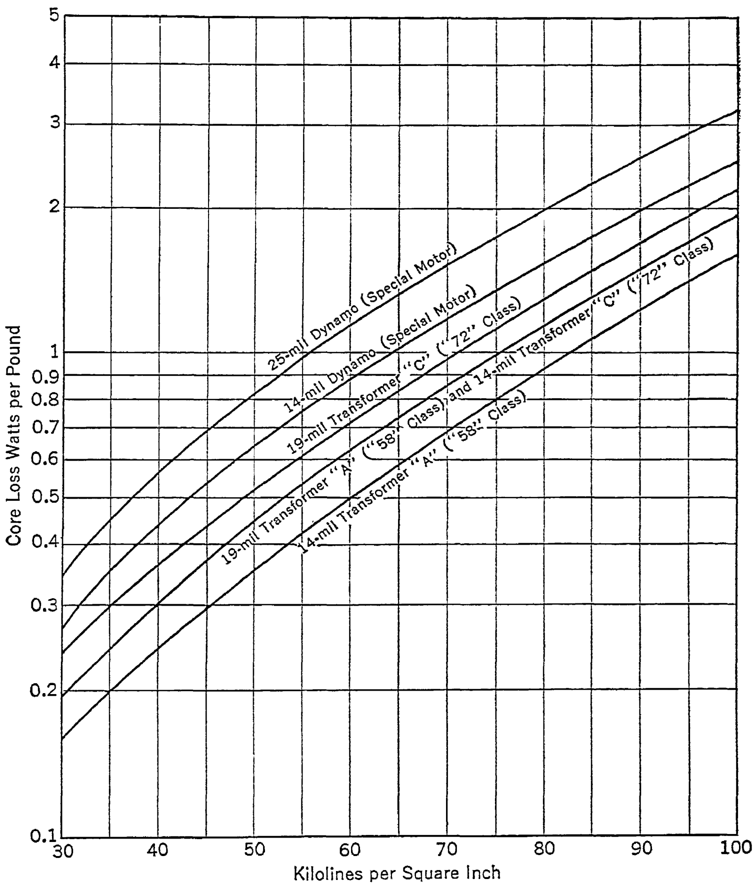

Fig. 22. Core Loss. Silicon Steel at 60 Cycles

definite relationship between window area and core cross-section, $W = 0.75A$. Equation (24), for this case, can be simplified to

$$A = 0.18\sqrt{E \times I} \quad \text{approximately} \tag{25}$$

These formulas are fairly accurate for the average run of power transformers. However, if operating voltages are high, or if the number of secondaries exceeds three, a larger than usual part of the window is taken up by insulation, leaving less space for wire. To allow for this, a somewhat larger core size should be chosen. Often, in such cases, a lamination shape is desirable, having more window area than the EI-scrapless lamination, such as the EE-scrapless style.

CONSTRUCTION OF POWER TRANSFORMERS. Compactness is accomplished by the use of a shell-type core, using laminations of the EI-scrapless or EE-scrapless shapes. Laminations are stacked alternately, or interleaved, one each way or two each way. Core material is almost always silicon steel having 2.5 per cent silicon content, or higher. Lamination thickness may be 14-mil (U. S. gage No. 29), 19-mil (U. S. gage No. 26), or 25-mil (U. S. gage No. 24). The choice of silicon content and lamination thickness is a compromise between cost and core loss, the lower silicon content and greater thickness having the higher core loss. Core loss vs. flux density for several typical grades and thickness of laminations are given in Fig. 22. See Ferrous-cored Inductors, for lamination shapes, kinds of core material, and references.

Coil construction usually follows a conventional pattern, because a particular routine of winding has been found to be most convenient. A single coil, which consists of the various windings, is made, and is placed upon the center leg of the shell-type core. The primary is wound first, over a formed spool of paper or fiber. The winding is layer wound, with paper insulation between layers. Next, an electrostatic shield, consisting of one turn of thin copper, the overlapping ends being insulated from each other, is placed over the primary. The high-voltage or plate winding is wound on next. Up to this point, the winding is done in multiple, ten or more coils being wound at a time. Generally, at this point, the coils are sawed apart. The primary and plate windings ordinarily use wire of sizes too small to be brought out of the windings as leads. So flexible, insulated leads are anchored on top of the plate winding, the wire from the primary and plate windings being brought around the ends of the windings and soldered to these leads. Then the filament windings, which usually consist of a few turns of large wire, are wound on singly, either one over the other or side by side, depending on the number of turns, wire size, and wire traverse required. Generally the wires used for filament windings are sufficiently large and rugged to be extended out of the windings as leads. See Ferrous-cored Inductors. and also H. C. Roters, *Electromagnetic Devices*, Chapter VI.

The coil, or the core and coil together, are baked dry and impregnated with varnish, wax, or asphaltic compound to exclude moisture, strengthen the coil mechanically, and reduce lamination hum.

DESIGN PROCEDURE is relatively straightforward for power transformers, so that design calculations are often made on a standard form sheet, or calculation sheet. Steps are as follows:

1. Determine the rms voltages and currents of the secondary windings and the total volt-ampere rating of all the secondaries.
2. Choose a core size which will satisfy eqs. (24) or (25).
3. Determine, approximately, the primary current. Assume 90 per cent efficiency and 90 per cent power factor as a first approximation. If the plate winding is not center-tapped, the volt-ampere input to the primary will be

$$(\text{Filament volt-amps} + \text{Plate volt-amps}) \div 0.81$$

If the plate winding is center-tapped, the volt-ampere input to the primary will be

$$(\text{Filament volt-amps} + 0.707 \text{ Plate volt-amps}) \div 0.81$$

4. Calculate primary turns, N_p.

$$N_p = \frac{E_p}{4.44BAkf} \times 10^8 \tag{26}$$

in which E_p = primary voltage, f = frequency, B = flux density in lines per square inch, A = cross-sectional area of core in square inches, and k = stacking factor. Flux density is usually around 70 kilolines per square inch, at the nominal primary voltage, for 60-cycle designs.

5. Calculate secondary turns. Assuming a regulation of 10 per cent, as a first trial,

$$N_s = \frac{E_s}{E_p} \times N_p \times 1.10 \tag{27}$$

If the number of turns on the low-voltage filament windings comes out fractional, the turns on all windings should be increased or decreased sufficiently to give each low-voltage winding a whole number of turns.

6. Determine wire sizes of all windings. The rule of 1000 circular mils per ampere is very convenient to use as a first approximation and is usually not far from the correct value arrived at in the final design.
7. Lay out the windings. This is done by calculating the number of turns per layer, the number of layers, and the build of each winding. See above, "Construction of Power Transformers," and Ferrous-cored Inductors. Margins are usually 1/8 in. It is considered good practice to use a double thickness of layer insulation between the two inside layers and between the two outside layers of the high-voltage winding, to provide a factor of safety against transients caused by line surges or switching. The total build of the coil,

including spool, insulation, and outside wrapper, should not exceed 90 per cent of the window height.

Insulation between windings is determined by the operating voltage. The rule of twice normal plus 1000 volts, for test voltage, is commonly used. Insulation must, of course, be able to stand something more than the test voltage. The factor of safety allowed is governed by cost and by the type of service which the radio or communications equipment is required to give. For test voltages of 2500 rms or less, several thicknesses of Kraft paper or two turns of varnished cambric are enough insulation between windings. Margins of $^1/_8$ in. are adequate for creepage. Above 2500 volts rms test, wider margins are necessary as well as better insulation between windings. If, for example, the test voltage is 4000, and a two-to-one safety factor is allowed in the design, the margins must be wide enough to withstand 8000 volts rms creepage. This requires about $^7/_{16}$-in. margins. A point is reached where the margins required for creepage use up too much of the available winding space. Such windings are insulated by wrapping them with half-lapped tape, of varnished cambric, Fiberglas, or other insulating material. A narrow-windowed lamination or side-by-side sections of the winding are employed with very high voltage coils, of 1000 volts or higher, in order to keep the turns per layer and the voltage per layer low.

CALCULATION OF PERFORMANCE. The procedure outlined above will give a design which is usually not very far from a satisfactory final design. It is necessary, however, to calculate the output voltages of the secondaries, the heating, regulation, and efficiency, and then to make minor adjustments in the design as required.

1. Resistance of each winding is calculated from the mean length of turn, in feet, the number of turns, and the resistance of copper wire, of the particular size, in ohms per 1000 ft (see Section 2, for tables). The d-c resistance of the wire is used. An allowance should be made for the fact that ordinary power transformer windings operate at temperatures higher than 20 deg cent, usually in the neighborhood of 80 deg cent. The resistance of copper wire increases about 0.4 per cent per degree centigrade above 20 deg cent. The mean length of turn, m, in feet, is given by

$$m = \frac{2(X + Y) - 8R + \pi(2R + b)}{12} \tag{28}$$

in which X and Y = inside dimensions of the winding, R = inside corner radius, and b = build of the winding, all dimensions being expressed in inches.

2. Copper loss of each winding is the rms current squared $\times$ resistance of that winding. Total copper loss is the sum of the copper losses of the individual windings.

3. Core loss is the product of the watts per pound (Fig. 22) times the weight of the core in pounds. Flux density, for determining watts per pound, is calculated from eq. (26). Actually, the flux density, under load, is somewhat less than given by this equation, owing to voltage drop in the primary winding, but the error is very small. See *Magnetic Circuits and Transformers*, Chapter V.

4. Heating may be calculated from the losses. There is no accurate formula for heating of a power transformer in radio or communications equipment, because so many unpredictable factors are involved. The proximity of other hot objects, such as rectifier tubes or bleeder resistors, the amount of ventilation, the nature of the surfaces toward which the transformer is radiating heat, whether dull or shiny, the kind of finish on the outside of the transformer, and the characteristics of the potting compound, if the transformer is potted, all influence the temperature rise of the transformer. However, a rough rule can be worked out, based upon the Stefan-Boltzmann law for radiation from a black body, which gives an approximate figure for temperature rise and is valuable as a basis for comparing one transformer design against another. The radiation surface of a core and coil is only slightly more than the total surface of the core, including window area. That is, the coil surface adds very little to the radiation surface of the core and coil. E.g., if the outer dimensions of a laminated core are 2 $^1/_2$ by 3 in. and the stack is 1 in., the total core surface is 26 sq. in. This surface is very easy to compute from the core dimensions and may be taken as the radiating surface of the core and coil. Calling this surface A, in square inches, and the total watts loss W, the temperature rise in degrees centigrade, ΔT, is roughly given by

$$\Delta T = \frac{200W}{A} \tag{29}$$

See *Magnetic Circuits and Transformers*, Chapter VIII; Thermal Characteristics of Transformers, V. M. Montsinger, *Gen. Elec. Rev.*, April 1946; and R. Lee, *Electronic Transformers and Circuits*, Wiley, pp. 37–44.

5. Output voltages of the secondaries under load, and the regulation of a transformer, are calculated from the resistances of the various windings. Voltage drop in a transformer,

due to leakage reactance, is very small at 60 cycles and is usually not worth the trouble of computing. An allowance of 1 per cent leakage-reactance drop is usually accurate enough. The full-load voltage of the various secondary windings is obtained as follows:

A. Primary per cent IR drop is

$$\text{Pri. }\% = \frac{I_p \times r_1 \times 100}{E_p} \tag{30}$$

in which I_p = in-phase component of primary current = rms primary current ÷ power factor, r_1 = resistance of primary winding, E_p = impressed primary voltage.

B. No-load secondary voltages = impressed primary voltage × turns ratio, for the various secondary windings.

C. High-voltage winding, full-load voltage is

$$E_2 = \left[E_0 - \left(\frac{\text{Pri. }\% \times E_0}{100} + nI_{\text{dc}}r_2\right)\right] \times 0.99 \tag{31}$$

in which E_0 = no-load voltage of winding, I_{dc} = direct-current rectifier load, n = factor depending on type of rectifier, and r_2 = resistance of high-voltage winding. The 0.99 multiplier is an allowance for leakage-reactance drop. Values of the n factor are given in Table 1. To illustrate where the n factor comes from, consider a full-wave, inductor-input rectifier with winding center-tapped. The direct current flows in one half of the plate winding at a time, so the voltage drop in the plate winding is $0.5 \times r_2 \times I_{\text{dc}}$. The value of n is 0.5.

D. Filament winding, full-load voltage is

$$E_3 = \left[E_0 - \left(\frac{\text{Pri. }\% \times E_0}{100} + I_3r_3\right)\right] \times 0.99 \tag{32}$$

in which E_0 = no-load voltage of the filament winding, I_3 = rms load current, r_3 = resistance of filament winding.

The regulation of each secondary winding, expressed in per cent, is

$$\frac{\text{No-load volts} - \text{Full-load volts}}{\text{Full-load volts}} \times 100$$

Ordinarily, regulation is between 5 and 10 per cent.

6. Efficiency is the ratio, output watts ÷ input watts. The output wattage of any filament winding is simply the product of a-c voltage, under load, by a-c load current. The output wattage of a plate winding is a complicated product of a sinusoidal voltage and a non-sinusoidal current. As an approximation, multiply the rms voltage of the total plate winding by the volt-drop current as given in Table 1. Then the output wattage of the transformer is the sum of the wattages of the various secondaries.

Input wattage is computed by multiplying the *no-load* voltage of each secondary by its rms load current if a filament winding, or by the volt-drop current if a plate winding, and adding the core-loss watts. The efficiency of a typical power transformer is about 90 per cent.

15. VIBRATOR TRANSFORMER

Function. The vibrator transformer is used in radio and communications equipment when the source of power is a battery instead of an a-c line. This occurs in mobile applications, such as automobile, aircraft, and railroad. The vibrator transformer takes the place of the usual power transformer, supplying the proper voltages to rectifier anodes and to heaters.

The center tap of the primary winding is connected permanently to one end of the battery. The other end of the battery is connected alternately to one end or the other of the primary winding by means of contacts on a vibrating reed. The frequency of the reed is usually between 100 and 200 cycles per second, although frequencies as high as 400 cycles are used. This applies an alternating voltage, of square wave form, to the primary of the transformer. The frequency of this alternating voltage is, of course, the same as the vibration frequency of the reed. The transformer is able to step this primary voltage up or down, as required, in much the same manner as an ordinary a-c voltage.

An appreciable time is required for the reed to move from one side to the other, so that the contacts are closed, one way or the other, only about 80 per cent of the time. The transformer is connected across the battery only that percentage of the time. The portion of the time that the vibrator contacts are closed is called the **time efficiency** of the vibrator.

A capacitor, called a "buffer" capacitor, must be connected across either the primary or the secondary winding. Usually it is placed across the highest voltage winding because a smaller value of capacitance will suffice there. The buffer capacitor is an essential part of the transformer. When the correct value of buffer is used, it gives a smooth cross-over of the transformer voltage during the time interval when the vibrator contacts are open. In so doing, it prevents sparking and high-frequency transients at the break and at the make.

Often, heater circuits are connected directly to the battery, leaving only rectifier anode voltage to be supplied by the vibrator transformer. The rectifier winding may be connected to vacuum-tube rectifiers in the same manner as the plate winding of an ordinary power transformer. Or rectification may be accomplished by using a second pair of contacts on the vibrator which switch the load back and forth across the secondary in synchronism with the switching of the battery across the primary. Figure 23 shows the circuit of a synchronous vibrator transformer.

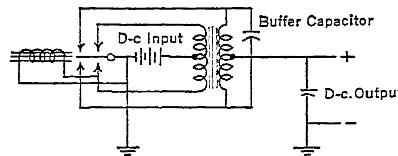

FIG. 23. Circuit of Synchronous Vibrator

DESIGN. (Rectifier secondary only.) A. Core size is much larger than for an ordinary power transformer of the same frequency and giving the same d-c voltage and current. As battery voltage varies widely, flux density must be kept low. The primary winding is almost twice as bulky as that of an ordinary transformer. The current is flowing only part of the time, and so larger wire is required for the same average current. On the other hand, if the frequency of the vibrator is much higher than 60 cycles, e.g., 150 cycles, the higher frequency will reduce the size of the vibrator transformer. It will still be somewhat larger than an equivalent 60-cycle power transformer.

B. Flux density and primary turns. The flux density in a vibrator-transformer core is given by

$$B_{\text{max}} = \frac{(1+p)E_1}{4N_pAkf} \times 10^8 \quad \text{lines per square inch} \tag{33}$$

in which E_1 = normal voltage of the battery, p = time efficiency, N_p = total primary turns, A = cross-section of core in square inches, k = stacking factor of core, and f = vibrator frequency. Flux density should be kept below 40,000 lines per square inch at normal battery voltage. A still lower figure may be desirable at higher frequencies because of core loss.

C. Secondary turns. As a first approximation, use

$$N_s = 1.33 \times N_p \times \frac{\text{Desired d-c output volts}}{\text{Battery volts}} \tag{34}$$

D. Current and wire size. The rms current in the secondary winding is

$$I_s = \frac{0.707 \times I_{\text{dc}}}{\sqrt{p}} \tag{35a}$$

The rms current in the primary winding is

$$I_p = \frac{0.707 \times I_{\text{dc}}}{\sqrt{p}} \times \frac{N_s}{N_p} \tag{35b}$$

in which I_{dc} = d-c load current of the secondary. Wire sizes should be chosen to have about 800 circular mils per ampere. Usually the primary has relatively few turns because the battery voltage is a low voltage. The primary wire size should be chosen so as to give 2, 4, 6, or 8 even layers. This will place the center tap at the end of a layer, which is convenient for multiple winding.

E. Output voltage. The total resistance of the transformer and associated circuits, referred to the working half of the secondary, is

$$r_T = \left(\frac{r_1}{2} + r_v + r_L\right)\left(\frac{N_s}{N_p}\right)^2 + \frac{r_2}{2} + r_3 \quad \text{ohms} \tag{36}$$

in which the r symbols indicate resistances, as follows: r_1 = total primary, r_v = vibrator contact, r_L = battery leads, r_2 = total secondary, and r_3 = rectifier tube, if any.

During the time that the vibrator contacts are closed, the secondary current = I_{dc}/p. Then, the IR drop expressed in volts on the secondary is $r_T \times I_{\text{dc}}/p$.

The no-load d-c voltage across the first filter capacitor is

$$E_0 = aE_1 \frac{N_s}{N_p} \tag{37}$$

a being a constant which takes care of imperfect contacts, primary and secondary contacts not exactly synchronized, etc., = 0.94 for synchronous rectifier, 0.98 for tube rectifier.

Then the full-load d-c voltage across the first filter capacitor is

$$E_2 = E_0 - \frac{r_T I_{dc}}{p} \tag{38}$$

See T. T. Short and J. P. Coughlin, Try the Inverter Transformer, *Elec. Mfg.*, June 1946; F. E. Terman, *Radio Engineering*, pp. 500–501; Mallory Vibrator Data Book.

16. PULSE TRANSFORMER

In radar work, iron-cored transformers are used, which have voltage impressed upon them for very short periods. These pulses are repeated at regular intervals, the time interval between pulses being perhaps 1000 times the pulse duration. Analysis of such pulse transformers cannot be made on a basis of Fourier analysis of the wave form because of the relatively great time interval between pulses. Each pulse is a separate transient, the effect of which dies out before the next pulse, except for core magnetization.

If a voltage is applied suddenly to the primary, through a generator resistance such as the plate resistance of a modulator tube, then is held constant for a short time interval, and then is suddenly removed, the input voltage will be of square pulse shape. The transformer will step up, or step down, this voltage, in accordance with its turns ratio, but the output voltage will not faithfully follow the square pulse shape. An appreciable time is required for the secondary voltage to build up from zero to its maximum value. This "rise time" is caused by the leakage inductance and capacitance of the transformer. During the time that the input voltage is being held constant, the output voltage will be falling off, the amount of drop from a constant voltage value being inversely proportional to the primary inductance. When the input voltage is removed, the secondary voltage does not drop instantly to zero but drags out through several damped oscillations caused by the discharge of magnetic energy stored in the core through the winding capacitances and load resistance. Figure 24 illustrates the kind of deformation of a pulse that occurs when it is passed through a transformer. See R. Lee, Iron-core Components in Pulse Amplifiers, *Electronics*, August 1943, and R. Lee, *Electronic Transformers and Circuits*, Wiley, Chapter IX.

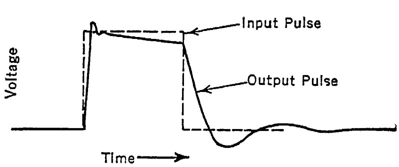

FIG. 24. Deforming of Pulse Shape by Transformer

The pulse transformer has a number of unique features. Because of the very low-duty cycle, tremendous pulse power can be handled by a very small transformer. The requirement of low leakage inductance is met by close spacing between the primary and secondary windings and by making the primary layer or layers exactly the same length as those of the secondary, even to the extent of winding several wires in parallel on the low-voltage winding. If a winding requires more than one layer, the conventional forward-and-back method of winding is not used; layers are all started from the same end to minimize capacitance between layers.

The small physical size and the relatively few turns which are essential to obtain low leakage inductance together with very high pulse voltages make voltage gradients necessary that are unheard of in ordinary transformer design. For example, 200 or more volts per turn is not uncommon. This is accomplished by using Formvar-coated wire and impregnating the transformer with transformer oil under a very high vacuum to remove every trace of air.

High primary inductance is required, to keep the drop of voltage during the pulse to the minimum. A new conception of incremental permeability is necessary in calculating the inductance. All the pulses are of the same polarity; consequently the core is left in a partially magnetized condition, owing to remanence. The hysteresis loop described by the core has this remanent point as one of its ends. The shape of the loop is largely controlled by eddy-current loss when the pulses are very short, such as of 1 microsecond duration. Under these conditions incremental permeability is much lower than when a core is operated with alternating current, and core material having low eddy-current loss is desirable. Ribbon cores of very thin silicon-steel ribbon, 1 to 3 mils thick, are very satisfactory for pulse transformer cores. Their incremental permeability under microsecond pulse conditions is about 300.

ELECTRIC WAVE FILTERS

By A. J. Grossman

A wave filter is a device for separating waves characterized by a difference in frequency. The general purpose of an electric wave filter is to separate sinusoidal electrical currents of different frequencies. Ideally, a filter transmits freely the currents of all frequencies lying within a specified range and excludes currents of all other frequencies. It may be used to transmit the intelligence contained in a certain band and exclude adjacent steady-state interference; combinations of filters may divide a wide frequency band into a number of relatively narrow channels or may direct selected bands from one transmission path into two or more different paths. Except in the simplest forms, a filter is a composite network made up of several sections connected in tandem. Each section consists of simple arrangements of two-terminal reactance networks. These reactances are provided by combinations of ordinary coils and condensers, crystals, coaxial lines, and/or wave guides.

The point of view developed by Bode, Campbell, Cauer, Foster, and others for the analysis of a network is to regard the combination of inductances and capacitances as a system excited by a vibratory disturbance to which the methods of particle dynamics can be applied. It is convenient to express the analysis in terms derived from the classical theory of wave propagation in continuous media. These terms are the image impedance and the image transfer constant. In this terminology a filter is described as a system having the following idealized properties. Signals lying within a preassigned frequency band are transmitted without reduction in amplitude. This band is bounded by cutoff frequencies at which there is an abrupt transition from free transmission to attenuation. The attenuation increases more or less rapidly with frequency as the departure from a cutoff increases. Concomitantly, the impedance is a pure resistance in the pass band and changes abruptly at a cutoff to a pure reactance.

These idealized characteristics are approached in an actual filter inserted between resistance terminations. The insertion loss for frequencies in the pass band remote from the cutoff is essentially nil (apart from the effect due to dissipation in the components). As the cutoff is approached the loss increases. The transition from the theoretical pass band to the attenuating band is smooth. This transition interval can be made extremely narrow in an elaborate design. The cutoff is not a frequency at which there is an abrupt change from zero attenuation to a large value; it may mark the point at which there is a rapid change from a small to a large value of attenuation, but at a finite rate. This departure from the idealized characteristics arises from the fact that the filter is not terminated in its image impedances. In simple cases, the image impedance varies considerably with frequency, and, consequently, the input impedance of the filter has a non-constant resistance component and an associated reactance component. By careful design the image impedance may be maintained nearly constant over almost all of the pass band. Nevertheless, there is still the smooth, but rapid, transition of the input impedance from a predominantly resistive characteristic in the pass band to a predominantly reactive characteristic in the attenuating band. The usual types of filters are low-pass, high-pass, and band-pass.

17. INTRODUCTION

A general filter network may be represented by a box, as in Fig. 1, having two pairs of accessible terminals. The performance of this network is described in terms of its image impedances and image transfer constant. The image impedances are defined as those impedances with which the network must be terminated so that there will not be reflections at the junctions 1–1′ and 2–2′. That is, when the terminating impedance, Z_{I_1}, is connected across 1–1′, then the impedance measured at the 2–2′ terminals is Z_{I_2}; and, similarly, when Z_{I_2} is connected across 2–2′, the impedance measured at 1–1′ is Z_{I_1}.

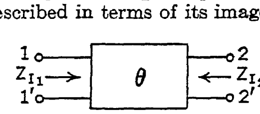

FIG. 1. A General Filter Network

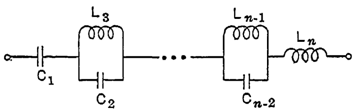
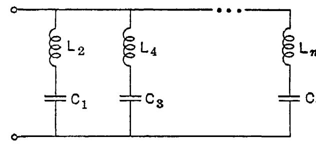
The image transfer constant, θ, is defined to be equal to one-half the natural logarithm of the ratio of the volt-amperes flowing into the network to the volt-amperes flowing

(1) $$Z = \frac{H(\omega_1^2 - \omega^2)(\omega_3^2 - \omega^2)\cdots(\omega_{n-1}^2 - \omega^2)}{j\omega(\omega_2^2 - \omega^2)(\omega_4^2 - \omega^2)\cdots(\omega_{n-2}^2 - \omega^2)}; \quad n = \text{even integer}$$





$C_{2k} = \left[\frac{j\omega}{(\omega_{2k}^2 - \omega^2)Z}\right]_{\omega=\omega_{2k}}; \ k = 1, 2, \cdots, \frac{n-2}{2}$	$L_{2k} = \left[\frac{j\omega Z}{(\omega_{2k-1}^2 - \omega^2)}\right]_{\omega=\omega_{2k-1}}; \ k = 1, 2, \cdots, \frac{n}{2}$
$L_{2k+1} = \frac{1}{\omega_{2k}^2 C_{2k}}$	$C_{2k-1} = \frac{1}{\omega_{2k-1}^2 L_{2k}}$

FIG. 2. Design Information for

out of the network when the network is terminated in its image impedances. These quantities are an exact measure of the performance of the filter only if the actual terminations are equal to the image impedances. In a practical design, account must be taken of reflection and interaction effects arising from the mismatch between the terminating impedances of the filter and its image impedances. These effects may be evaluated by the method described in Section 5. They will not be considered in detail here. It will be assumed that the performance of the filter is described by its image transfer constant.

By writing the mesh or nodal equations for the network, it may be shown that:

$$Z_{I_1} = \sqrt{Z_{s1}Z_{01}} \tag{1}$$

$$Z_{I_2} = \sqrt{Z_{s2}Z_{02}} \tag{2}$$

$$\tanh\theta = \sqrt{\frac{Z_{s1}}{Z_{01}}} = \sqrt{\frac{Z_{s2}}{Z_{02}}} \tag{3}$$

where Z_{s1} is the impedance measured at the 1–1′ terminals when a short circuit is placed across the 2–2′ terminals, and Z_{01} is the impedance measured at the 1–1′ terminals when the 2–2′ terminals are open. The short- and open-circuit impedances Z_{s2} and Z_{02} at the 2–2′ terminals are measured similarly.

(3) $$Z = j\frac{H\omega(\omega_2^2-\omega^2)(\omega_4^2-\omega^2)\cdots(\omega_{n-1}^2-\omega^2)}{(\omega_1^2-\omega^2)(\omega_3^2-\omega^2)\cdots(\omega_{n-2}^2-\omega^2)};\quad n = \text{odd integer}$$

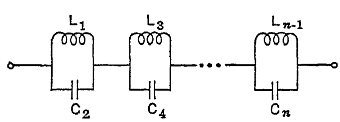
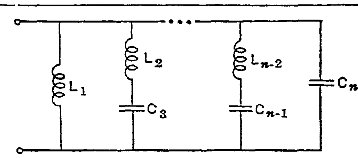
$L_{2k-1} = \frac{1}{\omega_{2k-1}^2 C_{2k}}$	$C_{2k+1} = \frac{1}{\omega_{2k}^2 L_{2k}}$
$L_n = H$	$L_1 = H\cdot\left[\frac{\omega_2\omega_4\cdots\omega_{n-1}}{\omega_1\omega_3\cdots\omega_{n-2}}\right]^2$

(4) $$Z = j\frac{H\omega(\omega_2^2-\omega^2)(\omega_4^2-\omega^2)\cdots(\omega_{n-2}^2-\omega^2)}{(\omega_1^2-\omega^2)(\omega_3^2-\omega^2)\cdots(\omega_{n-1}^2-\omega^2)};\quad n = \text{even integer}$$





Series type	Parallel type
$C_{2k} = \left[\frac{j\omega}{(\omega_{2k-1}^2-\omega^2)Z}\right]_{\omega=\omega_{2k-1}}$; $k = 1, 2, \cdots, \frac{n}{2}$	$L_{2k} = \left[\frac{j\omega Z}{(\omega_{2k}^2-\omega^2)}\right]_{\omega=\omega_{2k}}$; $k = 1, 2, \cdots, \frac{n-2}{2}$
$L_{2k-1} = \frac{1}{\omega_{2k-1}^2 C_{2k}}$	$C_{2k+1} = \frac{1}{\omega_{2k}^2 L_{2k}}$
	$L_1 = H\cdot\left[\frac{\omega_2\omega_4\cdots\omega_{n-2}}{\omega_1\omega_3\cdots\omega_{n-1}}\right]^2$
	$C_n = \frac{1}{H}$

Two-terminal Reactive Networks

The short- and open-circuit impedances are driving point impedances of a purely reactive network. The requirements on such an impedance are (by Foster's theorem):

It is an odd rational function of the frequency, $\omega/2\pi$, which is completely determined, except for a constant factor, H, by assigning the resonant and antiresonant frequencies, subject to the condition that they alternate and include both zero and infinity. Such an impedance function may be physically realized by several canonical structures, among them a combination of antiresonant circuits connected in series and a combination of resonant circuits connected in parallel.

Figure 2 illustrates the four possible reactance functions which are distinguished by their behavior at zero and infinite frequency. The series-type networks are specified in the left-hand column, and the parallel type in the right-hand. The number of elements in each configuration is the minimum, and equal to the number of critical frequencies plus 1.

The operations required to evaluate an expression such as

$$C_{2k} = \left[\frac{j\omega}{(\omega_{2k}^2-\omega^2)Z}\right]_{\omega=\omega_{2k}}$$

are to be performed in the following sequence: (1) multiply $\frac{1}{Z}$ by $\frac{j\omega}{\omega_{2k}^2-\omega^2}$; (2) cancel the common factor $(\omega_{2k}^2-\omega^2)$; (3) replace ω by ω_{2k}.

Illustration.

$$Z = \frac{H(\omega_1^2 - \omega^2)(\omega_3^2 - \omega^2)}{j\omega(\omega_2^2 - \omega^2)(\omega_4^2 - \omega_2)}$$

This is realizable with the second pair of networks. For the series type:

$$C_2 = \frac{-\omega_2^2(\omega_4^2 - \omega_2^2)}{H(\omega_1^2 - \omega_2^2)(\omega_3^2 - \omega_2^2)}$$

$$C_4 = \frac{-\omega_4^2(\omega_2^2 - \omega_4^2)}{H(\omega_1^2 - \omega_4^2)(\omega_3^2 - \omega_4^2)}$$

$$L_3 = \frac{1}{\omega_2^2 C_2}$$

$$L_5 = \frac{1}{\omega_4^2 C_4}$$

$$C_1 = \frac{1}{H}\left(\frac{\omega_2\omega_4}{\omega_1\omega_3}\right)^2$$

For the parallel type:

$$L_2 = \frac{H(\omega_3^2 - \omega_1^2)}{(\omega_2^2 - \omega_1^2)(\omega_4^2 - \omega_1^2)}$$

$$L_4 = \frac{H(\omega_1^2 - \omega_3^2)}{(\omega_2^2 - \omega_3^2)(\omega_4^2 - \omega_3^2)}$$

$$C_1 = \frac{1}{\omega_1^2 L_2}$$

$$C_3 = \frac{1}{\omega_3^2 L_4}$$

$$C_5 = \frac{1}{H}$$

18. PROPERTIES OF THE IMAGE PARAMETERS

GENERAL CONDITIONS. In the pass band of a filter, the image impedances are positive real quantities, or resistances; the image transfer constant is pure imaginary, which signifies phase shift with zero attenuation. In the attenuating region, the image impedances are pure imaginary, or reactances; the transfer constant has a positive real component, which signifies attenuation.

COINCIDENCE CONDITIONS. According to eqs. (1) and (3), the image impedance at one end of the network, and the transfer function, depend only on the short- and open-circuit impedances measured at that end. Typical expressions for these impedances are:

$$Z_{s1} = \frac{H_1(a_1^2 - \omega^2)(a_3^2 - \omega^2)\cdots(a_m^2 - \omega^2)}{j\omega(a_2^2 - \omega^2)(a_4^2 - \omega^2)\cdots(a_{m-1}^2 - \omega^2)} \tag{4}$$

$$Z_{01} = \frac{H_2(b_1^2 - \omega^2)(b_3^2 - \omega^2)\cdots(b_k^2 - \omega^2)}{j\omega(b_2^2 - \omega^2)(b_4^2 - \omega^2)\cdots(b_{k-1}^2 - \omega^2)} \tag{5}$$

where a_1, a_3, a_5, $\cdots$ are values of the angular frequency at which the short-circuited network is resonant, and a_2, a_4, $\cdots$ are values of the angular frequency at which it is antiresonant. Similarly, the b's with odd subscripts are the resonant, and the b's with even subscripts the antiresonant, angular frequencies of the network when the far end is open-circuited.

The expressions for the image impedance and transfer constant obtained with these impedance functions are:

$$Z_{I_1}^2 = \frac{H_1H_2}{-\omega^2}\cdot\frac{(a_1^2 - \omega^2)\cdots(a_m^2 - \omega^2)}{(a_2^2 - \omega^2)\cdots(a_{m-1}^2 - \omega^2)}\cdot\frac{(b_1^2 - \omega^2)\cdots(b_k^2 - \omega^2)}{(b_2^2 - \omega^2)\cdots(b_{k-1}^2 - \omega^2)} \tag{6}$$

$$\tanh^2\theta = \frac{H_1}{H_2}\cdot\frac{(a_1^2 - \omega^2)\cdots(a_m^2 - \omega^2)}{(a_2^2 - \omega^2)\cdots(a_{m-1}^2 - \omega^2)}\cdot\frac{(b_2^2 - \omega^2)\cdots(b_{k-1}^2 - \omega^2)}{(b_1^2 - \omega^2)\cdots(b_k^2 - \omega^2)} \tag{7}$$

The statement of the general conditions on the image parameters indicates that the network transmits freely when $Z_{I_1}^2$ is positive and $\tanh^2\theta$ is negative; it attenuates those frequencies for which $Z_{I_1}^2$ is negative and $\tanh^2\theta$ is positive. In general, the expressions (6) and (7) change sign as the frequency passes through each a and b, and the network has a multitude of pass and attenuating bands. In order that the network be a filter which

FIG. 3. Illustrative Expressions for the Short- and Open-circuit Impedance, Image Impedance, and Image Transfer Functions

passes one continuous band of frequencies and attenuates all other bands, it is necessary to place certain evident restrictions on the critical frequencies of its short- and open-circuit impedances. If, for example, $a_1 = b_1 = \omega_1$, the factors $(a_1^2 - \omega^2)$ and $(b_1^2 - \omega^2)$ cancel each other in $\tanh^2 \theta$ but form the factor $(\omega_1^2 - \omega^2)^2$ in $Z_{I_1}^2$. In either event, as ω passes through the value ω_1 the sign of the expression does not change. It follows that the elements of the network must be so chosen that all the a's are equal to, or coincide with, b's except possibly in two cases. These exceptional cases correspond to cutoff frequencies at which the network changes from a condition of free transmission to attenuation, or vice versa. These transition points may be two a's or two b's or one a and one b.

For the typical short- and open-circuit impedances under consideration, it is seen from (6) and (7) that $Z_{I_1}^2$ is negative and $\tanh^2 \theta$ is positive at zero frequency. That is, the filter attenuates zero frequency. This condition will continue over a frequency band provided that $a_1 = b_1$, $a_2 = b_2$, or, in general, $a_j = b_j$. The attenuation band is terminated at a cutoff frequency by locating an a at that frequency without a corresponding b, or vice versa. In either case, if a continuous pass band is to extend beyond the cutoff, it is necessary that the subsequent coincidences of critical frequencies be of a type specified by the formula $a_j = b_{j\pm 1}$, since the sequence either of a's or of b's has lost a step at the cutoff. The pass band may continue to infinite frequency or it may be terminated at a second cutoff. This cutoff may be specified by either an a or a b. Then the coincidences in the attenuating band above this cutoff are given by the formula $a_j = b_j$ or $a_j = b_{j\pm 2}$. The first relation holds if one cutoff is an a and the other a b; the second, if both cutoffs are a's or b's.

Inspection of eqs. (6) and (7) leads to the following conclusions: (*a*) coincidences of the type $a_j = b_j$ and $a_j = b_{j\pm 2}$ produce double zeros or poles in $Z_{I_1}^2$ but cancel out in $\tanh^2 \theta$; (*b*) coincidences of the type $a_j = b_{j\pm 1}$ produce double zeros or poles in $\tanh^2 \theta$ but cancel out in $Z_{I_1}^2$; (*c*) critical frequency coincidences of the first type produce image-impedance-controlling factors; those of the second type produce transfer-constant-controlling factors.

SUMMARY OF PROPERTIES OF THE IMAGE PARAMETERS.

1. $\tanh^2 \theta$ is the ratio of two impedance functions of a reactive network, and Z_I^2 is the product of two such functions. $\tanh^2 \theta$ and Z_I^2 contain only double zeros and poles except possibly for two zeros or poles, which are simple.

2. The simple zeros or poles represent cutoff frequencies and occur at positive values of ω^2. They are the same for the two expressions except for the possibility that either or both may be a zero in one expression and a pole in the other.

3. The zeros and poles of $\tanh^2 \theta$ alternate with each other in each continuous pass band; the zeros and poles of Z_I^2 alternate with each other in each continuous attenuating band. The step between bands may interrupt the alternation since the cutoffs may both be zeros or both poles.

Illustration. Examples of expressions for the short- and open-circuit impedances and the image parameters are given in Fig. 3. The frequency pattern is a convenient schematic representation of these functions. It is a plot of the location of the zeros and poles of a function in the frequency scale. The conventions are: circles denote zeros of the function (or resonances of the impedance); crosses denote poles of the function (or antiresonances of the impedance); squares represent cutoffs. These diagrams serve to illustrate the properties of the image parameters summarized above. The network configurations shown in the table are "possible" in the sense that they will be obtained for an appropriate choice of the multipliers H_1 and H_2 and the critical frequencies of the short- and open-circuit impedances.

19. OPEN-CIRCUIT TRANSFER IMPEDANCE

Two important filter theorems, due to H. W. Bode, can be derived from the properties of the open-circuit transfer impedance. This impedance, designated Z_{012}, is the ratio of the voltage appearing across the open output terminals of the network to the current fed into the input terminals. For a purely reactive network, this impedance function has real coefficients and is imaginary at real values of frequency. It is expressed in terms of the short- and open-circuit impedances by:

$$Z_{012}^2 = Z_{01}Z_{02} - Z_{01}Z_{02} = Z_{01}Z_{02} - Z_{01}Z_{02} \tag{8}$$

By use of eqs. (1)–(3), this may be written:

$$Z_{012}^2 = (Z_{I_1}Z_{I_2})\left(\frac{1}{\tanh^2 \theta} - 1\right) \tag{9}$$

Since Z_{012} is imaginary along the real frequency axis, Z_{012}^2 must be negative there. Consequently, if $Z_{I_1}Z_{I_2}$ changes sign, then $\dfrac{1}{\tanh^2 \theta} - 1$ must change sign at the same time, and conversely.

In the pass band, the image impedances are resistances, and the transfer constant is imaginary, and so the requirement on Z_{012}^2 is satisfied. In the attenuating band where the image impedances are reactances, and $\tanh\theta$ is real, there are two possibilities:

(a) If the image impedances are reactances of the same sign, the product $Z_{I_1}Z_{I_2}$ is negative. Therefore, $\tanh\theta$ must be equal to or less than unity. This interval will be called a type I attenuating band and will be designated ABI.

(b) If the image impedances are reactances of opposite sign, $Z_{I_1}Z_{I_2}$ is positive. Therefore, $\tanh\theta$ must be equal to or greater than unity. This interval will be called a type II attenuating band and will be designated ABII.

20. TRANSFER CONSTANT THEOREM

The transfer constant of any physically realizable filter is uniquely determined by the cutoff frequencies and by the frequencies of infinite attenuation.

The frequencies at which the attenuation is infinite are the roots of the equation $\tanh\theta = 1$. In practice, they are found by determining the roots of the equation $\tanh^2\theta - 1 = 0$. The number of roots in terms of ω^2 is equal to the number of pole-zero intervals of $\tanh\theta$ in the pass band or, equivalently, the total phase shift in radians divided by $\pi/2$. From a consideration of the properties of the open-circuit transfer impedance, it is deduced that the admissible roots of a physically realizable filter are the following: (a) roots of even multiplicity located at positive values of ω^2; (b) roots of even multiplicity located at negative values of ω^2; (c) roots of even multiplicity located at conjugate complex values of ω^2; (d) roots of odd multiplicity located at positive values of ω^2. As the later discussion shows, filter sections having roots of even multiplicity are the rule rather than the exception. They are symmetrical sections, for which the restrictions on the image impedance are the minimum. They are usually designed to have the simplest image impedances.

There are two additional restrictions on the expression for $\tanh\theta$: (a) If zero or infinite frequency lies in a pass band, $\tanh\theta$ must have a zero at this frequency; (b) if zero or infinite frequency lies in an attenuating band, $\tanh\theta$ must be equal to or less than unity at this frequency; in particular, $\tanh\theta = 1$, if this frequency lies in an ABII.

The significance of the above theorem is that if an expression for $\tanh\theta$ is found which contains the chosen cutoff frequencies, and is equal to unity at the chosen (admissible) frequencies of infinite attenuation, it is the only such expression that does exist, and it will lead to a physically realizable filter. Such an expression can always be found.

Illustration. (a) Test the expression

$$\tanh\theta = \frac{j\omega\sqrt{2-\omega^2}}{1-\omega^2}$$

for physical realizability. The equation $\tanh\theta = 1$ has two roots. By forming

$$\tanh^2\theta - 1 = \frac{-1}{(1-\omega^2)^2} = 0$$

both are found to be located at $\omega^2 = \infty$. Therefore, this expression has a physical representation.

(b) Test the expression

$$\tanh\theta = \frac{j\omega\sqrt{3-\omega^2}}{1-\omega^2}$$

for physical realizability. From

$$\tanh^2\theta - 1 = \frac{-(1+\omega^2)}{(1-\omega^2)^2} = 0$$

it is seen that there is a single root at $\omega^2 = -1$ and another at $\omega^2 = \infty$. Therefore, this expression for the transfer constant is not realizable.

21. IMAGE IMPEDANCE THEOREM

The second image impedance of a filter is uniquely determined at all frequencies, except for an arbitrary constant multiplier, by the transfer constant and the first image impedance.

This theorem may be demonstrated by an examination of the properties of the open-circuit transfer impedance. The formation of the expression for the second image impedance is accomplished by the application of the following rules:

(a) At the boundary of a pass band and ABI, the cutoff factor appears in the numerator of $\tanh\theta$ and in the numerator or denominator of both Z_{I_1} and Z_{I_2}.

(*b*) At the boundary of a pass band and *AB*II, the cutoff factor appears in the denominator of $\tanh \theta$ and in the numerator of one image impedance and in the denominator of the other image impedance.

(*c*) At the boundary, *AB*I/*AB*II, of the two types of attenuating bands, the equation $\tanh^2 \theta = 1$ has a root of odd multiplicity One image impedance must have a zero, or pole, at this frequency which does not appear in the other image impedance.

(*d*) All other zeros and poles of one image impedance give rise to corresponding zeros and poles (or poles and zeros) in the second image impedance. Attention must be given to the requirement that the zeros and poles of each impedance alternate in an attenuation band.

(*e*) Roots of even multiplicity can be introduced in $(\tanh^2 \theta - 1)$ without regard to the image impedances.

Illustration. The expressions for the transfer constant and the image impedance at one end of a band-pass filter are:

$$\tanh \theta = \sqrt{\frac{\omega_1^2 - \omega^2}{\omega_2^2 - \omega^2}}$$

$$Z_{I_1} = Hj\omega\sqrt{\frac{\omega_2^2 - \omega^2}{\omega_1^2 - \omega^2}}$$

where ω_1 is the lower cutoff, and ω_2 the upper cutoff. The region from zero frequency to ω_1 is an *AB*I, and, by rule (*a*), the cutoff factor corresponding to ω_1 appears in the denominator of Z_{I_2}. The region from ω_2 to infinity is an *AB*II, and, by rule (*b*), the cutoff factor corresponding to ω_2 appears in the denominator of Z_{I_2}. The expression:

$$\tanh^2 \theta - 1 = \frac{\omega_1^2 - \omega_2^2}{\omega_2^2 - \omega^2}$$

has one root in ω^2, and that is at infinity. Thus, there are no other internal zeros or poles in Z_{I_2}. Finally, with the aid of rule (*d*),

$$Z_{I_2} = \frac{Kj\omega}{\sqrt{(\omega_1^2 - \omega^2)(\omega_2^2 - \omega^2)}}$$

The elements of the filter may be found from the short- and open-circuit impedances:

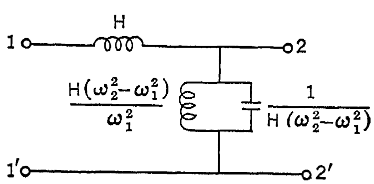

Fig. 4. Illustration for the Method of Obtaining the Second Image Impedance from the Transfer Function and the First Image Impedance

$$Z_{s1} = Z_{I_1} \tanh \theta = Hj\omega$$

$$Z_{01} = \frac{Z_{I_1}}{\tanh \theta} = \frac{Hj\omega(\omega_2^2 - \omega^2)}{(\omega_1^2 - \omega^2)}$$

$$Z_{s2} = Z_{I_2} \tanh \theta = \frac{Kj\omega}{\omega_2^2 - \omega^2}$$

$$Z_{02} = \frac{Z_{I_2}}{\tanh \theta} = \frac{Kj\omega}{\omega_1^2 - \omega^2}$$

The network obtained by setting $K = H(\omega_2^2 - \omega_1^2)$ is shown in Fig. 4.

22. THE GENERAL COMPOSITE FILTER

As exemplified by the preceding illustration, a possible filter design method consists of setting up physically realizable expressions for the desired transfer constant and image impedance at one end of the filter. Then, the expression for the second image impedance is found with the aid of the rules associated with the image impedance theorem. The corresponding short- and open-circuit impedances are computed. From these, it is possible to find the elements of the filter. In general, this may require some ingenuity.

The design method which is used most frequently is based on the fact that every filter can be regarded as the combination of certain elementary sections. As shown in Fig. 5, the composite filter is made up of N elementary sections connected in tandem. Section *A* provides one or more frequencies of infinite attenuation (in terms of ω^2) and has the image impedance Z_{I_1} specified for the input side of the filter. The secondimage im pedance Z_{I_a} is determined by Z_{I_1} and the roots of $(\tanh \theta = 1)$ provided by section *A*. Section *B* has

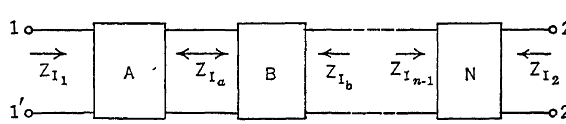

Fig. 5. The General Composite Filter

the image impedance Z_{I_a} to match A and provides one or more of the remaining frequencies of infinite attenuation. Its other image impedance is Z_{I_b}. The last section has the image impedance Z_{I_2}, consistent with the specification of Z_{I_1} and all the frequencies of infinite attenuation, that is, all the roots of $\tanh \theta = 1$.

The first step in the application of this design method is the selection of the terminating sections to furnish the desired image impedance. They provide a simple image impedance (i.e., one without impedance controlling factors) at their inner pairs of terminals. These sections correspond to A and N in Fig. 5. The transfer constant contributed by these sections is subtracted from the required overall transfer constant. The balance is supplied by elementary sections of known transfer constant characteristics which have simple image impedances. These are inserted between the terminating sections.

An alternative design procedure is applicable where it is convenient to establish a physically realizable expression for the transfer function, $\tanh \theta$, which meets the requirements of the design objective. Such a case arises, for example, if the objective is to attain linearity of phase over the pass band; another objective which can be handled in this way, as will be described later in this article, is to provide a prescribed minimum of attenuation over a specified interval of the attenuating band. The next step in the design is the determination of the frequencies of infinite attenuation by solving the equation $\tanh \theta = 1$. Then these frequencies are assigned to the appropriate elementary sections, and the sections are assembled to form a composite filter.

These design procedures are facilitated if there is available a list of the characteristics and element values of the elementary sections and the terminating sections. Such a tabulation should contain sections which provide double positive and negative roots in ω^2, double pairs of conjugate complex roots, simple positive roots. In general, the double roots correspond to the elementary symmetrical sections which form the main body of the filter, and the simple roots correspond to the unsymmetrical sections which are used for terminations. The tabulations of these sections are discussed in the following two paragraphs.

23. SYMMETRICAL SECTIONS

The problem associated with the design of symmetrical filters is much simpler than the general design problem. The configuration which is convenient for analysis is the lattice, shown in Fig. 6. From the fundamental eqs. (1)–(3) for the image parameters, it may be shown that:

$$Z_I = \sqrt{Z_x Z_y} \tag{10}$$

$$\tanh \frac{\theta}{2} = \sqrt{\frac{Z_x}{Z_y}} \tag{11}$$

By identifying Z_x with Z_{s1}, and Z_y with Z_{01}, the analysis in terms of critical frequencies, given in article 18, is directly applicable. The restrictions on Z_I and $\tanh \theta/2$ are simply those summarized there for Z_I and $\tanh \theta$. The only distinction is that the resulting transfer constant, θ, of the lattice is twice the value $\theta/2$ appearing in eq. (11). The restrictions contained in the transfer constant and image impedance theorems are satisfied since all the roots of ($\tanh \theta = 1$) are of even multiplicity. This means that the expressions for the transfer constant and image impedance can be chosen independently except for the cutoff frequencies which are the same in the two expressions. The branch impedances are:

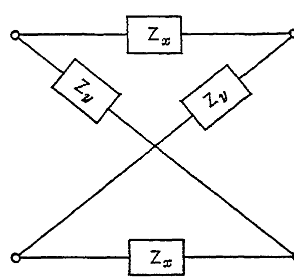

FIG. 6. The General Symmetrical Lattice Configuration

$$Z_x = Z_I \tanh \frac{\theta}{2} \tag{12}$$

$$Z_y = \frac{Z_I}{\tanh (\theta/2)} \tag{13}$$

These impedances satisfy the requirements of Foster's theorem and may be developed into the structures listed in Fig. 2.

It is evident that these branches will contain a large number of elements for all but the simplest filters. Since attenuation is obtained by bridge balance, these elements must be held to close limits if the required attenuation is great. Consequently, though the lattice is much used in theoretical work, it is usually converted, when possible, to other configurations. The first step in the conversion process is to apply the concept of the

composite filter. Then, after the original lattice is separated into a combination of the simplest lattices, these, in turn, are converted to other configurations. Some of the most useful conversions, based on Bartlett's bisection theorem, are given in Fig. 7. (Broken lines are used to simplify the drawings. It is understood that the lattice branches represented by these lines are duplicates of the corresponding ones shown explicitly.)

ELEMENTARY STRUCTURES. The elementary symmetrical sections which provide the double positive and negative roots required in forming a composite filter are listed in Figs. 8, 9, 10. Since a double root of $(\tanh^2 \theta - 1)$ corresponds to a simple root of $\left(\tanh^2 \frac{\theta}{2} - 1\right)$, it is possible to use the more convenient expression, $\tanh(\theta/2)$, in describing these sections. Each of the configurations provides one double peak of infinite attenuation. The associated image impedances are the simplest possible. The transfer constant, $\theta = \alpha + j\beta$, where α is the attenuation constant in nepers, and β is the phase constant in radians, is computed from the expression for $\tanh(\theta/2)$. If the arithmetical value of this expression is denoted by Q, then, in the pass band:

$$\tanh \frac{\theta}{2} = jQ$$

$$\alpha = 0$$

$$\beta = 2 \operatorname{arc} \tan Q; \quad \left(\frac{d\beta}{d\omega} \geq 0\right)$$

In the attenuating band:

$$\tanh \frac{\theta}{2} = Q; \quad (Q \geq 0)$$

There are two possibilities, depending on the value of Q relative to unity. Either:

$$\alpha = 2 \arg \tanh Q; \quad (Q \leq 1)$$

$$\beta = 0$$

or

$$\alpha = 2 \arg \tanh \frac{1}{Q}; \quad (Q \geq 1)$$

$$\beta = \pm\pi$$

The element values specified in these tabulations, as well as all that follow, apply to the filter sections as drawn. That is, each section is considered to be a building block in the composite filter. For example, if two ladder-type mid-series terminated sections having the same image impedance are joined together, the intermediate series impedance becomes equal to the sum of the values given in the figures; similarly, if two ladder-type mid-shunt terminated sections are joined together, the intermediate shunt admittance becomes equal to the sum of the values given.

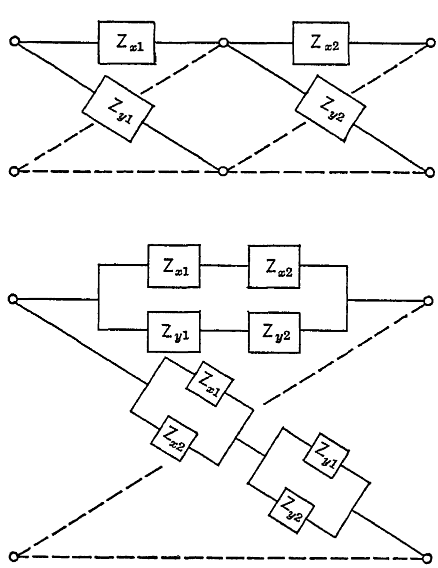

FIG. 11. Combination of Two Lattice Sections Which Have the Same Image Impedance

Figures 8 and 9 contain the design information for low-pass and high-pass sections, respectively. The cutoff frequency is denoted by f_c and the frequency of infinite attenuation by f_∞. The image impedance is equal to R at zero frequency for the low pass, and at infinite frequency for the high pass. The sections numbered (1) and (3) provide double peaks of attenuation at real frequencies. They are the m-derived sections introduced by O. J. Zobel. The special case for which $m = 1$ is the constant-K section. Sections (2) and (4) provide double peaks at real frequencies for values of the parameter m lying in the range $0 < m \leq 1$, and double peaks at imaginary values of frequency (i.e., negative values of ω^2) for values of m greater than unity.

The elementary band-pass sections are shown in Figs. 10a and b. The lower cutoff frequency is denoted by f_1, the upper cutoff by f_2, and the peak of infinite attenuation by f_∞. The image impedance is equal to R at the mid-band frequency, $f_m = \sqrt{f_1 f_2}$. A

Type	Image Impedance	Configuration
Low-pass	$\frac{R}{f_c}\sqrt{f_c^2 - f^2}$		$\frac{Rf_c}{\sqrt{f_c^2 - f^2}}$	High-pass	$\frac{R}{jf}\sqrt{f_c^2 - f^2}$		$\frac{jfR}{\sqrt{f_c^2 - f^2}}$	Band-pass	$\frac{R\sqrt{(f_1^2 - f^2)(f_2^2 - f^2)}}{jf(f_2 - f_1)}$		$\frac{jf(f_2 - f_1)R}{\sqrt{(f_1^2 - f^2)(f_2^2 - f^2)}}$		$\frac{f_2 R}{jf}\sqrt{\frac{f_1^2 - f^2}{f_2^2 - f^2}}$		$\frac{jfR}{f_2}\sqrt{\frac{f_2^2 - f^2}{f_1^2 - f^2}}$	
FIG. 12. Elementary Constituents of the General Composite Filter Which Provide Attenuation Peaks at Complex Values of Frequency

uniform definition for the parameter m is used throughout, with the result that the range of values is extended beyond the conventional zero to unity. The odd-numbered sections in Fig. 10a correspond to the usual m-derived sections which have a peak of attenuation below the lower cutoff. The special cases, for which $m = 1$, are the so-called three-element type band-pass sections having a peak at zero frequency. The lattice sections provide a peak below the lower cutoff for $0 < m \leq 1$, and a peak above the upper cutoff for $f_2/f_1 \leq m < \infty$. For the range $1 < m < f_2/f_1$, the peak is located at an imaginary value of frequency. In all cases, the phase shift is $(-\pi)$ radians at f_1 and zero at f_2.

The odd-numbered sections in Fig. 10*b* correspond to the usual m-derived sections which have a peak of attenuation above the upper cutoff. The three-element type sections having a peak at infinite frequency are special cases, for which $m = f_2/f_1$. The lattice sections are the same as those shown in Fig. 10*a* except that the branches are interchanged. In all cases, the phase shift is zero at f_1, and $(+\pi)$ radians at f_2.

The elementary sections which provide the double pairs of conjugate complex roots have a double peak of attenuation at the complex value of frequency, f_∞, and a double peak at the conjugate value, $\bar{f}_\infty$. They can be derived by combining two lattice sections of the type tabulated in Figs. 8–10. The method for combining two symmetrical lattice sections which have the same image impedance is shown in Fig. 11. By using the definitions for the parameter m given in the previous figures, a complex value, $m = m_1 + jm_2$, is obtained for the section which provides the peak at the complex value of frequency, f_∞; the conjugate complex value, $\bar{m} = m_1 - jm_2$, is obtained for the section which provides the peak at the conjugate complex value, $\bar{f}_\infty$. (The real part, m_1, must be positive.) The elements of the individual lattice sections are proportional to m and $\bar{m}$, and their reciprocals, and therefore are complex quantities. However, upon combining the two sections, the resulting elements are ordinary coils and condensers. These sections are displayed in Fig. 12.

24. UNSYMMETRICAL SECTIONS

The unsymmetrical sections provide the simple positive roots of $(\tanh^2 \theta - 1)$ in terms of ω^2. Generally, they are viewed as the means for converting the simple image impedance of the main part of the composite filter into an image impedance which approximates as closely as required to a constant value, equal to the resistance in which the filter is terminated. For low- and high-pass filters, the conversion is from a constant-K type image impedance to one having one or more impedance-controlling frequencies. For band-pass filters, there is a greater variety of possibilities. However, as a practical matter, the terminating sections are usually designed to convert a constant-K image impedance into one having one or more pairs of impedance-controlling frequencies. The product of the frequencies making up a pair is equal to the square of the mid-band frequency. For completeness, it is necessary to have available the simple sections which convert a three-element type image impedance into the geometrically symmetrical constant-K type.

The design information for the simple sections which are used to obtain either a mid-series or mid-shunt constant-K image impedance is given in Fig. 13. They are all "half-sections," and the element values apply to the sections as drawn. Comparison of the formulas for the element values and image impedance of the three-element band-pass sections with those given for the special cases in Figs. 10*a*–*b* shows that they differ by a factor which is a function of the cutoff frequencies. This arises from the fact that the symmetrical sections are designed to give an image impedance equal to R at the mid-band frequency, while those in Fig. 13 satisfy this condition only at the constant-K end of the structure. Hence, the impedance level of one or the other must be changed by the factor specified in the lower part of Fig. 13 before they can be joined without reflection. In general, the level of the symmetrical sections is changed so that the constant-K impedance of the terminating section has a mid-band value equal to the termination. For example, the inductances of sections 7 and 8 of Fig. 10*a* are multiplied by the factor $(f_2 + f_1)/f_2$, and the capacitances divided by this factor, if the section is joined to the first band-pass section of Fig. 13.

***m*-DERIVED SECTIONS.** The design information for terminating sections which present a constant-K image impedance at one end and an image impedance having one controlling frequency (or one geometrically symmetrical pair) at the other end is given in Fig. 14. It follows from the rules associated with the image impedance theorem that the low- and high-pass sections have one simple attenuation peak at the impedance controlling frequency, and the band-pass sections have a geometrically symmetrical pair. It is convenient to use a universal frequency variable, denoted by x, in the description of all the sections. The definition of this variable for each type of filter is included in the figure. For the low-pass sections, the pass band extends from $x = 0$ to $+1$, and the attenuation band from $x = +1$ to plus infinity. For the high-pass sections, the pass band extends from $x = 0$ to $x = -1$, and the attenuation band from $x = -1$ to minus infinity. For the band-pass sections, the pass band extends from $x = -1$ to $x = +1$ with the mid-band at $x = 0$; the attenuation band above the upper cutoff extends from $x = +1$ to plus infinity, while the attenuation band below the lower cutoff extends from $x = -1$ to minus infinity.

FIG. 14. Design Information for m-Derived Terminating Sections

The choice of a particular value of the parameter m is dictated by the image impedance characteristic that is desired (on the assumption that the location of the associated attenuation peak is satisfactory). Several characteristics are shown in Fig. 15 including the constant-K type, for which $m = 1.0$. These curves exhibit the course of the mid-series image impedance and the mid-shunt image admittance as a function of the frequency variable, x. A generally satisfactory value of the parameter is $m = 0.6$. It is seen that the image impedance of this section remains within about 4 per cent of a constant value over 87 per cent of the pass band. The actual impedance measured at the terminals of

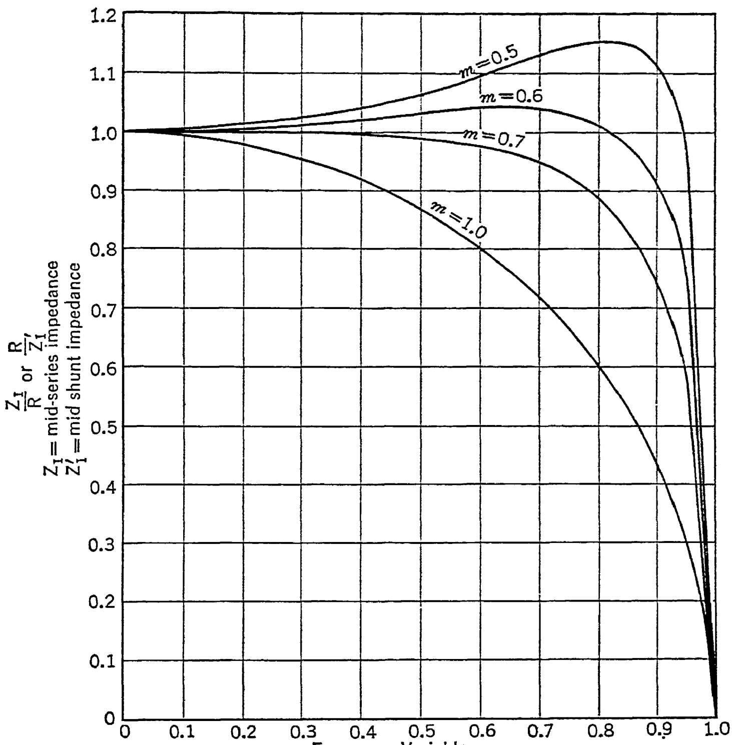

FIG. 15. Image Impedance Characteristics of Several m-derived Filter Sections

the filter is identical with the image impedance only if the other end of the filter is terminated in the image impedance at that end. A general formula for computing this impedance is

$$Z = Z_{I_1}\left[\frac{R_t + Z_{I_2}\tanh\theta}{Z_{I_2} + R_t\tanh\theta}\right]$$

where Z_I is the image impedance at the end of the filter for which the driving point impedance Z is being calculated; Z_{I_2} is the image impedance at the far end which is terminated by the load impedance R_t; and θ is the total image transfer constant of the complete filter. Evidently, if $Z_{I_2} = R_t$, then $Z = Z_{I_1}$.

TWO-FREQUENCY CONTROL SECTIONS. Terminating sections which present an image impedance having two controlling frequencies may be derived in a number of ways and exist in various forms. The sections listed in Fig. 16 serve as a direct transition from a constant-K image impedance to a "two-frequency control" image impedance. They are units consisting of four branches which cannot be separated at any internal junction, even though they have the structural appearance of 1 1/2 section m-derived filters. The low- and high-pass sections have two simple attenuation peaks, and the band-pass have two geometrically symmetrical pairs of simple peaks. The behavior of

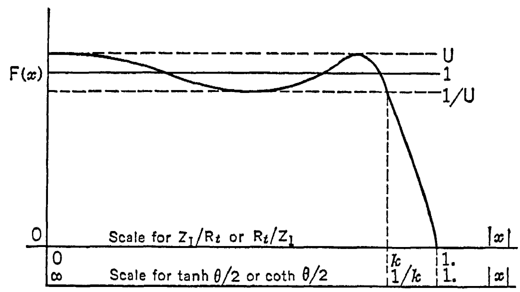
FIG. 16. Design Information for Terminating Sections Which Have Two Image Impedance Controlling Frequencies

the image impedance depends on the choice of the parameters, m_1 and m_2. Since the usual objective is to obtain an impedance which approximates closely to a constant resistance, these parameters may be determined most easily by the method described in the next section.

25. TCHEBYCHEFF TYPE CHARACTERISTICS

In the preceding two sections, attention has been directed at the building blocks that make up a composite filter. These elementary units can be assembled to give a great variety of characteristics. The characteristics desired in a filter design depend, of course, on the particular use for which the filter is intended. Many applications include the requirement that the image impedance should be substantially constant over a prescribed portion of the pass band. Another frequent specification is that the attenuation exceed a given value at all frequencies more than a certain distance beyond the cutoff. An equivalent statement of these requirements is: (1) the image impedance function, Z_I/R_t, should approximate to unity over a preassigned interval of the pass band; (2) the image transfer function, tanh θ, should approximate to unity over a preassigned interval of the attenuating band.



$$x = \frac{f}{f_c} \text{ for low-pass filter}$$

$$x = -\frac{f_c}{f} \text{ for high-pass filter}$$

$$x = \frac{f^2 - f_m^2}{f(f_2 - f_1)} \text{ for band-pass filter}$$

FIG. 17. The Tchebycheff Type of Approximation to a Constant Value

A desirable approximation is one for which the maximum departures of the function from unity are the minimum. This is known as the Tchebycheff approximation, proposed originally by W. Cauer for this application. In this type of approximation, as illustrated in Fig. 17, the function winds about unity in such a way that all the maximum values (U) are equal, and all the minimum values ($1/U$) are also equal. Unity is the geometric mean of the maximum and minimum values. The number of intersections with unity is determined by the degree of the function.

ATTENUATION CHARACTERISTIC. The image transfer function, tanh ($\theta/2$), of a symmetrical filter is written in terms of the frequency variable, $1/x$. The critical frequencies and the constant multiplier are so chosen that the function is constrained to lie between the limits U and $1/U$, in the frequency range from $1/k$ to infinity, as shown in Fig. 17. The intersections with unity correspond to peaks of infinite attenuation; the equal values of minimum attenuation, A_0, are equal either to 2 arg tanh U, or 2 arg coth U. For a given number of filter sections, there is a definite relation between k and A_0.

This relation is presented in chart form in Fig. 18. The parameter, N, is equal to the number of transfer constant controlling factors in the image transfer function. The number of m-derived low- and high-pass filter sections, Figs. 8 and 9, is equal to $(N + 1)$; the number of m-derived band-pass sections, Figs. 10a and 10b, is $[2(N + 1)]$. The horizontal scale of this chart is spread out considerably for values of k near unity by using the variable α defined by the equation $k = \sin \alpha$. The data required for making up this chart may be obtained from the following set of computations:

$$\alpha = \arc\sin k \tag{1}$$

$$2\epsilon = \frac{1 - \sqrt{\cos \alpha}}{1 + \sqrt{\cos \alpha}} \tag{2}$$

$$q = \epsilon + 2\epsilon^5 + 15\epsilon^9 + \cdots \tag{3}$$

$$A_0 \doteq 20(N + 1) \log \frac{1}{q} - 6.0 \quad \text{(in db)} \tag{4}$$

This relation, derived by S. Darlington, gives a result good to within 0.1 db provided A_0 is greater than about 6 db. A table of log q vs. α is contained in *Funktionentafeln* by Jahnke and Emde. This may be used in place of (2) and (3).

It is not likely that arbitrarily chosen values of A_0 and α will lie on one of the curves. Thus, a compromise must be made between minimum attenuation and the interval of the attenuating band that is covered. For example, if a filter is to be designed to attenuate frequencies above $x = 1.10$ by about 60 db, a choice must be made among the possibilities: $A_0 = 52$ db, $\alpha = 65°$, $1/k = 1.10$, $N = 2$; $A_0 = 60$ db, $\alpha = 58°$, $1/k = 1.18$, $N = 2$;

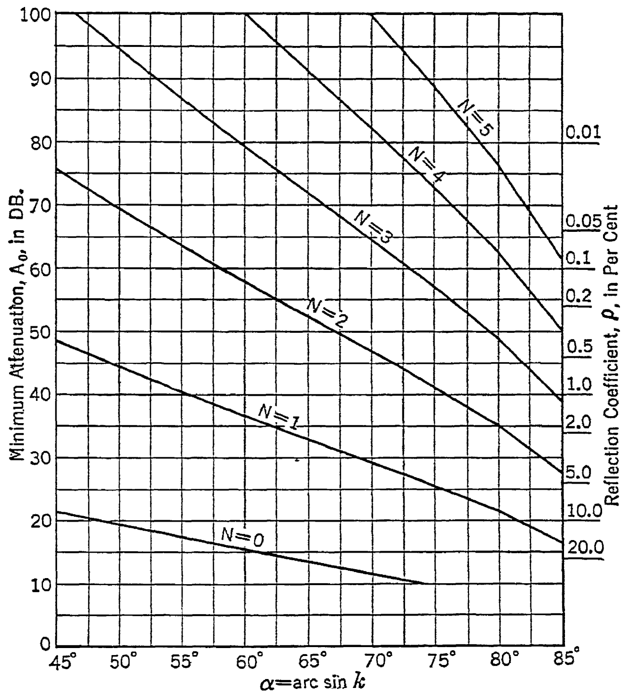


FIG. 18. Design Chart for Determining the Number, N, of Frequency Control Factors Required for a Specified Reflection Coefficient or Minimum Attenuation

$A_0 = 60$ db, $\alpha = 73°$, $1/k = 1.045$, $N = 3$. It is customary to design to a value of minimum attenuation which is 6 db greater than the desired minimum insertion loss. This allows for 3 db reflection gain at each end of the filter, which is the maximum value that may be realized.

The design formulas for the element values are expressed in terms of the impedance level, R, the cutoff frequency or frequencies, and the parameter, m. At this point it is assumed that the first two quantities are known. The values of m are determined from the frequencies of infinite attenuation. They are given by:

$$\frac{1}{x_s} = k \operatorname{sn}\left[\frac{(2s-1)K}{2(N+1)}, k\right]; \qquad s = 1, 2, \cdots, N+1$$

where sn denotes an elliptic sine function of modulus k, and K is the complete elliptic integral of the first kind. Each choice of the index s specifies an attenuation peak at the frequency corresponding to x_s.

The evaluation of the sn function can be performed by means of elliptic integral tables. However, a preferred method is to use the approximation:

$$\frac{1}{x_s} = \sqrt{k}\left[\frac{1 - u^r - u^{2-r} + u^{2+2r}}{1 + u^r + u^{2-r} + u^{2+2r}}\right]$$

where

$$2u = \frac{1-\sqrt{k}}{1+\sqrt{k}}$$

$$r = \frac{2s-1}{2(N+1)}; \qquad s = 1, 2, \cdots, N+1$$

The actual peak frequencies used in the definition of m in Figs. 8, 9, 10 are obtained from the normalized frequency for each type of filter from the following relations:

(a) low-pass $\quad f_\infty = f_c x_s$

(b) high-pass $\quad f_\infty = \dfrac{f_c}{x_s}$

(c) band-pass

$$f_\infty = f_m[Dx_s + \sqrt{1 + (Dx_s)^2}]; \quad (>f_2)$$

$$f_{-\infty} = f_m[-Dx_s + \sqrt{1 + (Dx_s)^2}]; \quad (<f_1)$$

$$D = \frac{f_2 - f_1}{2f_m}$$

$$f_m = \sqrt{f_1 f_2}$$

The band-pass attenuation characteristic is geometrically symmetrical about the mid-band frequency. That is, the attenuation at a frequency, f_x, above the upper cutoff is the same as the attenuation at the frequency $f_{-x} = f_m^2/f_x$ below the lower cutoff. Instead of designing the four-element band-pass sections, Fig. 10, it is more convenient and economical to use the six-element sections described in Fig. 14. Two half-sections must be joined together to realize the performance predicted by the above design method. It is to be noted that the parameter, m, is expressed directly in terms of x_s.

IMAGE IMPEDANCE CHARACTERISTIC. The image impedance function is written in the form Z_I/R_t in terms of the frequency variable x. The terminating resistance is denoted by R_t. The critical frequencies and the constant multiplier R are chosen in such a way that the function remains within the limits $U = R$ and $1/U = 1/R$ over the frequency range from zero to k, as shown in Fig. 17. Perfect match points correspond to the intersections with unity. Because of the reciprocal nature of the departures from unity, it is evident that the maximum departures of the magnitude of the reflection coefficient from zero are all equal over the approximation interval.

The relation between the reflection coefficient, ρ, and the pass-band interval, k, within which the reflection coefficient does not exceed the prescribed limit is presented in Fig. 18. (The scale chosen for the reflection coefficient is not a convenient one. However, it can be easily transformed into the db scale in accordance with the relation $A_0 = 20 \log (100/\rho)$, where ρ is in per cent, and A_0 in decibels.) The parameter N is equal to the number of impedance controlling factors in the expression for the image impedance. For the constant-K sections, Fig. 13, $N = 0$; for the usual m-derived sections, Fig. 14, $N = 1$; and for the "two-control" terminating sections shown in Fig. 16, $N = 2$.

The element values for the terminating sections depend on the cutoff frequencies, the impedance level, and the parameter m. It is assumed here that the cutoff frequencies are known. The impedance level is specified by:

$$\frac{R}{R_t} = \frac{1+\rho}{1-\rho} \quad \text{or} \quad \frac{1-\rho}{1+\rho}$$

where R_t is the terminating, or load, resistance, and ρ is the absolute value of the reflection coefficient (not in per cent). The first relation is used for a mid-series type impedance when N is even, and for a mid-shunt type when N is odd; the second relation is used for the other two possibilities.

The values for m are determined in terms of the frequencies of infinite attenuation. These are specified by:

$$\frac{1}{x_t} = \operatorname{sn}\left(\frac{tK}{N+1}, k\right); \qquad t = 1, 2, \cdots, N$$

The following approximation is usually more satisfactory for evaluating these peak frequencies than the use of a table:

$$\frac{1}{x_t} = \frac{1}{\sqrt{k}}\left[\frac{1 - u^v - u^{2-v} + u^{2+2v}}{1 + u^v + u^{2-v} + u^{2+2v}}\right]$$

where

$$2u = \frac{1-\sqrt{k}}{1+\sqrt{k}}$$

and

$$v = \frac{t}{N+1}; \qquad t = 1, 2, \cdots, N$$

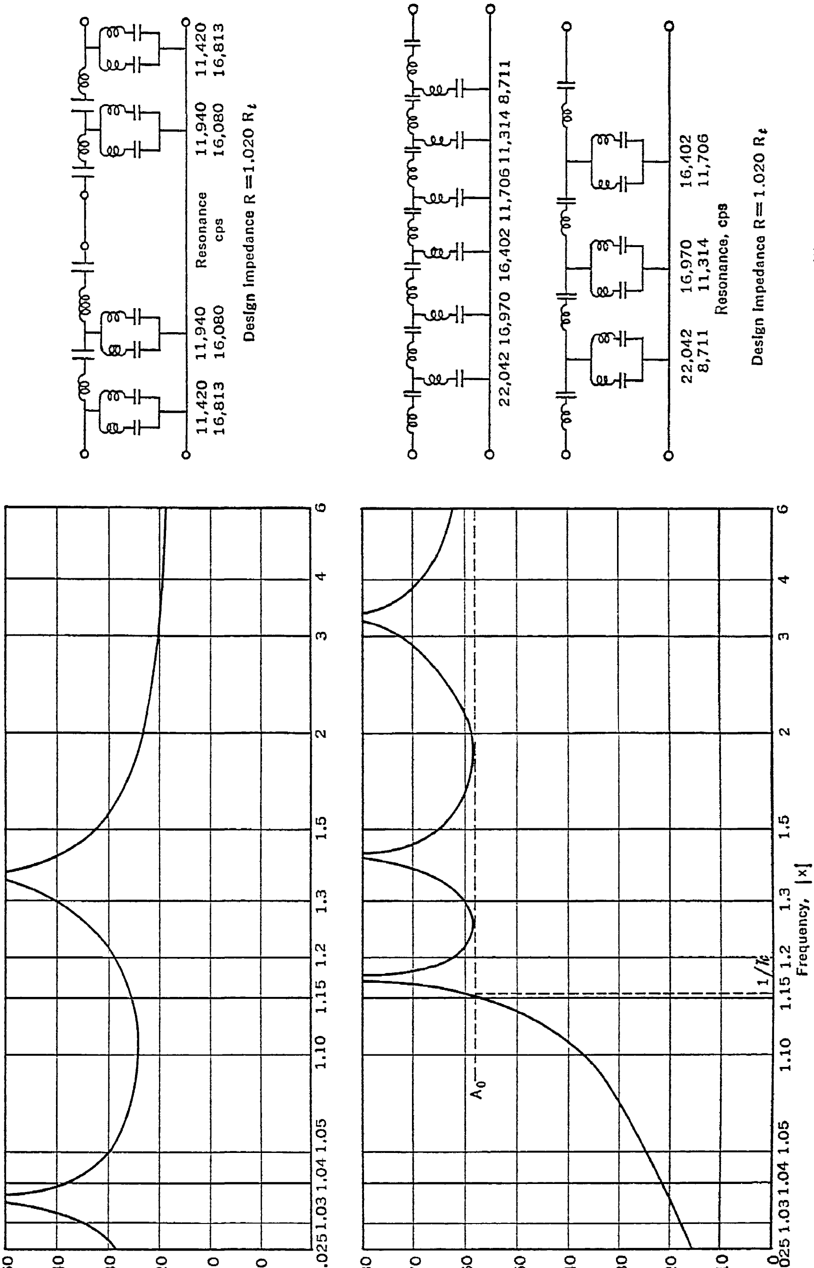

FIG. 19. Illustrative Design of a Band-pass Filter

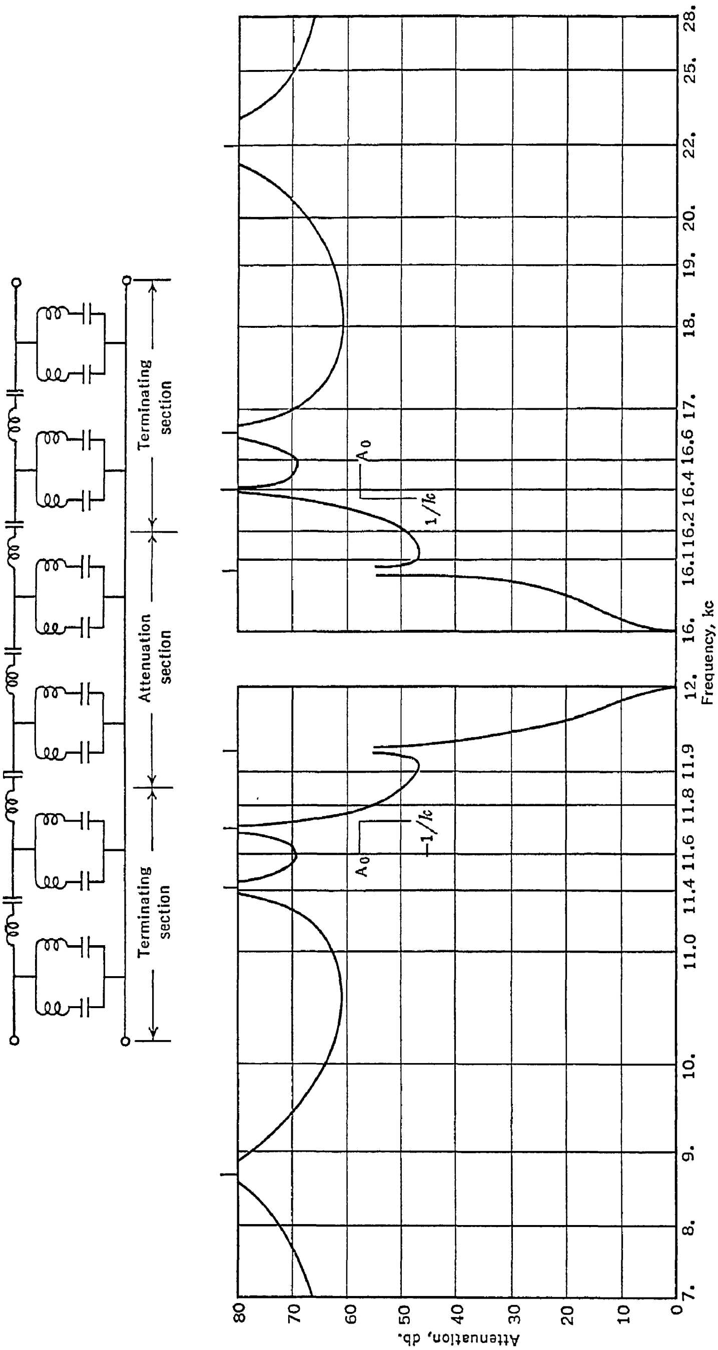

(c)

FIG. 19 (*Continued*). Illustrative Design of a Band-pass Filter

Illustration. The application of this technique to the design of a band-pass filter serves to clarify some of the details of the procedure. It is assumed that the lower cutoff is 12 kc and the upper cutoff is 16 kc. The minimum insertion loss should be at least 52 db above 16.4 kc, and below 11.6 kc. The reflection coefficient should be less than 1 per cent between 12.1 and 15.9 kc.

The terminating sections are designed first, so that the attenuation which they contribute may be deducted from the 58 db requirement (allowing 6 db for reflection gain). From the curve, $N = 2$, on Fig. 18, it is seen that a 1 per cent reflection coefficient can be realized over the portion of the pass band corresponding to $\alpha = 76°$ by using the sections shown in Fig. 16. The actual frequency range lies between the limits $f_+ = 15{,}931$ and $f_- = 12{,}050$ corresponding to $x = k = \sin 76° = 0.9703$, as computed from:

$$f = f_m[\pm Dx + \sqrt{1 + (Dx)^2}]$$

The plus sign gives the frequency above mid-band, and the minus sign the frequency below mid-band. The quantity D is the relative bandwidth equal to $(f_2 - f_1)/2f_m$. The distance between the upper and lower frequencies is proportional to the absolute band width, i.e., $(f_+ - f_-) = (f_2 - f_1)x$.

The impedance level of the section, for $\rho = 0.01$, is found to be $R = 1.020R_t$. For precise results, a value for the reflection coefficient, superior to that read from Fig. 18, may be calculated from the equation $\rho = 2q^{N+1}$. The image impedance characteristic is similar to the curve displayed in Fig. 17 with $U = 1.020$ and $k = 0.9703$. The negative half extending from zero to minus one, corresponding to the interval from mid-band to the lower cutoff, is a duplicate of the part shown.

The final step in the design is the evaluation of the peak frequencies by means of the approximation given above, with the index $v = 1/3$ and $2/3$. The results are $x_1 = 1.0351$ and $x_2 = 1.3484$; the corresponding values of the parameter are $m_1 = 0.25838$ and $m_2 = 0.67082$. The element values are obtained from Fig. 16. An appropriate configuration is shown in Fig. 19*a*, as well as the attenuation characteristic of the two terminating sections, which is obtained by doubling the result calculated from the formula in Fig. 16.

That part of the complete filter which is between the terminating sections supplies the balance of the required attenuation, i.e., the difference between 58 db and that shown in Fig. 19*a*. This unit may be designed by fitting together the attenuation characteristics of four *m*-derived sections (Fig. 10); several trials may be necessary. It is interesting to see how the design process under discussion leads directly to a satisfactory choice for these intermediate sections.

The chart, Fig. 18, is entered with $A_0 = 58$ db. This attenuation can be obtained with three sections at frequencies above and below those corresponding to $\alpha = 60°$. The limits are found to be $f_+ = 16{,}357$ and $f_- = 11{,}738$. The values for the peak frequencies are computed from the approximation given above, with the index $r = 1/6, 3/6, 5/6$. They are $x_1 = 1.1742$, and $x_2 = 1.4142$, and $x_3 = 3.333$; the corresponding values of the parameter are $m_1 = 0.52415$, and $m_2 = 0.70711$, and $m_3 = 0.95393$. The attenuation characteristics of the three sections are calculated from the formula given in Fig. 14 (this formula applies to a half-section so that the result must be doubled). Figure 19*b* is a sketch of the complete characteristic. Two of the possible configurations are shown; the first consists of sections chosen from Fig. 10, and the second is taken from Fig. 14 (an equivalent shunt branch is used).

The sum of the characteristics, Figs. 19*a* and *b*, is far in excess of the attenuation required. It is observed that the terminating section has a peak at $x_2 = 1.35$. This is close to the peak, $x_2 = 1.41$, of one of the attenuation sections. Consequently, this latter section may be omitted from the intermediate part of the complete filter without affecting greatly the minimum attenuation of 58 db. There is a considerable increase in attenuation between the cutoffs and the limit frequencies, $\pm 1/k$, owing to the first peak in the terminating sections. However, a large part of this surplus will be lost because of dissipation in the components. The overall attenuation is plotted on an arc sin frequency scale in Fig. 19*c*.

26. MAYER'S THEOREM

The effect of uniform dissipation in the elements on the characteristics of a reactive network can be estimated readily by means of Mayer's theorem. This states that:

$$A_d \doteq A + \frac{\omega}{Q} \cdot \frac{dB}{d\omega}$$

$$B_d \doteq B - \frac{\omega}{Q} \cdot \frac{dA}{d\omega}$$

A and B represent the real and imaginary parts, respectively, of a network characteristic in the absence of dissipation. A_d and B_d are the corresponding quantities when dissipation is present. As usual, ω is 2π times the frequency. The average dissipation is:

$$\frac{1}{Q} = \frac{1}{2}\left(\frac{1}{Q_L} + \frac{1}{Q_C}\right)$$

where Q_L is the average $\omega L/r$ for the coils, and Q_C is the average $\omega C/g$ for the condensers. Frequently, the condensers are considered relatively non-dissipative, so that $Q = 2Q_L$.

Since these relations come from a Taylor's series development of the network function, they are usable only in the regions where the function is well behaved. For example, if A and B represent image attenuation and image phase shift, the approximation fails in the neighborhood of the cutoffs and the attenuation peaks; on the other hand, if A and B represent the insertion loss and insertion phase shift, the approximation holds everywhere except near the loss peaks; a similar remark obtains for driving point impedance, current ratio, voltage ratio, etc., functions.

These formulas lead to some useful general conclusions. They indicate that, to a first approximation, the change produced in the real component of a network characteristic by dissipation is proportional to the slope of its imaginary component, and vice versa. It is particularly interesting to note the effect in respect to characteristics which approach the ideal. For example, the approximation to an ideal filter is designed to have a constant (zero) attenuation and a phase shift which varies linearly with frequency over most of the pass band. It is to be expected that the phase characteristic will be changed very little by dissipation since the slope of the attenuation is zero. On the other hand, the attenuation characteristic will be affected when dissipation is present. However, over the frequency range for which Q is proportional to frequency, the attenuation will be constant and proportional to the phase slope. Consequently, the filter introduces a flat loss but does not introduce distortion.

RADIO ANTENNAS

By J. C. Schelleng *

GENERAL FUNCTION AND DESCRIPTION. The antenna is the means of coupling between the medium of propagation and the transmitter or receiver. Its purpose is to convert power into outgoing electromagnetic waves, or to extract power from incoming waves. These two processes are reciprocal, but other factors such as discrimination against static introduce new requirements which differentiate a good transmitting from a good receiving antenna.

Not only should an antenna be an efficient converter between radiant and guided energy, but it should also be most effective in the direction of the station with which it is communicating. At the receiving end, directivity performs two useful functions. The first is that of impressing on the early stages of the receiver a relatively intense signal so as to override the inherent circuit or tube noises. The second and often the more important is that of discriminating against electrical disturbances in the medium, such as atmospheric noise, thereby increasing the ratio between signal and noise components. If the atmospherics should arrive from the direction of the signal, then, of course, no advantage would result from this means. When, on the average, they arrive with equal intensity from all directions, the advantage is considerable. If it happens, as in communication between Europe and America, that a very small part of the total noise arrives from the direction of the desired signal, a very great advantage is realized. Indeed, because of their ability to discriminate against atmospherics arriving from the rear, it is sometimes the practice to use as receiving antennas devices that would ordinarily be relatively poor radiators.

Practical antennas differ widely. Perhaps the simplest is a straight vertical wire as shown in Fig. 1*a*, *b*, *c*, and *d*. For the lowest frequencies used in radio the length is a very small fraction of a wavelength, but with higher frequencies the vertical wire may exceed a half-wavelength. The dotted lines indicate roughly the distribution of current. Several antennas may be arranged to form a directive array as shown in Fig. 1*l*. An antenna one-half wave long (Fig. 1*g*) is known as a half-wave linear antenna.

When the frequency is low (long waves), the antenna may take the form of an L or a T, a hundred or so feet high and several hundred long (see Fig. 1*e* and *f*). The horizontal portion is known as the *flat-top*, the vertical as the *lead-in*. Frequently a large coil of wire is used as an aerial as shown in Fig. 1*k*. It is known as a loop.

---

* In this revision a considerable amount of material from the article Radio Antennas (7–57) appearing in the 1936 Edition of the Pender-McIlwain *Handbook*, and written by G. C. Southworth, has been used.

In the highest decade of the radio spectrum (in 1949 the practical limit seems to be of the order of 30,000 megacycles per second, wavelength 1 cm), the low-frequency technique associated with radiation "from the outside" of the conductors has become relatively

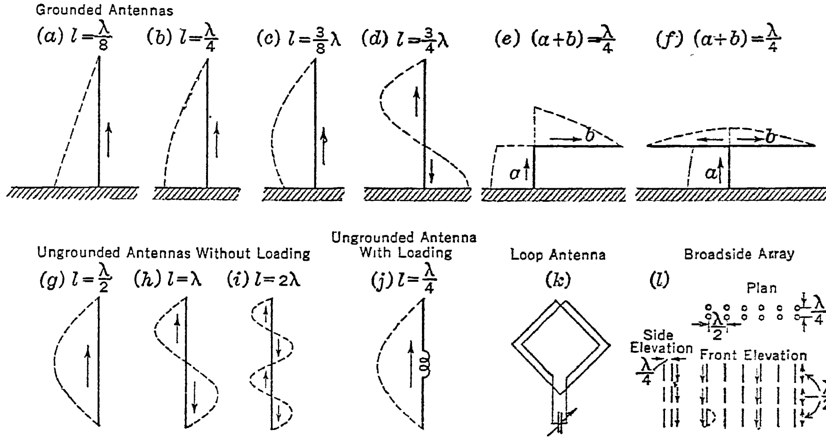

FIG. 1. Representative Forms of Antennas

difficult owing to the small size of the wavelength, and antenna designers tend to draw their inspiration from wave-guide principles and from optics. Typical antennas now are found to employ wave-guide apertures or horns, parabolic reflectors or lenses, as well as many

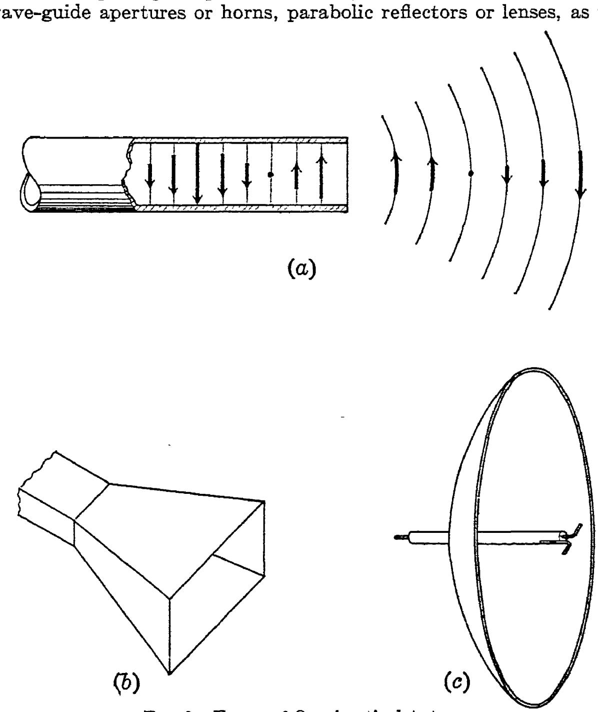

FIG. 2. Forms of Quasi-optical Antenna

of the older techniques. Figure 2*a* illustrates radiation from the open end of a circular wave guide, 2*b* shows a pyramidal horn formed by tapering from a small rectangular wave guide, and 2*c* shows a linear half-wave antenna at the focus of a paraboloidal antenna.

CLASSIFICATION. Table 1 is an attempt to classify the many diverse forms of antennas which have found use. Ignoring distinctions between transmitting and receiving, it gives one type of classification based on general form rather than specific application. In spite of a degree of artificiality it covers most of the common types. The relatively non-directional appear early in the list; the highly directional are found at the end.

Table 1. Classification of Antennas

Linear Conductor Antennas
- L, T, umbrella, multiple-tuned electric dipoles, "vertical radiators," whip, trailing-wire, vertical wire, horizontal wire, wave antenna, loops, etc.

Wave-guide Antennas
- Small wave-guide apertures:
  - Open-end wave guide.
  - Slot antennas.
  - Various reflector or lens feeds, etc.
- Large wave-guide apertures: Horns.
- Dielectric antennas: Polyrods.

Quasi-optical Devices: Antennas Using Reflectors or Lenses for Collimating
- Spherical optics: Point sources ("dipoles" or wave-guide apertures) in conjunction with spherical reflectors or lenses.
- Cylindrical optics: Line sources (arrays, reflectors, lenses) in conjunction with cylindrical reflectors or lenses.

Arrays or Combinations of Above Devices
- Long-wire antennas.
  - Wave antenna.
  - V-antenna.
  - Rhombic antenna, etc.
- Linear arrays.
  - Broadside array.
  - End-fire array.
  - Fishbone.
  - Musa.
  - Turnstile.
  - Clover leaf, etc.
- Curtain arrays.
  - Franklin.
  - Pine-tree.
  - Chireix-Mesny.
  - Sterba.
- Arrays of: Horns; quasi-optical devices; wave-guide apertures.

RADIATION, ABSORPTION, AND RECIPROCITY. In general, the radiation from an antenna can be calculated if the tangential magnetic and electric fields subsisting over any closed surface containing the antenna are known. The tangential magnetic field measures linear density of an equivalent electric current in the surface at right angles to the tangential field; likewise the tangential electric field measures a linear density of "magnetic current." General formulas (beyond the scope of this article) exist for calculating from these the radiated field (S. A. Schelkunoff, Reference 1, 9.1-7, 9.1-9 and 9.1-10). They are necessary, for example, in calculating the radiation from an electromagnetic horn. In many other cases, including practically all antennas of older types where the energy prior to radiation was guided near the outside of conductors rather than through hollow guides, this procedure simplifies: the closed surface now may be taken as the surface of the conductor of the antenna itself and the electric currents of the equivalent sheet become the usual antenna currents, while the "magnetic currents" become zero owing to the disappearance of a tangential electric field at the surface of the conductor. The fact that in the lower-frequency ranges the electric current in conductors can be conveniently measured by ammeters gives a special importance in those ranges to formulas in which the antenna current is assumed to be known.

An analogous process occurs in reception, in which equations might be set up for integrating the total effect on the receiver due to the electric and magnetic distributions over a closed surface containing the antenna, but, since these fields are in part reradiation associated with the response of the receiving antenna, the problem is more involved than that of the transmitting antenna and it is common to invoke the law of reciprocity instead. As applied to radio wave propagation through a simple linear medium (excluding nonlinear circuit elements and the ionosphere), this law says that, if there is a single zero-impedance generator in the transmitter and a zero-impedance ammeter in the receiver, the generator and the ammeter may be interchanged without affecting the current measured. An alternative expression of the law is: if a constant-current generator in the transmitter produces a reading in an infinite-impedance voltmeter in the receiver, the generator and the voltmeter may be interchanged without affecting the reading. These statements say nothing explicitly about the power transfer, but the following one does: if the internal resistance R of a generator having zero reactance is matched to the transmitting antenna, and if the receiving antenna is matched to a load whose impedance is R, then the power transfer will not be affected by interchanging the generator and the load. It follows from any of these statements that *a given antenna has the same directional pattern for receiving as for transmitting.*

27. PRINCIPLES OF LINEAR CONDUCTOR ANTENNAS

What takes place in even a simple transmitting antenna is a matter of such great complexity that a rigorous description is beyond the scope of this article; nevertheless it will be well to recognize the nature of the problem. One aspect of it is the calculation of external fields, assuming a knowledge of the distribution of current in the conductors.

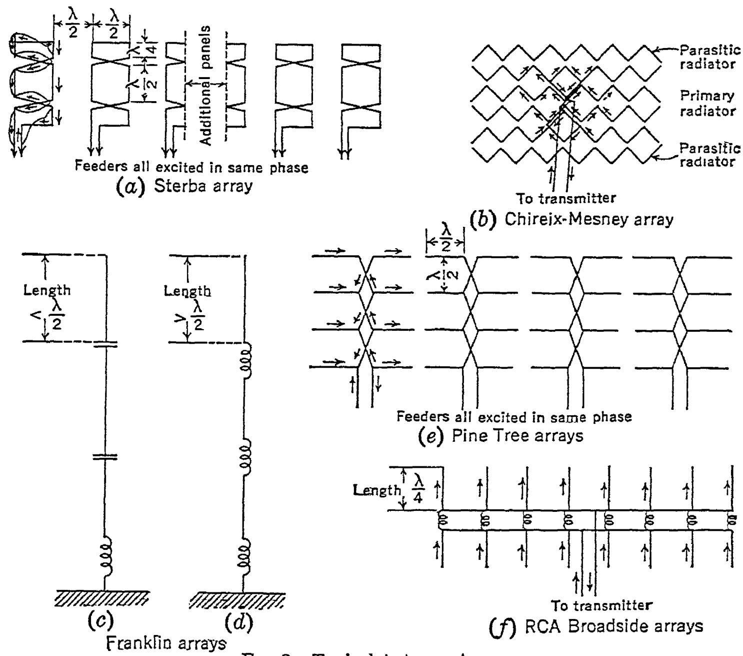

FIG. 3. Typical Antenna Arrays

This problem is completely solved by integrating for each point in space the retarded effects of currents at different parts of the antenna. To the extent that we are satisfied with the assumed current distribution, a satisfactorily complete formal solution is always possible. Many results of great engineering usefulness have been so obtained; the usual assumption is that the current is distributed sinusoidally, that the standing-wave pattern is formed by equal waves traveling oppositely with the velocity of light (3×10^8 meters per second), with current nodes at open ends of conductors. This means that the standing wave will have minima at intervals of one-half wave, with maxima at intermediate points, the instantaneous current being oppositely directed either side of a minimum, as shown in Fig. 1*d*, 1*h*, and 1*i*. In certain problems it is convenient to regard the radiation as issuing from certain centers, such as the midpoint or maximum between adjacent minima. On this view a small radiator may have a center of radiation much as an extended body has a center of mass. For sections of conductor whose length is small compared with a wavelength the current distribution may be substantially uniform, as in the vertical lead of a large flat-top antenna, or in a loop small compared with a wavelength. There is a considerable field where the engineer may employ this concept without apology to the mathematician.

There are other cases where he needs to watch his step carefully, as for example in the antenna shown in Fig. 3*a* where for qualitative purposes the standing wave is shown along the folds of the wire. The existence of current minima in this antenna was checked experimentally by E. J. Sterba, but he found that, as the antenna was extended by adding more sections at the top, the lower minima became less definite and ceased to be nulls. This is an extreme case perhaps beyond mathematical solution, but it illustrates the matter.

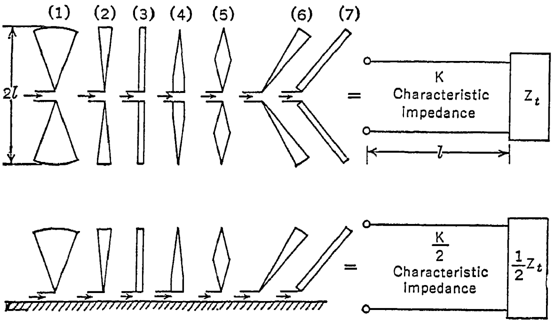

FIG. 4. The input impedance of a conical antenna of any size is equal to the input impedance of a uniform transmission line with a certain "output" impedance Z_t. The input impedance of a thin antenna of any shape is similarly represented, except that the characteristic impedance is variable.

A second aspect of this theoretical problem is the actual determination of the currents and voltages that exist on an antenna having specified the applied or external forces. S. A. Schelkunoff has given a general theory of certain forms of antenna which is especially attractive to the engineer (see Reference 1). In ordinary transmission lines, the distribution of a linear charge density is the same as that of voltage, but this is not generally true in antennas. The explanation is that antennas, unlike ordinary transmission lines, support more than one mode of propagation. As far as

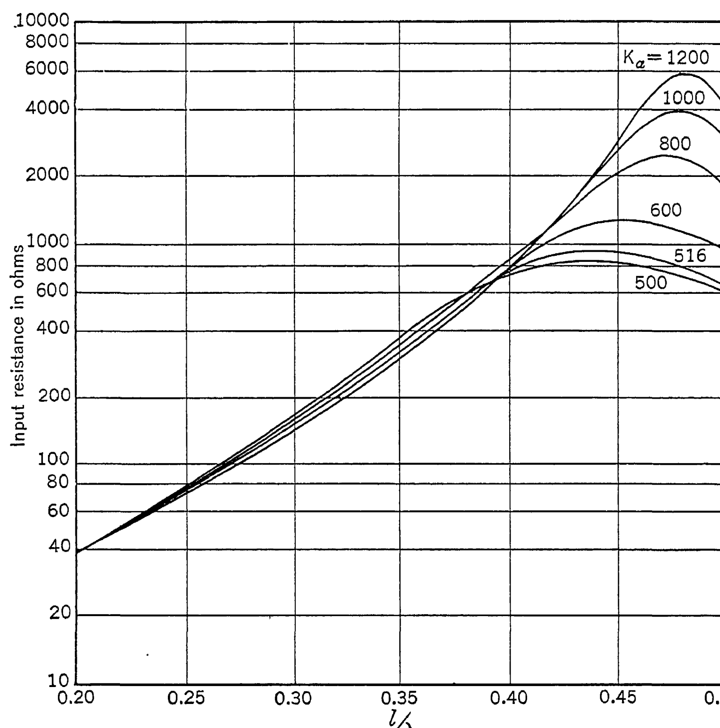

FIG. 5. The Input Resistance of Hollow Cylindrical Antennas in Free Space. For vertical antennas over a perfectly conducting ground divide the ordinates and K_a by 2.

the current associated with the principal mode is concerned (the mode that we are thinking of when we draw the oversimplified current-distribution curves which we have just been discussing), radiation is strictly an end effect: "It is permissible to think that a wave emerging from a generator in the center of an antenna is guided by the antenna until it reaches its boundary sphere passing through the ends of the antenna and separating the antenna region from external space; at the boundary sphere some energy passes into external space and some is reflected back—a situation existing at the juncture between two transmission lines with different characteristic impedances." This will be clearer by reference to Fig. 4, taken from Schelkunoff, where the "antenna region" or sphere is replaced by a transmission line having length equal that of the antenna, the line having appropriate characteristic impedance K and terminating impedance Z_t. The legend makes the figure self-explanatory.

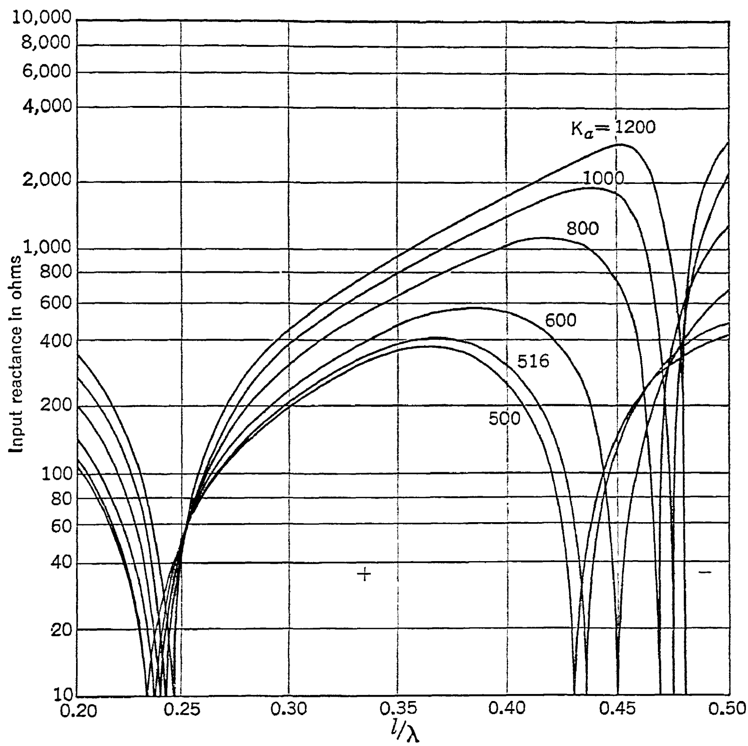

FIG. 6. The Input Reactance of Hollow Cylindrical Antennas in Free Space. For vertical antennas over a perfectly conducting ground divide the ordinates and K_a by 2.

The input resistance and reactance of perfectly conducting cylindrical antennas in free space as given by Schelkunoff are plotted in Figs. 5 and 6, the parameter K_a, the characteristic impedance, being given in Fig. 7. These curves were obtained on the assumption that the current flowing over the edge at the top of the antenna is zero. For $K_a < 700$ there is a small current over the edge which, if included in the calculations, would increase the maxima of the input resistance and reactance by a small percentage. Note the points where input reactance is zero, and the deviation of the lengths from 0.25λ and 0.5λ, as found experimentally by C. R. Englund.

In some low-frequency antennas where radiation resistance is low, the input reactance has often been calculated by regarding the antenna as a transmission line without resistance, using the formula

$$x = -\sqrt{\frac{L_1}{C_1}} \cot (\omega l\sqrt{L_1C_1}) \tag{1}$$

where L_1 and C_1 are inductance and capacitance per unit length, l the total length, and ω the angular frequency. Such a line is resonant when $l = \lambda/4$, $3\lambda/4$, etc., and antiresonant when $l = \lambda/2$, λ, etc. If a lumped inductance is connected in series with the long antenna assumed, resonance will occur when

$$\omega L - \sqrt{\frac{L_1}{C_1}} \cot (\omega l \sqrt{L_1 C_1}) = 0$$

The effect of capacitive loading may be found in a similar manner.

When an antenna of this kind does not exceed a quarter-wave in length it may be roughly considered part of a resonant circuit made up of lumped inductance and capacitance as

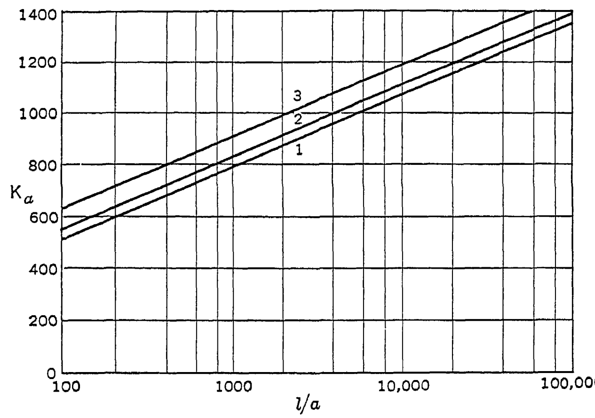

FIG. 7. The Average Characteristic Impedance: (1) Cylindrical Antenna, (2) Spheroidal Antenna, (3) Antenna of Rhombic Cross-section. l is the length from middle of antenna to the ends; a is the maximum radius of conductor.

follows: $L_e = lL_1/3$ henrys and $C_e = lC_1$ farads together with whatever loading may have been added. The shorter the antenna the better is the approximation.

RESISTANCE OF ACTUAL ANTENNAS. Antenna resistance is the quotient of the mean power supplied to the antenna divided by the mean square of the current referred to a specified point of the antenna. It thus includes a component associated with the useful radiation of power and others related to undesirable losses in the conductors, ground, etc. Radiation resistance is thus the quotient of the mean radiated power divided by the mean square of the current referred to the specified point, and radiation efficiency is the ratio of radiation resistance to total resistance.

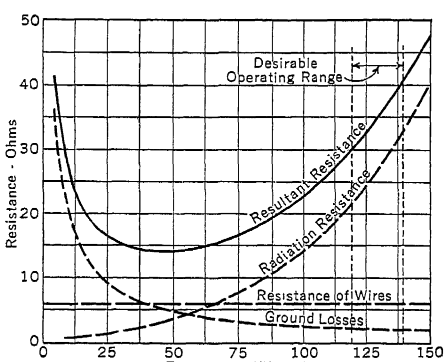

FIG. 8. Components Which Go to Make Up the Total Resistance of a Simple Antenna

Figure 8 shows the general way in which radiation resistance, with the losses in the ground and in the conductors, varies with frequency. An efficient antenna being one in which radiation resistance predominates, the desirable operating range is well to the right in the figure. At the lowest of radio frequencies, however, economic factors makes high efficiencies unrealizable, and efficiencies of a few per cent, or less, are representative. In the example shown in Fig. 8, the wire resistance is substantially independent of frequency, but in general this is not true.

The radiation resistance of a straight vertical wire of infinitesimal diameter referred to the point where it connects through a coupling or load impedance to a perfect ground varies from zero to 36.6 ohms as its length increases from zero to a quarter-wave (half the value given in Fig. 5). A convenient approximation for the radiation resistance provided that the actual height is well below $\lambda/4$ is $160\pi^2h^2/\lambda^2$, where h is an effective vertical length of the radiator and λ is the wavelength in the same units. If, for example, we consider a vertical wire $\lambda/4$ long (which we have just stated is too long for this approximation), the assumed sinusoidal current distribution makes $h = 2/\pi \cdot \lambda/4 = \lambda/2\pi$, and radiation resistance of 40 ohms is indicated. Comparison with the correct value of 36.6 ohms indicates that for antennas shorter than $\lambda/8$ the approximation will usually be acceptable.

When the operating frequency is low it is uneconomic to construct a vertical wire even approaching a quarter-wave in length. Under these circumstances it is customary to combine a rather large flat-top with a moderate vertical lead, in order to hold costs to the minimum. This leads, however, to low radiation resistance and so requires that other resistances be kept correspondingly low. Thus, if the radiation resistance should be as low as 0.05 ohm, an elaborate counterpoise or other ground system would be necessary to keep the losses within reasonable bounds.

ANTENNA IMAGES. A portion of the wave radiated from an antenna is "reflected" by the ear that points some distance away. To an observer located at a considerable distance the total radiation appears to be made up of two components, one which arrives directly from the antenna itself and the other which appears to be coming from a virtual antenna located below the surface of the earth. The latter, sometimes known as an image antenna, behaves in different ways depending on the soil adjacent to the antenna. Figure 9 pictures the relation between the effective currents in real and image antenna, assuming the earth to be perfectly reflecting.

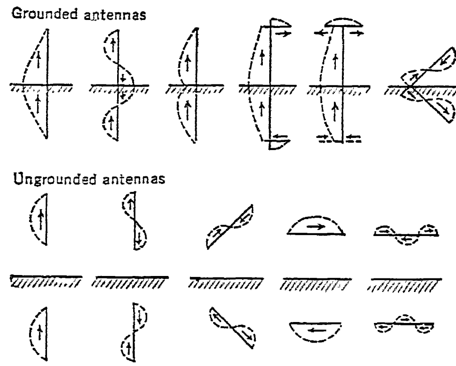

FIG. 9. Images of Representative Forms of Antennas

FIELDS ASSOCIATED WITH AN ANTENNA. The wave radiated from an antenna appears as two fields, (1) an electric field $\mathcal{E}$ which may be measured in volts per meter, and (2) a magnetic field which may be specified in amperes per meter. These components are so inseparable as to be regarded as two aspects of the same thing. They are perpendicular to each other and to the direction of wave propagation and at any point of observation are in the same phase, reaching zeros and maxima at the same time. For a fundamental discussion on this subject the reader is referred to Section 5, articles 26–28.

The electric field produced at a distance of a few wavelengths from an antenna may be calculated by means of the general formula applying to an elemental doublet

$$\mathcal{E} = \frac{60\pi}{dc} f \delta l I \cos \omega \left(t - \frac{d}{c} \right) \cos \theta \tag{2}$$

where $\mathcal{E}$ = the field intensity of the wave measured in volts per meter; $I \cos(\omega t + 90°)$ = current flowing in the wire in amperes; f = frequency of the current in cycles per second; λ = wavelength corresponding to frequency f; $\omega = 2\pi f$; t = time in seconds; d = distance to the antenna in meters; c = velocity of light = 2.998×10^8 meters per second; δl = the elementary length of wire or doublet from which radiation takes place—it is measured in the same units as λ; and θ = angle of elevation of point at which the field is desired measured relative to a plane perpendicular to the conductor δl. In the formulas in this section, any other unit of length can be used, provided it is used consistently in $\mathcal{E}$, λ, d, c, A, etc. The meter, however, is preferred.

Equations for the fields radiated by antennas of various shapes, such as given just below, are obtained by integrating the above doublet expression over the entire conductor system, having due regard for the distribution of the current. The fields at great distances from antennas are usually much less than those calculated by these formulas. (See Section 10.)

The *voltage induced* in an incremental length of conducting wire by a passing wave may be found by either of two methods. The one starting with the electric field of the wave is used the more. That component of the length lying parallel to the electric vector in the wave front is multiplied by $\mathcal{E}$ measured in volts per unit length to give the required emf. This same voltage may also be derived from the simple dynamo concept of the number of lines of magnetic force cut per second; it will be realized, however, that this is not another component of induced voltage but merely another approach to the same one made possible by the identities expressed by Maxwell's equations.

The instantaneous radiated power flowing through each unit of area perpendicular to a plane wave front may be calculated by the expression

$$P = 0.00265\mathcal{E}^2 \quad \text{watt per square meter} \tag{3}$$

(See also Sect. 3 art 28 eq. [16].)

If eq. (3) is used for calculating the power picked up by a single wire, it must be assumed that power is absorbed from a section of the wave front extending to about a quarter of a wavelength either side of the conductor.

The field intensity at a horizontal distance d from a *vertical grounded wire*, length h, carrying a uniform current I is approximately

$$\mathcal{E} = \frac{120\pi fhI}{dc} \quad \text{volts per meter} \tag{4}$$

This applies to the vertical lead to an antenna having a relatively large flat top, the antenna being located over a perfectly conducting earth.

The corresponding value for a coil or *loop* located *in free space* and having dimensions small compared with the wavelength is

$$\mathcal{E} = \frac{120\pi^2 f^2}{dc^2} ANI \quad \text{volts per meter} \tag{5}$$

where N is the number of turns and A is the area in square meters.

The effective vertical length of a *loop in free space* is given by

$$h = \frac{2\pi AN}{\lambda} \quad \text{meters} \tag{6}$$

The field intensity for a simple *vertical quarter-wave* antenna grounded at its lower end is approximately

$$\mathcal{E} = \frac{60I}{d} \quad \text{volts per meter} \tag{7}$$

The effective vertical length of a *grounded-quarter-wave* antenna is

$$h = \frac{\lambda}{2\pi} \quad \text{meters} \tag{8}$$

In all these cases the current is to be measured at the point in the antenna where this quantity is a maximum.

For formulas for field strength in terms of radiated power, see Section 10, Articles 20–24 of this handbook.

Figure 10 gives the directional diagram of a simple electric or magnetic radiating element (a short wire or a small loop). It is worth noting that the same diagram applies to both.

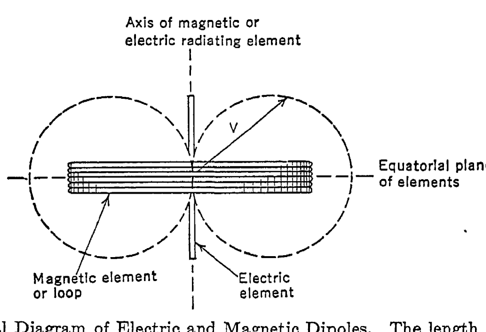

Fig. 10. Directional Diagram of Electric and Magnetic Dipoles. The length of the vector V is proportional to signal intensity.

The directional diagrams for both the quarter-wave and half-wave antennas as well as for an antenna 0.62 wavelength long are given in Fig. 11. It is to be noted that for this latter a pronounced spurious lobe is formed. This continues to grow as the antenna is further lengthened, thereby leading to a considerable amount of high-angle radiation and possibly also to fading. The field laid down in the horizontal direction is for a given power calculated to be a maximum when the length of the antenna is about 0.62 wave. (See reference 2.) The half-wave antenna together with its earth image is roughly equivalent to two collinear equiphased radiators and therefore is a special case of arrays discussed below. Antennas a half-wave or so long have become widely used in broadcasting. See "Antennas for Medium-frequency Broadcasting," article 31.

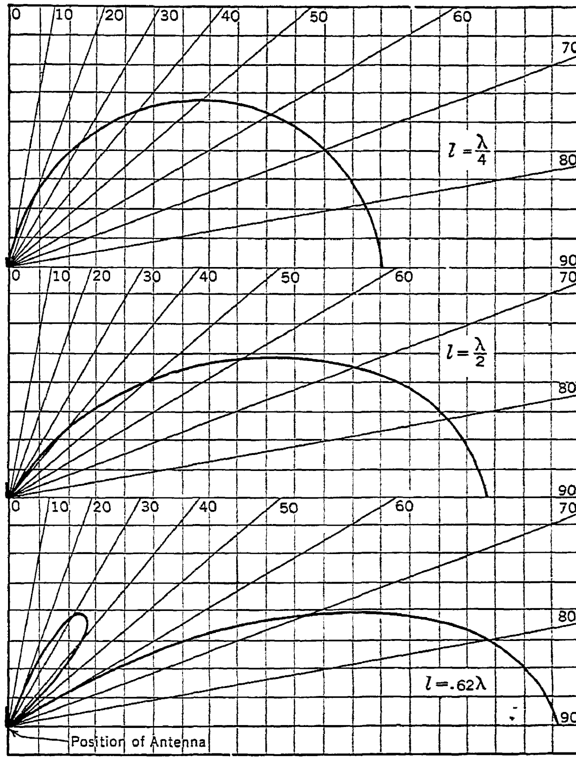

Fig. 11. Vertical Plane Directional Diagram of a Single Vertical Antenna of Various Lengths. (Only one-half of the total vertical section is shown.)

28. PRINCIPLES OF DIRECTIVITY

An antenna which radiates or receives with uniform efficiency within a range of direction is said to be *non-directional* within those limits; when it favors a given direction, on the other hand, it is *directional*. Thus, a vertical wire is non-directional in azimuth, though it is directional in elevation. Ignoring non-coherent radiation, such as light, it may be said that, for pure sinusoidal currents, a completely non-directional antenna does not exist. It is, however, a useful concept to define the directivity of actual antennas in terms of this imaginary non-directional source. Thus, the *absolute gain* is commonly defined as

$$G = \frac{P}{P_0} \tag{9}$$

where P is the power flow per unit area in the plane linearly polarized wave which the antenna causes in a distant region (usually in the direction of maximum radiation), and P_0 is the power flow per unit area which would have been produced if all the power had been radiated equally in all directions. Where gain is referred to any other standard, it will be specifically mentioned.

One special form of radiator, the current element short in comparison with a half-wave, has frequently been used for reference in discussing directivity. It is, in fact, as non-directional as a simple radiator can be. Actually, however, it has a power gain of 1.5 over the standard described in the preceding paragraph.

Though considerable directivity can at least in theory be accomplished with an antenna whose largest dimension is small compared with one wavelength, it is not far from the truth to say that all practical high-gain antennas depend primarily on having current distributed over dimensions of several wavelengths. This statement applies both to linear-conductor antennas and to quasi-optical devices.

The requirements of directivity are various. It may be necessary to limit antenna effectiveness to a certain azimuth, to a certain elevation, or to both. A narrow beam may be required in azimuth coupled with a wider one in elevation, as in some transatlantic antennas used in the range of high frequencies; or a relatively sharp beam may be wanted in elevation with little or no directivity in azimuth, as in television broadcasting; or sharpness may be needed in azimuth with a specified variation of intensity in elevation, as in the "cosecant" antennas of radar, etc.

The special distribution of current needed for directivity may be provided by arrays of similar smaller radiating elements or by combinations of dissimilar elements. These building blocks may be half-wave wires, loops, flat-top antennas, and so forth. The distribution may be continuous: for example, an electromagnetic horn may be thought of as an array of an infinite number of infinitesimal radiators.

An almost unlimited number of combinations is possible, since the directive effects produced depend not only on the relative positions and spacings of the various units but also on the amplitudes and phases of their currents as well. (See reference 3.)

Perhaps the best-known arrangement is that of a number of identical parallel antennas arrayed laterally along a straight line. Usually the element antennas carry equal in-phase currents. This produces the strongest signal in a direction perpendicular to the line of the array and is thus known as a *broadside array.* An example is shown in Fig. 1*l*, above. In some cases the phasing of the currents is progressively delayed from antenna to antenna to correspond exactly with the delay in that direction due to finite wave velocity. Such an antenna is called an *end-fire* array because the radiation is most intense along the line of the array.

EFFECTIVE AREA OF ANTENNAS. A wave incident upon a receiving antenna may be thought of as a stream of energy possessing a certain power per unit of cross-sectional area. If the receiver load is coupled to the antenna so as to abstract the maximum power available, then the ratio of this maximum power to the power incident on the antenna per unit area is defined as the effective area of the receiving antenna. A somewhat oversimplified view is that the antenna presents this area to the energy stream and canalizes the corresponding power flow into the receiver. An excellent treatment of relations to be discussed in this section will be found in an article by H. T. Friis and W. D. Lewis. (See reference 4.)

The effective area of a receiving antenna being by definition proportional to its power gain, we may make the general statement that the ratio power-gain divided by effective area has the same constant value for all antennas. Numerically it turns out that this ratio is:

$$\frac{\text{Gain}}{\text{Eff. gain}} = \frac{G}{A_{\text{eff.}}} = \frac{4\pi}{\lambda^2} \tag{10}$$

an important relation in antenna theory. It can be shown that it has a useful interpretation in transmitting as well as in receiving: this same area then measures that broadside "uniformly excited" area which would give the same transmitting gain as does the actual transmitting antenna, the excitation being unidirectional (e.g., as when a reflector is used) and the dimensions of the area being large compared with a wavelength. Hence, a lossless transmitting antenna in which the radiation is associated with a large uniformly excited area would, as a receiving antenna, make available to the receiver all the energy intercepted by its actual area.

A very useful and simple *free space transmission law* (see reference 4) results by application of these concepts to wave propagation between antennas of effective area A_T and A_R (the subscripts refer to transmitter and receiver). The power delivered to the receiver is then P_R, which equals

$$\frac{\text{Total power}}{\text{Area of sphere of radius } d} \cdot G_T \cdot A_{\text{eff. (receiver)}} = \frac{P_T}{4\pi d^2} \cdot \frac{4\pi A_T}{\lambda^2} \cdot A_R$$

giving

$$P_R = P_T \frac{A_T A_R}{\lambda^2 d^2} \tag{11}$$

The fact that the numerical constant turns out to be unity recommends this formula to the memory.

29. DIRECTIVITY OF LINEAR CONDUCTOR ANTENNAS

ARRAYS. Of the many directive patterns that may result from the various spacings and phasings of two antennas, two are of especial interest. In the first the two sources are separated in space by one-fourth of a wavelength, and in phase by one-fourth of a period. This arrangement, which is sometimes known as a unidirectional couplet, gives a cardioid pattern as shown in Fig. 12*a*, where the unit antennas are vertical half-wave elements. As compared with a single element it effects a power gain of about 2 (3 db). In the other arrangement the two elements are spaced one-half wavelength and are driven in phase (see Fig. 12*b*). This also gives a theoretical gain of about 2 (actually somewhat greater). The two arrangements may be combined as in Fig. 12*c* to give a total gain of 4 (6 db). It is convenient to regard the two antennas at the rear as reflectors for those ahead. Directional effects such as these are used practically not only to increase signal in some desired direction but also to minimize its interfering effects in others.

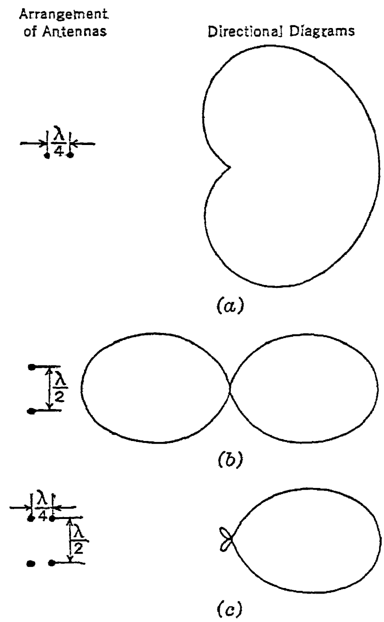

FIG. 12. Horizontal Directional Diagrams. (*a*) Unidirectional couplet. (*b*) Two equiphased antennas spaced one-half wave-length. (*c*) Two equiphased couplets.

Increased directivity may be obtained by adding couplets to the arrangement shown in Fig. 12*c*. The resulting increase is indicated by Fig. 13. Although it is often most convenient in practice to utilize spacings of one-half wave in the array front, any spacing up to about 3/4 wave may be used. For spacings less than 0.6λ it is the total length or aperture of the broadside which is the important criterion of gain, the gain variation due to spacing being inappreciable. Figure 14 facilitates determining the gain ratio of such arrays. The *aperture* there referred to is about one-half wave greater than the number of wavelengths measured between extreme conductors of the array. The reason for this rule is that the equivalent area of a thin wire properly coupled to the terminal is finite (see paragraph following eq. [3]).

When an array is formed by stacking similar units in tiers in the vertical direction, added directivity is provided at some angle from the vertical, commonly at 90°, that is, in the horizontal plane. The units may, for example, be the vertical elements previously described, and if the elements of a broadside array are so arranged the antenna resembles a curtain. For vertical elements the improvement obtained by adding a small number of tiers or stacks is less than that achieved by the lateral arrangement. (See reference 5.)

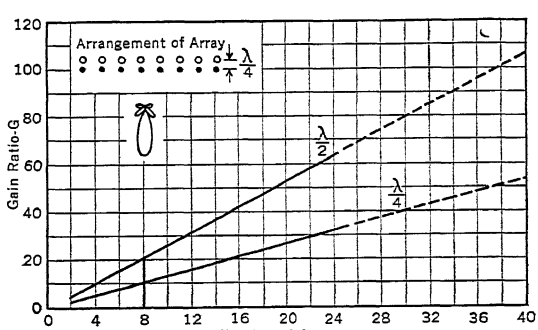

FIG. 13. Variation of Directivity with Number of Couplets Placed in Horizontal Array

Simple but approximate rules for unidirectional broadside arrays are as follows:

1. The gain ratio of a large array of vertical couplets extending both laterally and vertically (and including a reflecting curtain) follows the general rule for gain $G = 4\pi A/\lambda^2$ or, in terms of a short current element as standard, $G_d = 8/3 \cdot \pi A/\lambda^2 = 8.4A/\lambda^2$, where the effective length is taken one-half wave greater than the length between extreme conductors (see paragraph following

eq. [3]), and the height as $\lambda/2$ times the number of tiers or stacks. This assumes no appreciable gap between tiers. For a single-tier antenna $G_d = 10A/\lambda^2$.

2. Doubling the length or the height, or adding the "reflector" curtain to the front curtain, adds 3 db to the gain. Note the exception already indicated, however, that in going from one to two tiers the increase is only about 2 db.

Arrays of this type have achieved considerable importance both in long-distance transmission using short waves (high frequencies) and in medium-frequency broadcasting. In the former use very considerable power gains have been employed, varying up to more than 100. In the latter the gain has been valuable in extending coverage, but the most important aim has been the suppression of signals in certain directions at night in order to avoid interference with other stations. Thus the directivity of broadcast transmitting antennas has two aims essentially corresponding to those mentioned in the first section with respect to directivity in reception, viz., increase of signal and reduction of interference.

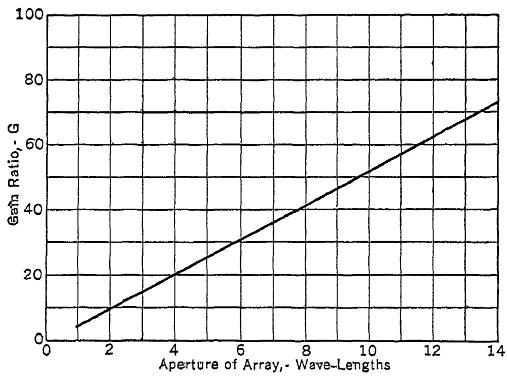

FIG. 14. Graph for Predicting Directivity of Arrays of Simple Half-wave Antennas. (Aperture is expressed in wavelengths and is one-half wavelength greater than the horizontal distance between the extreme outside antennas.)

The main problem in medium-frequency broadcasting which leads to the use of directional antennas is the difficulty of giving local coverage without causing interference at distances of a few hundred to a few thousand miles with other transmitters using the same frequency. This long-distance interference is propagated by reflection from the ionosphere, and therefore not only azimuth but also elevation must be considered. Regardless of the height of the reflecting layer, the azimuth of waves between two points lies along the great-circle path with considerable consistency, and an antenna which directs a minimum of signal at all elevations in the vulnerable azimuth is usually the most desirable solution. Sharp nulls in the elevational directive pattern are thus to be avoided if possible in view of the variability in the heights of the reflecting layers. Often, however, a host of practical considerations requires a compromise solution. (See reference 6.) Commonly, also, the problem is complicated by the existence of more than one vulnerable direction. The necessity of having the correct relative phases in the unit antennas has required the development of techniques for controlling, measuring, and maintaining phases in practical installations. (See reference 7.)

DIRECTIONAL CHARACTERISTICS OF LONG WIRES. When the length of a wire carrying a high-frequency current is progressively increased, it breaks up into oscillating sections as was shown in Fig. 1*i*. This gives rise to radiation along certain preferred directions in which in-phase components prevail. Figure 15 shows the directional patterns for certain representative cases. It will be noted that the lobe designated as No. 1 ear becomes progressively sharper and approaches the axis of the wire. At the same time smaller lobes designated as No. 2, 3, and 4 ears are formed.

Several long wires each having characteristics of this kind may be so combined as to give the arrangement as a whole very useful directional properties. In general, this is accomplished by choosing arrangements that enhance the main lobe and at the same time discourage the spurious lobes. The so-called tilted wire, folded wire, and rhombic antennas are based on this principle. (See reference 8.)

EFFECTS OF SOIL AND TERRAIN ON DIRECTIVITY. The directive effects described above assume that the array is divorced from any influence of the earth. In practice, of course, this is not true. If the earth were perfectly conducting the array could be so elevated as to make the image effect add to that of the array, thereby giving added gain and a maximum intensity along the surface of the earth. These ideal conditions are seldom attained in practice. At the frequencies at which directive antennas are most used, there is a substantial refractive effect in addition to absorption that together tend to distort the vertical directive characteristic.

Figure 16 shows the calculated directional distortion imposed by imperfectness of earth conductivity on both a horizontal and a vertical receiving doublet for a representative case. It is to be noted that the effect is less marked with a horizontal half-wave antenna than with a vertical half-wave, and in both forms it is such as to cut down very materially the intensities of waves along the horizontal. It fortunately happens that distant signals

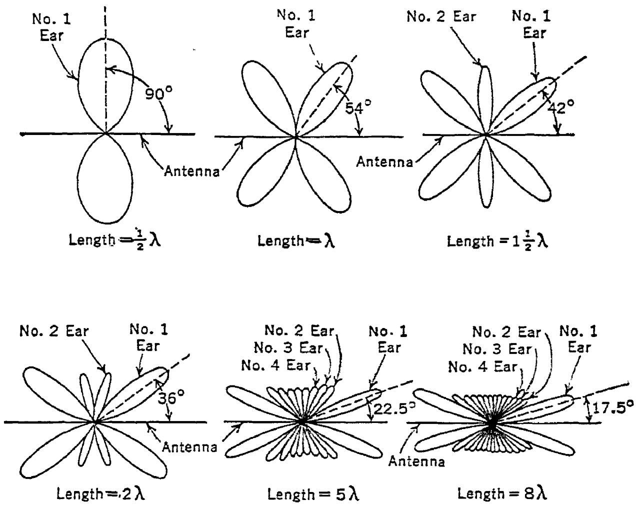

FIG. 15. Directional Diagrams of Isolated Wires of Various Lengths

arrive at an appreciable angle above the horizon, so that such devices are still very effective. While this angle for transmission and reception of short waves may, for short distances, be nearly 90°, for long distances it varies, say, from 30° for the lower frequencies to very small angles for the higher frequencies. It would appear, therefore, that the distortion of the vertical directive pattern caused by a soil of finite resistivity might constitute a definite limitation in working with very high-frequency stations. It is seen from Fig. 16 that horizontal antennas are inherently high-angle devices and that vertical antennas may also be high-angle devices except when located over a low-loss earth.

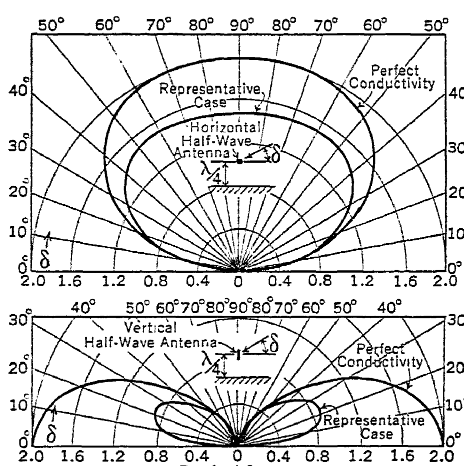

FIG. 16. Vertical Directional Diagrams of Horizontal and Vertical Half-wave Antennas as Influenced by Finite Conductivity of Earth

Advantages ranging up to 10 db (see reference 9) have been obtained by locating short-wave antennas and arrays at the tops of sharp declivities or long slopes. These gains are comparable with those of the arrays themselves and are such as may warrant considerable time in the selection of the site of a short-wave radio station. They may be explained either as due to the antenna being in a position where the field distribution is more favorable or by saying that the declivity has effectively lowered the angle of elevation of the antenna itself.

As the factors that effect vertical directivity vary markedly from point to point over the country it is difficult to present any considerable number of representative data in the space here available. However, both terrain and soil conditions are important in antenna design and should be considered when any large expenditures are to be made.

30. DIRECTIVITY OF QUASI-OPTICAL ANTENNAS AND HORNS

(See reference 4)

THE HUYGENS SOURCE. The optical concept of wave propagation according to which a wave front is considered an array of secondary sources is of great importance in analyzing the behavior of quasi-optical antennas. A formulation consistent with fundamental electromagnetics has been given by S. A. Schelkunoff (reference 1, 9.1 and 9.24). Commonly its usefulness arises in situations like that, for example, at the mouth of an electromagnetic horn, where we have reason to believe that the currents represented by the wave front predominate in ultimate effect over currents elsewhere, such as those on the outside of the horn. If we know the distribution of intensities over this aperture, Huygens' principle can be applied. In general, over this surface, polarization is distributed in both the x and y directions, but for simplicity we write the equation for only the first of these. Assuming the dimensions of the aperture great enough to give sharp directivity, we are mainly concerned with directions not far removed from the center of the main beam, which is near the axis of the reflector. Under these conditions the field at a distance r in front of the mirror is parallel to E_0 in the aperture and is given by the expression:

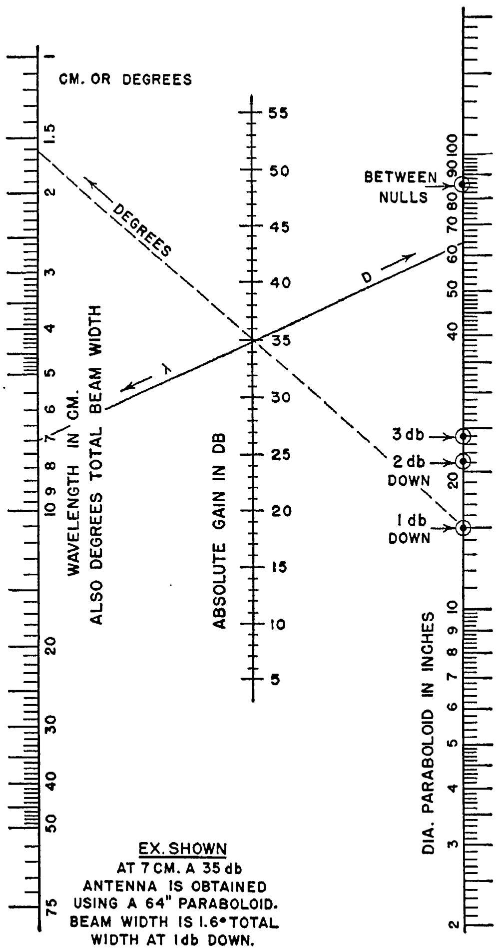

FIG. 17. Nomogram—Paraboloid Antenna Data

$$\mathcal{E}_x = \frac{i}{\lambda}\int\!\!\int \frac{\mathcal{E}_0 e^{-2\pi i r/\lambda}}{r}\, dS$$

dS being the element of area of the aperture, and λ the wavelength.

THE APERTURE. The theoretical performance of a non-dissipative antenna, which as a transmitter has a uniformly equal distribution of E_0 over its aperture, is useful for comparison with actual transmitting or receiving antennas. It can be shown from the above equation (see reference 10) that for reception its effective area equals the actual area of its aperture. In other words, it can be expected to capture from the wave all the energy "intercepted." Note, however, that antennas in reception usually cannot do this, since as a rule they do not, in transmitting, produce a constant E_0 over the whole aperture, and since, moreover, they may not be large enough compared with a wavelength to validate our assumptions. As applied to transmitting, the term effective area may be interpreted as the area of uniform excitation which would give the same field at the same distance and with the same total power as would the actual antenna.

In practice the effective area of large apertures is usually considerably less than the actual area, and the ratio is an "efficiency" factor which usually lies within the range 0.4 to 0.7, the deficiency being due primarily to the non-uniformity of intensity across the aperture. It should be observed that requirements other than gain may make it necessary to avoid uniformity across the aperture, such as the desirability of suppressing minor lobes of the directional pattern.

Other points in connection with the aperture are: (1) whether or not the amplitude is uniform, it is usually important that both phase and polarization be the same at all points in a plane perpendicular to the desired direction of transmission; (2) the width of the

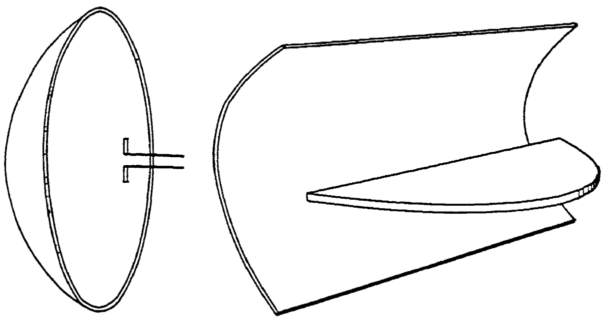

FIG. 18. Examples of Cylindrical and Spherical Optics

aperture a of a broadside antenna is inversely as the angular beam width required in the plane containing that dimension. At the half-power points the beam width is 51 λ/a in degrees for uniform illumination through a rectangular aperture and for non-uniform illumination of circular or elliptical apertures it is typically 65 λ/a. The gain and beam width of circular apertures having tapers of illumination commonly used at present are given in the nomogram, Fig. 17. When the beam width required is different in the two planes, the aperture widths are affected inversely, an elliptical shape being common. (See reference 11.)

Although the operation of most microwave directional antennas is best understood in terms of generation of a plane wave front, there are notable exceptions, such as linear end-fire arrays and polyrods.

POINT SOURCES AND LINE SOURCES. In transmitters and receivers, the power is conveyed to and from the antenna in transmission lines which are smaller than a

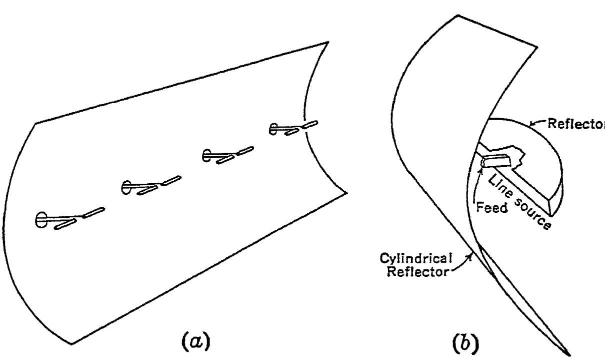

FIG. 19. Cylindrical Collimation

wavelength in cross-section, whereas in the antenna the dimensions may be of many wavelengths. The antenna must, therefore, include a distribution system. This may consist of a branching system, such as that used commonly in arrays. In most microwave antennas it consists of a "primary feed" or radiator which launches a wave, this wave then being allowed to spread in azimuth and elevation simultaneously (spherical optics), or in azimuth and in elevation successively (cylindrical optics). The latter two processes are indicated in Fig. 18.

In spherical expansion the wave must first be launched by a primary feed antenna which is basically a point source. Examples will be given later. When, on the other hand, successive cylindrical expansion is used, the wave from a point source is usually first confined between closely spaced plates and allowed to expand in a plane, and then the line of the wave front is converted from a circular arc to a segment of straight line; thereafter, the three-dimensional wave front expands from this line as a cylinder whose elements are parallel to it. These operations may be followed in the example given in Fig. 18 or 19*b*. The line source can be formed in other ways, such as a linear array of half-wave antennas, thus avoiding the first step of cylindrical expansion (Fig. 19*a*).

COLLIMATING DEVICES: REFLECTORS AND LENSES. Starting with the energy diverging from a point source, some device is needed to convert the wave front to a plane, that is, to make the emergent "rays" parallel. For this purpose reflectors or lenses are used.

(a) Parabolic Reflectors. The choice between a paraboloid and parabolic cylinders (see Fig. 18), depends on many mechanical and electrical considerations. In the past, the paraboloid has been the more used. Among the advantages sometimes claimed for it are greater electrical simplicity, lower weight and better efficiency, better directional pattern in the desired polarization, and adaptability to conical lobing or spiral scanning.

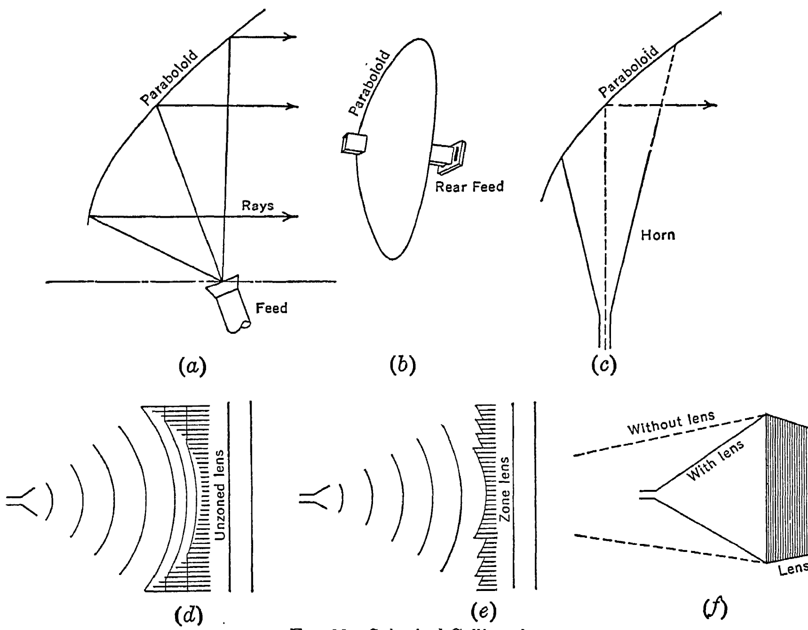

Fig. 20. Spherical Collimation

The cylinders, on the other hand, may be simpler mechanically and possess separate control of directivity in azimuth and elevation, a point of controlling importance in some applications.

For both types of parabolic reflectors, the feed is located at or near the focus, and the section used may be symmetrical about the axis or off to one side (usually the former).

(b) Lenses. Dielectric lenses can be used, and they have found considerable application in the first step of cylindrical expansion described above, i.e., in the formation of line sources, low-loss polymers being commonly used as dielectric. For spherical optics, however, such a lens becomes too massive. W. E. Kock (see reference 12) has developed other types of lenses particularly suitable for microwave use, for example that which employs metal plates instead of dielectric material. All lenses depend on having a material in which the phase velocity is different from that of surrounding space. If a plane wave were incident on a bottomless metallic honeycomb in a direction parallel to the cells, it would pass through more or less unimpeded if the frequency were above the critical frequency of the individual cells considered as wave guides. However, the phase velocity in these wave-guide cells would be greater than that of light, and the material as a whole would therefore possess a refractive index less than unity. Lenses can, therefore, be constructed by grading the depth of the cells in a manner analogous to that of optical lens practice, with this difference, that a form which causes divergence in a lens of glass will produce convergence in a lens of this cellular material; for example, a planoconcave cellular lens can be used as a collimator. If the wave is linearly polarized the cell spaces may be made indefinitely wide in the direction of the electric vector, the lens then becoming an assembly of spaced metallic plates; if in this case, however, the electric vector is made perpendicular to the plates, the wave passes through but with substantially the velocity of light, so that the device does not act as a lens. The lens can be given a stepwise reduction in thickness by means of "zoning," the "riser" of the step being that length of wave guide necessary to include one cycle less than a corresponding distance in free space. (See Fig. 20.)

HORNS. Just as the hollow wave guide is the analog of the speaking tube, so the electromagnetic horn is the analog of the acoustical horn in function as well as in appearance. It is usually the tapered extension of a metallic wave guide, as shown in Fig. 2*a* and *b* though it can be excited in other ways.

As in parabolic reflectors, the directional properties and gain of horns are determined by the excitation across the aperture, and the considerations given at the beginning of

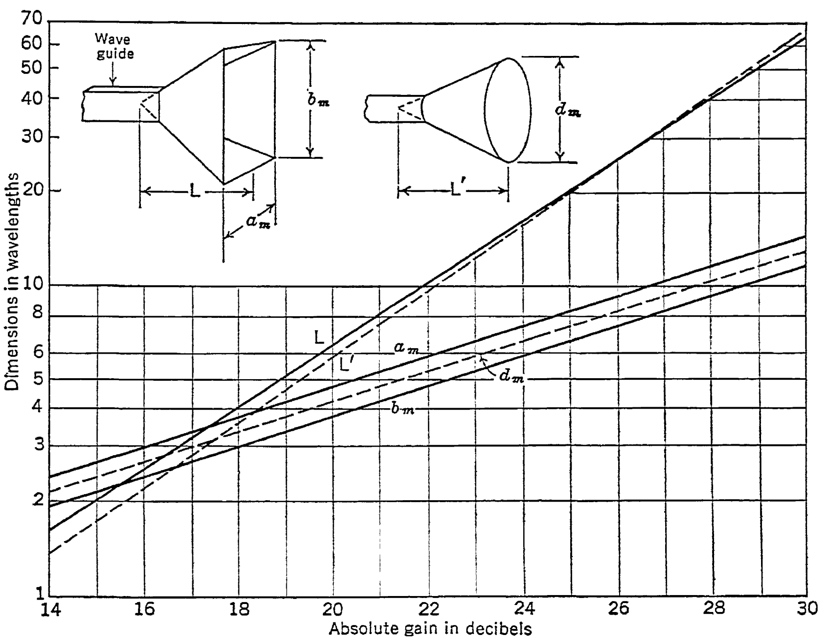

FIG. 21. Optimum Horn Data. The electric vector is parallel to the dimension b_m

this article on "The Aperture" apply approximately. The distribution of intensity in the aperture of horns tends to be uniform in the E plane and sinusoidal in the H, a condition resulting from the maintenance of the distribution natural to a small wave guide in passing from the throat through the taper to the aperture. Roughly then the half-power beam width in the E plane of large horns approximates 51 λ/a_E, and in the H plane 65 λ/a_H, provided that a, the aperture dimension, is larger than one wavelength.

The phase at the center of the aperture of a pyramidal horn tends to lead that at the edge owing to the difference in distance to the throat. For a given size of aperture this phase difference approaches zero as the length is increased, and the best length is infinity since any phase difference tends to reduce the gain. In a simple horn, therefore, the length is more likely to set a practical limit than the aperture, and for a given practical length it is often important to know the flare or aperture that will give greatest gain. This "optimum horn" can also be defined as the minimum length of horn that will give a required power gain. It does not provide greatest efficiency of aperture area but deliberately tolerates an increase in area for a decrease in length.

Figure 21 gives the essential dimensions of optimum horns, conical and pyramidal, which are taken from the article by A. P. King. (See reference 13.) The area efficiency of a large conical optimum horn is about 55 per cent; that of a very long horn of the same aperture is near 80 per cent. (See reference 13.)

Among the forms of horn are the conical, biconical, sectoral, and pyramidal. Horns can be used with lenses to avoid the undesirable phase difference across the aperture. Solid or metal plate lenses may be used. The advantage of a lens is that it very greatly reduces the length of the horn for a given aperture. (See Fig. 20.)

31. PRACTICAL ANTENNA SYSTEMS

In modern radio practice the highest frequencies are more than one million times as great as the lowest, extending as they do beyond the range from 30,000 cycles to 30,000 megacycles. We have emphasized the unity of principle within this gamut of frequency. On the other hand, in covering the field of practical antennas it is necessary to examine types in great diversity. Space prevents any attempt to be comprehensive. In this article we can consider only representative antennas which illustrate different engineering problems to be met in practice.

ANTENNAS FOR LOW FREQUENCIES. In Fig. 1*e* and *f* are shown prototypes of antennas important during the first two decades of "wireless," antennas which still are of practical importance below 1000 kc. Their common characteristic is the use of a flat-top

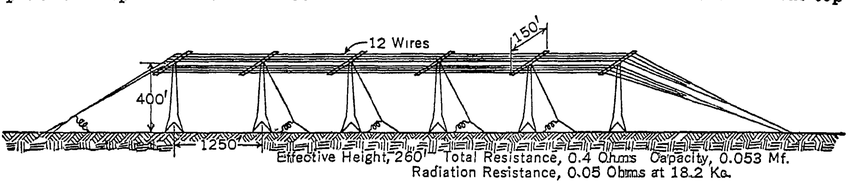

Fig. 22. Typical Multiple-tuned Antenna

and a down-lead, but these have taken on many special forms—L, T, umbrella—with single or multiple down-leads. Except in favored situations (e.g., on board a ship), it has been necessary to build more or less elaborate ground systems comprising buried wires or an overhead "counterpoise" in order to raise the radiation efficiency to an acceptable value, and even then this efficiency might at the lowest frequencies be only a few per cent. Two general methods of improving efficiency are, first, to increase the height of the towers used (increase radiation resistance), and second, to use ground systems as already stated, frequently accompanied by multiple tuning (decrease the ground losses). Figure 22 shows an Alexanderson multiple-tuned antenna having six multipled down-leads and six tuning coils; its effectiveness depends on the fact that, although the ground resistances associated with the various down-leads act as though in parallel to give a low resultant ground resistance, radiation resistance is not correspondingly reduced. Obviously structures built on so large a scale are very expensive and have to be designed with great attention to economic factors. (See reference 14.)

Figure 23 shows an antenna installation for a 150-kc land station such as has been used in communication with ships at sea.

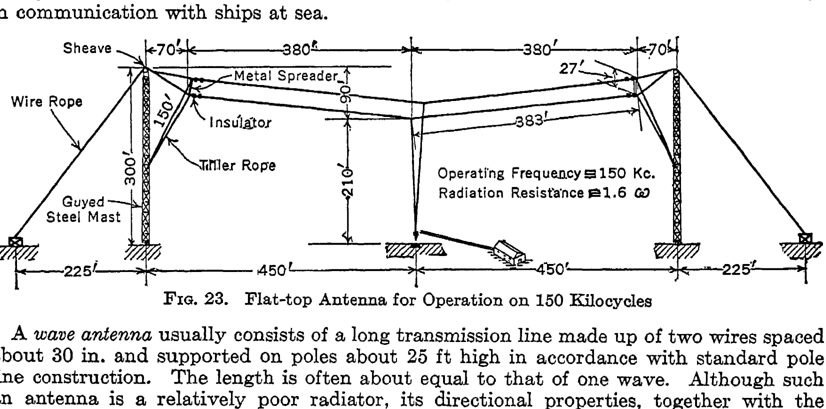

Fig. 23. Flat-top Antenna for Operation on 150 Kilocycles

A *wave antenna* usually consists of a long transmission line made up of two wires spaced about 30 in. and supported on poles about 25 ft high in accordance with standard pole line construction. The length is often about equal to that of one wave. Although such an antenna is a relatively poor radiator, its directional properties, together with the rather wide band of frequencies which it can accommodate, make it exceedingly useful in long-wave work. In particular, when used as a receiver, it is able to discriminate markedly against static arriving from other than the preferred direction of reception.

This provides a favorable ratio of signal to static. Because of its broad frequency characteristic it is possible to attach two or more receivers and simultaneously receive several frequencies. These signals must, of course, be arriving from the same general direction. The directional characteristic depends among other things on soil resistivity. Such antennas have not proved particularly effective in regions of high rainfall and high conductivity. Several wave antennas may be placed in broadside array as described above or they may be placed one back of another and sidestepped to form a staggered array.

Figure 24 shows in schematic form a wave antenna and its associated terminating network. The impedance Z is equal approximately to the characteristic impedance of the

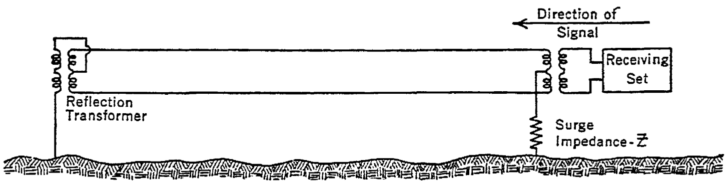

FIG. 24. Schematic of Wave Antenna. (The length may be as much as a mile, the height about 25 feet.)

antenna. This prevents reflection and renders the device essentially unidirectional. The reflection transformer shown is an ingenious means whereby the accumulated signal received between the two wires and ground may be transmitted back to a receiver located at the incident end, over the metallic circuit consisting of the two wires themselves. (See reference 15.)

ANTENNAS FOR MEDIUM-FREQUENCY BROADCASTING. Resonant antennas of the general type discussed in the previous sections (e.g., Fig. 23) have been used in broadcasting. A more common form, however, uses a tower or mast itself as the current-carrying conductor and radiator. Some of the forms which it takes, shown in Fig. 25, illustrate its basic simplicity. The self-supporting towers may be of constant cross-section or tapered to a point at the top. The masts, supported by guys sectionalized by insulators to prevent them from taking part as radiators, are commonly tapered over the lower fraction of their height to a single compression insulator and ball-and-socket joint at the base. The upper portion of the mast may be tapered toward the top, but a top without this taper is probably more common. (See reference 16.)

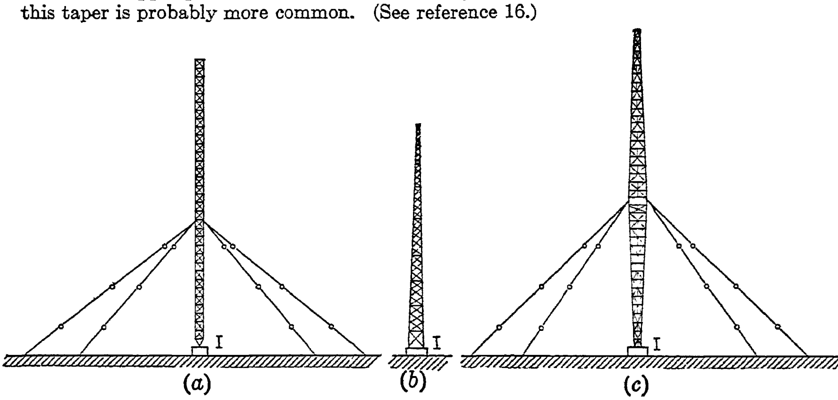

FIG. 25. Typical Forms of Broadcast Antenna

All the antennas shown in Fig. 25 are insulated at the base. There is a form called the "shunt-fed antenna" (see reference 16), however, in which the tower is connected directly to the ground network. The feed wire is connected, not at the base, but sufficiently far above it to include an appreciable tower inductance.

For daytime coverage in this frequency range the desideratum is a strong field in the horizontal direction, since waves leaving in an upward direction are ineffective either for good or for ill because they are absorbed by he ionosphere. Assuming antenna resistance to be confined to radiation and current to be distributed sinusoidally, the maximum horizontal field theoretically is obtainable when the height of the radiator is $^5/_8$ wavelengths

(225 electrical degrees, assuming that length of wave on the tower is the same as in free space). As shown in Fig. 11, however, such an antenna will have a strong minor lobe at 30° from the vertical, and at night when ionospheric absorption tends to disappear waves may thus be received strong enough to be comparable with the ground wave. Undesirable fading may then be as serious as insufficient field strength would be, particularly in the upper half of the daytime frequency range. It has, therefore, become the practice to use radiators of that height and current distribution which gives the best compromise between field strength and freedom from fading, and tower heights from 0.53 to 0.55 λ (190° to 200°) are widely used. (See reference 6.)

The considerations of directional pattern just described aim to protect the station's listeners from its own sky wave. At points beyond the normal ground-wave range are receiving sets tuned to other broadcasters operating on the same frequency, and they must be protected from interference. New minima of signal strength in the elevation plane must therefore be provided in that azimuth, and in view of the great distances of the receivers the minima must be aimed far from the vertical, typically in the order of 75°. For this purpose arrays of antennas are common; such arrays for broadcasting have been discussed above under "Directivity of Linear Conductor Antennas: Arrays." The proper design of such an array is a matter of some complication; not only is the accurate locating of towers and the specifying of their relative currents an exacting matter for calculation but also the experimental realization of the desired amplitudes and phases in the presence of the large mutual impedances which exist between towers makes it necessary to provide means for accurately adjusting measuring and maintaining the currents both in amplitude and in phase. (See reference 7.)

SPECIAL ANTENNAS FOR BROADCAST RECEPTION. Many broadcast receivers are supplied with built-in antennas which, although inefficient as compared with the "custom-built" antennas that are feasible in point-to-point work, give adequate performance, thanks to the high gains of receivers and the surplus signal laid down most of the time by powerful transmitters. In the few cases where both received field and atmospherics are below set noise advantage may be taken of large antennas. If the antenna is located where the ratio of ambient noise to ambient signal is too great, it can frequently be relocated in a quieter spot remote from the receiver and may be connected to the receiver by a shielded transmission line. This is sometimes done in apartment houses, a broad-band amplifier then being employed to permit distribution to a large number of users. In the nature of the case broadcast reception of medium frequencies does not ordinarily permit the use of much directivity. (See reference 17.)

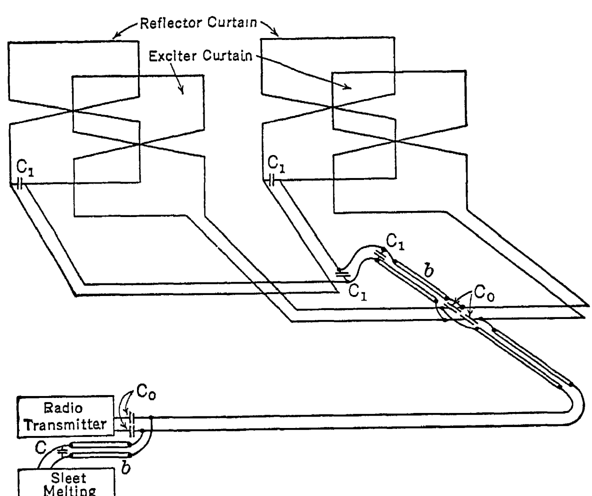

FIG. 26. Arrangement of Conductors and Impedance Matching Devices in a Sterba Array

ANTENNAS FOR HIGH FREQUENCIES (2500 TO 25,000 KC). In this band of frequencies, almost exclusively used for long distances, the wavelength is small enough to make directivity feasible. Formerly the majority of directional-antenna installations employed broadside arrays of half-wave elements operative over a relatively narrow band of frequencies. Many of these have been replaced by some form of long wire, which gives considerable directivity at moderate cost and is sensibly aperiodic so that it may be operated at several frequencies simultaneously. Resonant antennas still find use, however, for example, where space considerations do not permit the more extended aperiodic types.

Figure 3 shows schematics of various forms of broadside array. Several types of curtain arrays were described by C. S. Franklin, two of which are shown in the figure. Figure 26 shows in somewhat greater detail the Sterba array, including feed lines, impedance matching devices and provisions for sleet melting. (See reference 5.) As will be noted by tracing the connections, it is possible without interrupting service to apply a 60-cycle power to this antenna for purposes of melting sleet, a provision found in earlier forms of linear conductor antennas (e.g., Fig. 22).

It has already been pointed out that the directional characteristic of a long straight wire may be used to produce antennas of marked directivity. Two forms are represented in Fig. 27. The one at the left, called a "rhombic" antenna (E. Bruce, reference 8), presents

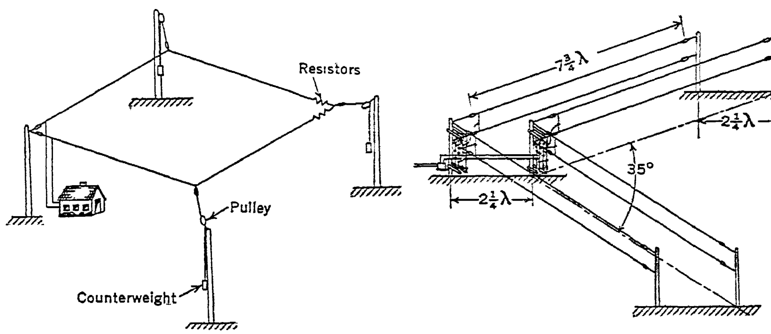

FIG. 27. Alternative Forms of Folded Wire Arrays

an impedance to the terminal equipment which has a constant resistive value, making it suitable over a wide frequency range (typically 2 to 1) provided that the accompanying shift of directivity is appropriate to the medium of propagation; in transatlantic work it is a fortunate circumstance that the higher frequencies used by day call for a more nearly horizontal ray than the lower frequencies used at night, making such an antenna suitable for a wide range of conditions. When the antenna is used for transmitting a considerable power has to be dissipated in the terminating resistance. For details of the resonant-V antenna shown at the right of Fig. 27, as well as several other interesting types, reference may be made to Carter, Hansell, and Lindenblad (reference 8). Long wires are also used in the vertical plane for directional effects, as in the "inverted-V antenna" shown in Fig. 28.

An interesting application of array principles to reception of transoceanic telephony is afforded by the Musa receiving antenna, the arrays of which are constructed with rhombic antennas as the units. (See reference 18.) Over routes such as this, radio waves of high frequency usually travel by several paths simultaneously and arrive at different angles above the horizontal. These components arrive with unrelated radio-frequency phases and even with differences of time delay which are significant in the audio range (of the order of a few tenths of a millisecond). The Musa antenna (Multiple-Unit-Steerable-Antenna) takes advantage of the spread in angle of arrival to separate the component waves, which may then be used singly, or in "diversity reception," or combined with audio delay correction, etc. Since the waves are more reliably distinguished by differences in vertical rather than azimuthal angle of arrival, the unit antennas are arranged along the great-circle path rather than in broadside array. One antenna used commercially has 16 unit rhombic antennas in an array 2 miles long. The combining of units is not done in the radio-frequency circuits, but it is accomplished at intermediate frequency through the medium of a common beating oscillator. A multiple system of phase shifters permits the separation and simultaneous reception of the different components provided that they are sufficiently different in angle of arrival.

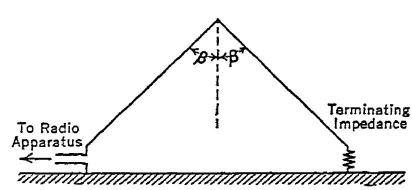

FIG. 28. Inverted-V Antenna

ANTENNAS FOR VERY HIGH AND ULTRA HIGH FREQUENCIES. The extensive application in point-to-point and mobile services of frequencies above 30 Mc has led to a diversity of antenna types. Figure 29 illustrates a few types useful for vertical electrical polarization and suitable for mounting on a pole. Except for one insulator which is specifically labeled, all lines shown represent conductive material, insulators being omitted in the interest of simple representation. The lower portion of (*a*) is the coaxial which feeds the upper $\lambda/2$ section at the middle in a series connection (the whole feed-line current flows into the antenna). The portion of large diameter does not touch the outer conductor of the feed line except at the top, an arrangement which tends to minimize waves standing on the supporting pole. In Fig. 29*b* there is a metallic conection between the top of the skirt and all adjacent parts; the feed is accomplished by bringing the inner conductor of the feed line through a hole in the outer one at a point inside the skirt which is protected from the weather. Figure 29*c* and *d* indicates two J-shaped antennas in which the radiating

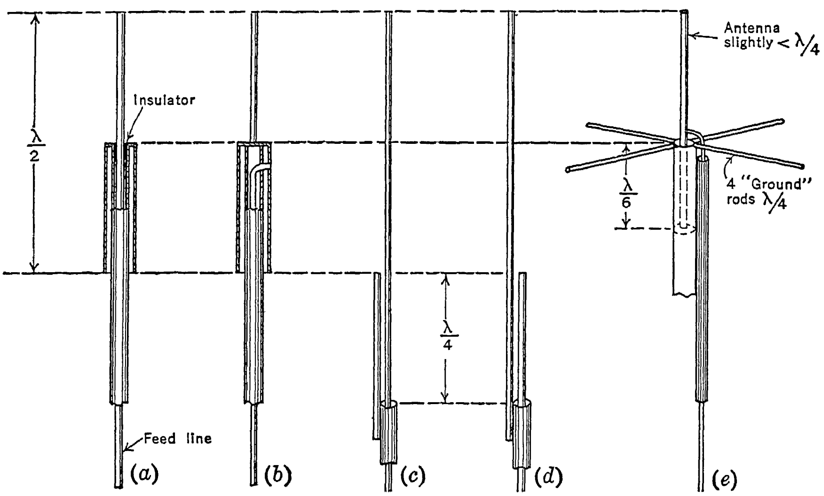

FIG. 29. Omnidirectional Antennas Using Vertical Polarization

section is the upper half-wave of one of the feed lines above the point where the other ends. (See reference 19.) Figure 29*e* shows a horizontal cross of four ground rods at the top of a large supporting cylinder, in the hollow end of which is mounted an inner conductor extending above it somewhat less than a quarter wavelength, the point of connection of the coaxial line being such as to match impedances. The section below this connection point provides a strong mechanical support for the radiating member above. (See reference 20.)

When horizontal polarization is used in ultra-high-frequency broadcasting there are several antenna types which may be considered. With this polarization it is easier than with vertical to increase the gain by "stacking." Several types are indicated in Fig. 30.

The "turnstile" antenna is shown in Fig. 30*a*. (See reference 21.) Essentially it has two half-wave horizontal radiating members crossed at 90° and phased in quadrature. It is fed by a system of transmission lines. When equal currents are used in the two radiators, the directional diagram in the horizontal plane is a circle deformed somewhat toward a square. The vertical separation between stacked elements is one-half wave. The turnstile antenna has been adapted for broad-band use by employment of large conductors and careful attention to detail. A cross-section of such an antenna on the Empire State Building is shown in Fig. 30*b*, where the cigar-shaped conductors and the adjacent central parts are surfaces of revolution about the lines *AC* and *BD*. Separate transmission lines are provided at *F* for each of the four radiators. (See references 21 and 24.)

Figure 30*c* is an "Alford loop," which is in the form of a horizontal square the length of whose edge is a matter of design, but which, for descriptive purposes, may be taken as of the order of one-third wavelength. Current is supplied as shown, the currents in the four radiating members being equal in magnitude and alike in phase as shown by the arrows in the diagram. In stacking a vertical spacing of one-half wave is used.

Figure 30*d* shows a circular antenna (see reference 22) which also is substantially a loop antenna. The two circular radiating conductors indicated are electrically broken at *B* by a parallel-plate condenser without loss of mechanical continuity and strength, the whole assembly being capable of support from point *A*. The lower circle is broken at *C*, from which point the system is fed in the manner of the "folded dipole," the "electrical length" of the circumference (taking account of the loading capacitance *B*) being one-half wave. Physically the circumference is less than this. This loop is attached to a vertical pole at *A* and is thus metallically grounded. The pole is inside the loop. The horizontal directional

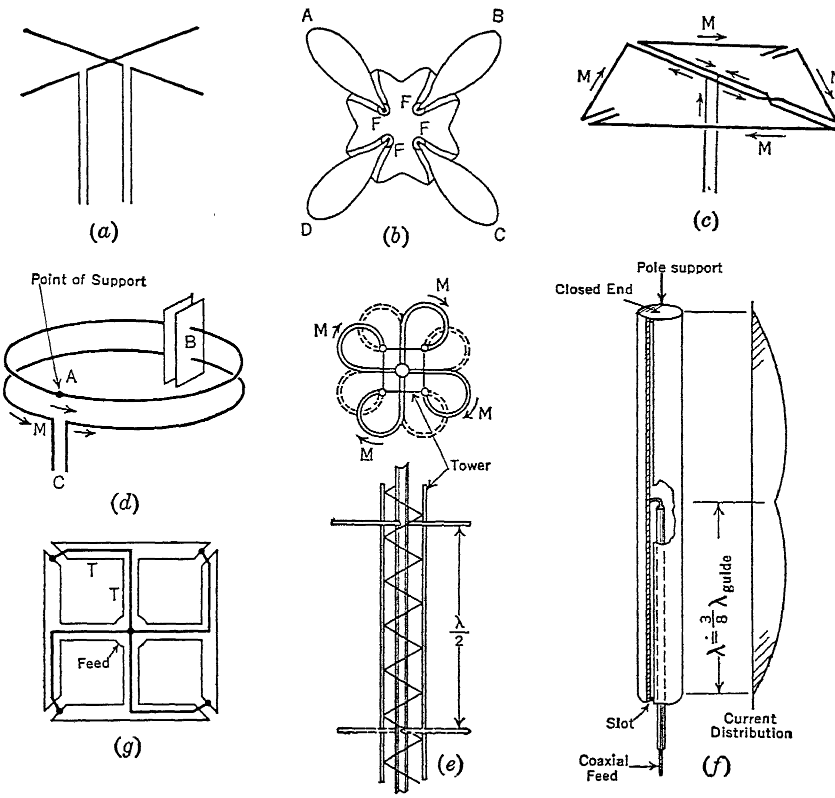

FIG. 30. Nondirectional Antennas Using Horizontal Polarization

pattern is elliptical, the maximum difference in field strength being somewhat less than 2 db. When these units are stacked the vertical spacing is one wavelength.

The "cloverleaf" antenna, due to P. H. Smith (reference 24) is shown in Fig. 30*e*. This consists of a slender tower (e.g., square) in the form of a conventional structural-steel lattice. Up the center is a conductor, which, together with the tower itself, forms a coaxial transmission system. The radiating "leaves" are attached as shown, forming a composite horizontal loop. The length of each of these conductors is about 0.4 λ. In stacking, a half-wave interval is used, and, because of the resulting phase reversal, a clockwise loop has counterclockwise loops immediately above and below it. Within a range from 88 to 108 Mc one antenna can be changed from one frequency to another by varying the vertical spacing between loops of one standard size. The horizontal diagram is substantially circular.

The "rocket" antenna, described by Andrew Alford and shown in Fig. 30*f*, is a vertical cylinder, metallically closed at both ends (in the form shown), but having an open slot along one element of the cylinder. It is fed as shown at the point where the cylinder is cut away by establishing a voltage across the slot. It may be thought of as a "lossy" wave guide supporting a transverse-electric mode, the critical frequency of which is (1) considerably less than that of the dominant mode of an unslotted cylinder owing to participation of the slot and of the space outside the cylinder in the propagation of the wave, and (2) somewhat less than the operating frequency. The metallic ends produce a standing-wave pattern which gives an approximation to uniform vertical distribution of radiating current over the outside, except near the ends. The antenna is in external effect somewhat like a vertical distribution of horizontal loops. In stacking the units are placed in close proximity. The field varies some 3 $^1/_2$ db in different azimuths. The diameter is somewhat less than one-half wavelength, and the driving-point impedance is tuned by folding the edges of the slot in. The "pylon" is a self-supporting antenna employing somewhat the same electrical principle.

A horizontal square loop employing an interesting coaxial feed system has been described (see reference 23) and is shown in Fig. 30*g*. The sides of the square are electrically 180° in length, and adjacent sides are fed at each corner in a pushpull manner from a vertical coaxial lying along the axis of symmetry, as shown. The "quarter-wave" sections T between the feed points and this coaxial also provide impedance transformation.

See reference 30 concerning some other antennas of interest in this frequency range.

MICROWAVE ANTENNAS. Practical microwave antennas employ many component devices in various combinations, but we can here recognize only general forms without elaboration. Brevity may lead to omission of types of greater future importance than those included, but this is unavoidable in a field so young and lusty.

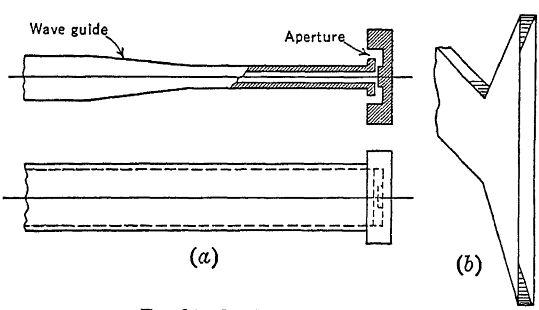

FIG. 31. Typical Point Sources

Devices used in the method of spherical optics are illustrated in Fig. 31, which depicts two point sources, and in Fig. 20, which shows corresponding methods of collimation (production of parallel rays). Figures 31*a* and 20*b* show a rear feed in which the energy comes through the wave guide from the left and is emitted from the two apertures *toward* the left. (See reference 26.) Where applicable, rear feeds for reflectors provide a desirable method of mechanical support without serious interference with the electrical functioning either of itself or of the reflector.

Conditions often dictate a "front" feed. Wave-guide apertures or horns are frequently used. One of the latter is illustrated in Fig. 31*b*, a sectoral horn in which the electric vector might with appropriate design be either vertical or horizontal. The horn shown could suitably be used with a paraboloidal reflector having an elliptical or rectangular shape, the greater dimension being the left-right one (note that this horn radiates a beam which is considerably wider horizontally than vertically if the aperture has a vertical dimension greater than a wavelength). A wave guide whose open end faces the reflector is often used (with or without a flare) particularly where the paraboloidal reflector subtends large angles both in elevation and azimuth.

When the feed is located in the path of the reflected wave, as in Fig. 20*b*, part of the energy will re-enter it and travel back along the transmission path into the transmitter. This may be great enough to cause trouble. One of the solutions for this difficulty is indicated in Fig. 20*a*, where the portion of the reflector which might cause a wave to be returned to the feed is omitted, and the feed, which is at the focus, is directed toward the active reflecting surface. A similar solution in which the path from feed to reflector is enclosed in a horn is indicated in Fig. 20*c*. Figure 20*d* shows how the spherically expanding wave from a point source can be collimated by a metal plate lens, such as has been described above. A lens in which zoning has been introduced to reduce lens thickness is indicated in Fig. 20*e*, while *f* suggests the advantage of a lens in shortening a highly directional horn.

Figure 19 illustrates some principles of design involving cylindrical optics. Figures 19*a* and 19*b* include line sources employing a linear array of dipoles and a sectoral parabola excited in the TE_{01} (rectangular) mode respectively. (Note that, according to the accepted convention, the designation TE_{10} of the most common mode in rectangular wave guides gives place to TE_{01} when the dimension parallel to the electric vector becomes greater than the other dimension of the cross-section.)

In some applications, such as air-borne radar, it may be necessary to have in azimuth a sharp concentration, and in elevation a wide spread of signal having intensity distributed according to some definite function of elevation angle. When this distribution gives uniform response along the ground the antenna is termed a *cosecant antenna.*

32. DIRECTION FINDING

Almost every type of directional antenna has, at some time or other, been used for direction finding, but there are a few types which are of especial importance due to their widespread use. (See reference 27.) Among those used in the lower frequencies are the loop in various forms and the Adcock antenna. Microwaves have their own distinctive methods, such as "lobing" and "scanning." The directivity may be in the receiver or in the transmitter, and in radar it is commonly used in both simultaneously.

The loop (see Fig. 1*k*) has great simplicity to recommend it but also these objectionable features to be avoided: it does not distinguish sense (e.g., east from west); it is sensitive to so-called antenna effect (response to electric vector independent of direction of arrival of the wave); and errors are found when the arriving waves have a downward direction.

Signals arriving in a horizontal direction induce emf's in a loop in proportion to its area and the magnetic field of the wave. At long waves most loops are small compared with a wavelength, and therefore they tend to pick up only small signals. This bona fide emf is therefore subject to interference from a spurious signal derived from the electric rather than the magnetic field (a more acceptable statement would be "from $\mathcal{E}$ rather than from

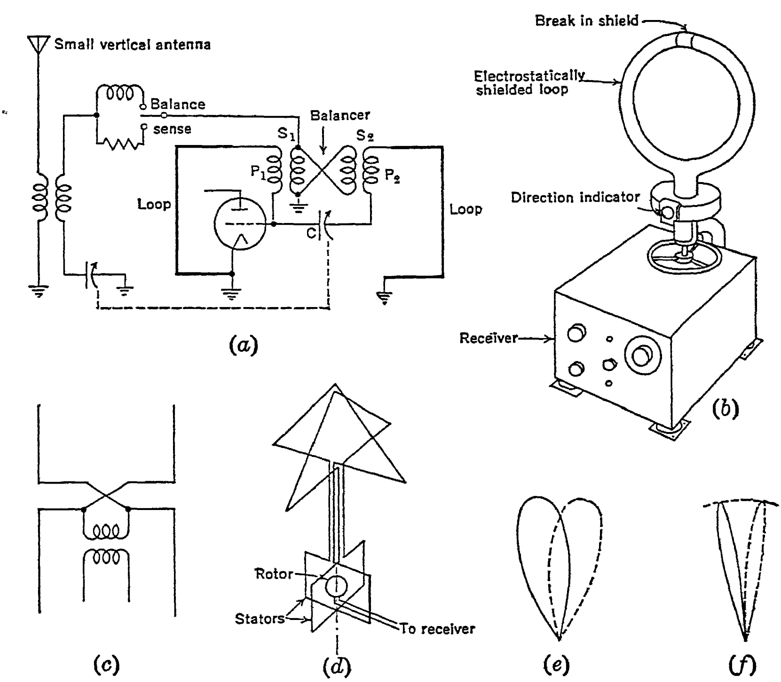

FIG. 32. Methods of Direction Finding

$\partial\mathcal{E}/\partial x$"). Although loops ideally possess symmetry which will suppress this component, as a practical matter it is likely to be an important source of error. Figure 32*a* (see reference 28) shows an application of a method for overcoming this difficulty by the addition of a signal from an auxiliary small vertical antenna to balance out this antenna effect, thus obtaining sharp nulls. The same circuit has provision by switching for altering the phase of the added signal by 90°, so that it aids one of the loop maxima and opposes the other, thus establishing the sense (east or west). A practical embodiment of this type of circuit is shown in Fig. 32*b* (see reference 28). It illustrates the important method of using a shielded loop to reduce the effect of local induction fields and to preserve electric symmetry.

The third kind of loop error occurs when the direction of arrival is not horizontal and there has been some rotation of the plane of polarization. It is really due to pick-up in the horizontal wires of the loop and can be combated by essentially getting rid of them. The Adcock antenna illustrated in Fig. 32*c* avoids this difficulty by eliminating the horizontal members and feeding the vertical ones by a shielded transmission line.

Figure 32*d* depicts the Bellini-Tosi loop method of direction finding in which the loops are fixed. By means of shielded transmission lines (usually horizontal rather than as shown in the figure) and a goniometer, the direction can be determined in an operating room somewhat removed from the antenna itself, which in this case may be a large one.

Figure 32*e* illustrates the principle of "lobing," in which by one of several devices the direction of beam can be alternated between the positions of the solid and the dotted lines. When the antenna is oriented so that the signals are equal, the intersection of the lobes indicates the direction. This is the method used in many radars.

Still another method is scanning, as indicated in Fig. 32*f*, where the beam, preferably very sharp, is swept periodically through a given range. The direction of maximum response gives the desired information.

33. MISCELLANEOUS

Antenna-testing methods are being studied by the Antenna Committee of the Institute of Radio Engineers, 1 East 79 Street, New York 21, N. Y. The report, when issued, will represent a much more complete document than that issued by the Committee in 1938. See reference 29. From the same source there is now available "Standards on Antennas, etc. Definitions of Terms," price 75 cents.

For information on *transmission lines* see reference 25.

For information on *antennas for aircraft* see reference 31.

SECTION 7

VACUUM-TUBE CIRCUIT ELEMENTS

VACUUM-TUBE CIRCUIT ELEMENTS

AMPLIFIERS

By Loy E. Barton

An amplifier is a device for increasing the energy associated with any phenomenon without appreciably altering its quality.

Amplifiers used in communication circuits almost invariably employ thermionic vacuum tubes as the amplifying elements. The vacuum tube is practically a pure resistance device at low frequencies. As the frequency increases to a point where the interelectrode capacity impedance becomes appreciable with respect to the internal resistance of the tube a phase shift is introduced which alters gain or amplification.

At still higher frequencies the time required for the electrons to reach the plate is appreciable with respect to a quarter cycle. When this transit time is about 20 to 30 electrical degrees the amplifier characteristics are modified considerably. These amplifiers still fall in one of the three basic classes of amplifiers.

A class A amplifier is an amplifier in which the grid bias voltage permits a steady plate current flow of such a value that the plate current varies directly as the grid voltage for the complete cycle of 360 electrical degrees. The resulting output voltage for an ideal class A amplifier is an exact reproduction of the grid voltage.

The characteristics of the class A amplifier are low power output with a theoretical maximum plate power efficiency of 50 per cent and an operating efficiency of about 30 per cent or less at full power outputs. The plate dissipation is maximum at zero output, and the plate circuit output network may be tuned or untuned for an undistorted output. The average value of plate current does not change during the cycle so that the input plate power is constant.

A class B amplifier is an amplifier in which the grid voltage permits essentially zero plate current with no signal applied to the grid and the plate current is proportional to the grid swing when the grid swings in a positive direction from the bias point so that plate current flows for approximately 180 electrical degrees.

The characteristics of the class B amplifier are comparatively high power output with a theoretical maximum plate efficiency of 78.5 per cent; in practice the efficiency approaches 65 per cent at full output. The plate dissipation is a minimum and is comparatively low at zero signal, increasing rapidly to approximately constant value at about 25 per cent full output. However, the power input to the plate increases, with signal and power output, until the peak output is reached. Therefore, the plate current is a variable and the plate supply voltage should have good regulation. The class B amplifier may be used as a single-tube tuned-plate circuit amplifier or the plate circuit may be untuned provided two tubes are used in a pushpull manner with appropriate input and output transformers.

A class B_1 amplifier is an amplifier biased and operated as a normal class B amplifier except that the grid swing does not go into the positive region.

In general such an amplifier uses low-mu tubes in order that high plate currents may be reached without driving the grid into the grid-current region. The efficiency of this amplifier is lower than that of an amplifier in which the grid is driven to plate-current saturation, and the power output is lower. However, the grids take no power so that input circuit losses and distortion may be low.

A class AB_1 amplifier is an amplifier so biased that the pushpull tubes act as a class A amplifier for low grid swings and go into class B_1 operation at higher grid swings. The grids are not driven positive.

The only advantage of this type of operation is that somewhat higher outputs may be obtained for a given plate dissipation than can be obtained for class A operation and a cathode resistor can be used for self-bias. However, distortion is comparatively high.

A class AB_2 amplifier is similar to the class AB_1 amplifier except that the grids are driven into the positive region for higher outputs.

The characteristics of the class AB_2 amplifier are much the same as those of the class AB_1 except that the power output is higher, and the grid driving problem is about equal to that of the class B amplifier.

A class C amplifier is an amplifier in which the grid bias voltage is appreciably higher than the bias required for plate-current cutoff, and the plate current flows for a period less than 180 electrical degrees during the half cycle when the grid swing is positive with respect to the bias voltage. The grid swing is usually to the point of plate-current saturation, in which case the rms plate current is proportional to plate voltage and is not proportional to the grid voltage.

The characteristics of the class C amplifier are high power output and an average plate efficiency in practice of 70 to 75 per cent, which may reach 85 to 90 per cent under special conditions. (See Fig. 35, p. 7-27, and discussion.) The theoretical maximum efficiency for the class C amplifier is 100 per cent.

1. CLASS A AMPLIFIERS

GENERAL USE. The class A amplifier is used for audio-frequency and radio-frequency voltage amplification, principally because the output voltage is a direct function of the input voltage. The amplifying action of the vacuum tube follows from the equations developed for its plate current in Section 5. If all the terms but the first in eq. (17), p. 5-43, are negligible, the voltage drop due to the plate current of the vacuum tube flowing through an external impedance is

$$e_z = zi_{pa} = \mu e_g \left[\times \frac{z}{r_p + z} \right] \tag{1}$$

or for a particular component of periodicity ω_m

$$E_z = \frac{\mu E_g z_m}{r_p + z_m} \tag{1a}$$

This voltage is a *magnified* replica of the grid voltage and is said to be amplified.

The voltage amplification is the ratio of the change in voltage across the external load to the change in input voltage, or

$$\text{V.A.} = \frac{\mu\sqrt{r^2 + x_m^2}}{\sqrt{(r + r_p)^2 + x_m^2}} = \frac{\mu z_m}{z'_m} \tag{2}$$

if there is no drop in the external grid circuit. Two special cases are of interest: First, when the load is a pure resistance; V.A. $= \mu r/(r_p + r)$ which will equal 0.9 μ when $r = 9r_p$. Second, when the load is a pure reactance, V.A. $= \mu x_m/\sqrt{r_p^2 + x_m^2}$, which will approximate 0.9 μ when $x_m = 2r_p$.

The power amplification is the ratio of the power delivered by the output circuit to the power supplied to the input circuit, or

$$\text{P.A.} = \frac{\mu^2 r z''^2}{[(r_p + r)^2 + x_m^2](r_i + r_e)} \tag{3}$$

where z'' is the total impedance in the grid circuit.

For small power outputs, the power amplification is very high and is usually limited only by the input circuit losses.

Cascade Amplifiers. The limitations of voltage and power amplification obtainable with one tube make it frequently desirable to use two or more tubes in cascade by coupling the plate circuit of the first tube to the grid circuit of the next tube, etc. Each tube with its associated circuits is called a *stage* of the amplifier, and the whole is termed a multistage or cascade amplifier. Cascade amplifiers are usually classified by the method of coupling used.

The amplification per stage is defined as the ratio of the grid voltage of one tube to the grid voltage of the preceding tube. This is frequently expressed in decibels.

For the resistance-coupled amplifier shown in Fig. 1, it is

$$\text{V.A.} = \frac{\mu}{\dfrac{r_p r_{i2}}{z_{i2}^2} + \dfrac{r_p}{r} + 1 - j\dfrac{r_p x_{i2}}{z_{i2}^2}} \tag{4}$$

For low frequencies, and when the grid biasing voltage is always negative, the amplification limit per stage of this type of amplifier is μ.

$$\text{V.A.} = \frac{\mu r}{r_p + r} \tag{5}$$

A direct resistance coupled amplifier of the type shown in Fig. 1 is used when it is necessary that a d-c voltage be amplified. It will be noted that the required B voltage increases with each stage and that independent filament supplies are needed for direct-heated tubes. In the case of indirectly heated cathodes a separate heater supply is usually needed because of the excessive heater cathode potential.

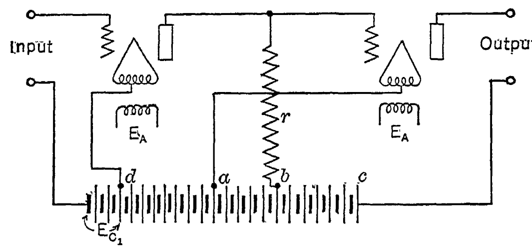

FIG. 1. Direct Resistance Coupled Amplifier, Common B and C Batteries, Separate A Batteries

The amplification per stage of the resistance-capacitance coupled amplifier shown in Fig. 2 is

$$\text{V.A.} = \frac{\mu}{\dfrac{z_c + r_p}{z_{i2}} + \dfrac{z_c + r_p}{r_K} + \dfrac{r_p z_c}{r r_{i2}} + \dfrac{r_p z_c}{r r_K} + \dfrac{r_p}{r} + 1} \tag{6}$$

in which z_c is the reactance of the coupling condenser C. A reactance may be substituted for either r or r_K, or both, in which case these constants are changed from r to z in eq. (6).

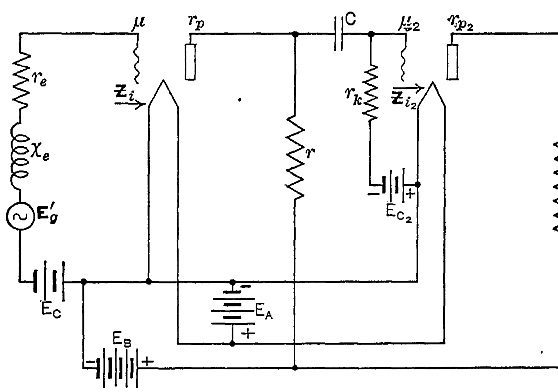

FIG. 2. Resistance-capacitance Coupling

If the input impedance to the second tube is very high and the impedance of the coupling condenser negligible eq. (6) reduces to

$$\text{V.A.} = \frac{\mu}{\dfrac{r_p}{r_K} + \dfrac{r_p}{r} + 1} \tag{6a}$$

from which it is seen that the higher the resistance of the parallel combination of r and r_K the greater the realized amplification will be. The limiting value of r_K is usually 1 megohm or less, so that it is of little value to make r greater than 75,000 to 100,000 ohms.

The plate voltage supply must be great enough to operate the tube at a desirable point and to supply the drop in the load resistor in order to obtain maximum voltage in the succeeding tube. A lower plate supply voltage may be used with a corresponding reduction of bias if maximum voltage output is not required. This will have little effect on the amount of amplification obtained.

Cascade operation of two or more resistance-capacitance coupled audio amplifier stages is subject to a low-frequency oscillation or "motor-boating," resulting from a feedback of low frequencies due to the common a-c impedance of the plate supply at frequencies so low that the filter condensers are not effective. To correct the motor-boating difficulty, it is usually necessary to limit the low-frequency response or isolate one or more of the resistance coupled stages. The low-frequency response is most easily reduced by decreasing the size of the coupling condenser (C in Fig. 2).

A transformer-coupled amplifier is shown in Fig. 3 and its equivalent circuit in Fig. 4. In the equivalent circuit, account is taken of the distributed capacitances (C_2 and C_5)

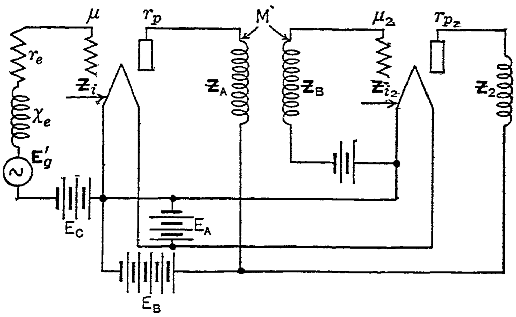

FIG. 3. Transformer Coupled Amplifier

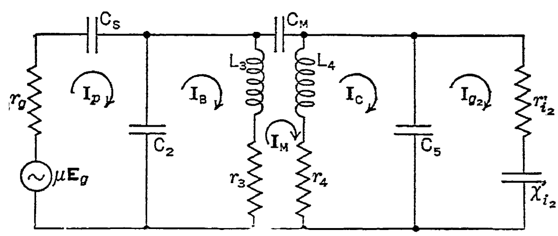

FIG. 4. Equivalent Circuit of the Transformer Coupled Amplifier of Fig. 3

of the windings and of the distributed capacitance (C_M) between windings. The transformer windings are assumed to be poled so that the effect of this latter is a minimum. The voltage amplification of each stage is then

$$\text{V.A.} = \frac{\mu z_M z_{i2}}{\left[z_i + \left(\dfrac{z_i + jx_2}{jx_2}\right) z_x\right]\left[z_{i2} + \left(\dfrac{z_{i2} + jx_5}{jx_5}\right) z_y\right] + \left(\dfrac{z_{i2}}{x_5} + j\right)\left(\dfrac{z_1}{x_2} + j\right) z^2_M} \quad (7)$$

where

$$z_M = \frac{z_3 z_4 + \omega^2 M^2 + \dfrac{M}{C_M}}{z_3 + z_4 - j2\omega M - \dfrac{j}{\omega C_M}}$$

$$z_x = \frac{z_3 z_4 + \omega^2 M^2 - j\dfrac{z_3}{\omega C_M}}{z_3 + z_4 - j2\omega M - \dfrac{j}{\omega C_M}}$$

and

$$z_y = \frac{z_3 z_4 + \omega^2 M^2 - j\dfrac{z_4}{\omega C_M}}{z_3 + z_4 - j2\omega M - \dfrac{j}{\omega C_M}}$$

Note that if the incidental resistances of the transformer windings are neglected z_M, z_x, and z_y are all pure imaginaries.

The maximum value of V.A. with respect to x_5 occurs under two conditions: one value (infinity) will give maximum value of V.A. for all frequencies; the other value, dependent in a complicated manner on the mesh parameters, will give a maximum for only one particular frequency. The same result is found when x_2 is considered the variable. These correspond to the cases of tuned and untuned transformers. (See p. 6-08.)

When substantially equal amplification is required over a broad frequency range the distributed capacitance should be made as small as possible. Assuming x_2 and x_5 infinite and C_M zero, eq. (7) reduces to

$$\text{V.A.} = \frac{\mu\omega M z_{i2}}{(z_1 + z_3)(z_{i2} + z_4) + \omega^2 M^2} \tag{7a}$$

By tuning primary and secondary circuits as shown in Fig. 5, the maximum amplification (at one frequency only) is

$$\text{V.A.} = \frac{\mu z_{i2}}{2\sqrt{(r_p + r_3)(r_{i2} + r_4)}} \tag{7b}$$

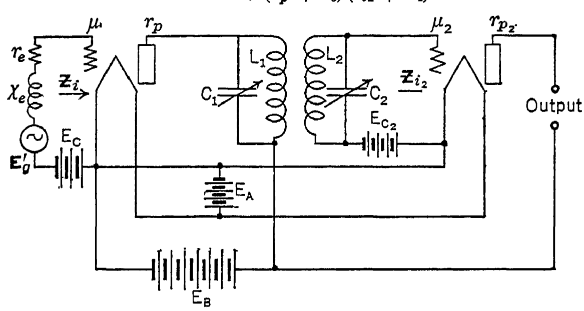

FIG. 5. Tuned Transformer Coupled Amplifier

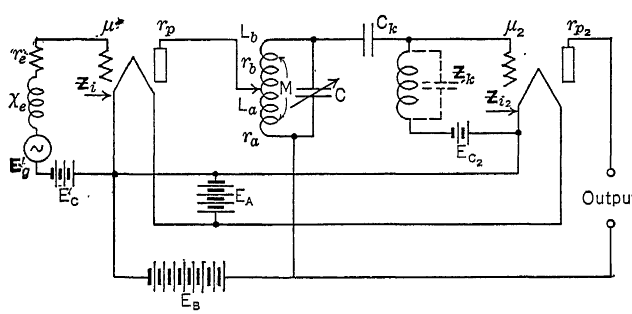

FIG. 6. Tuned Coupling. The tuned circuit is L_a–L_b–C. The coil Z_k and the capacitor C_k are inserted to get proper bias on the grid tube 2.

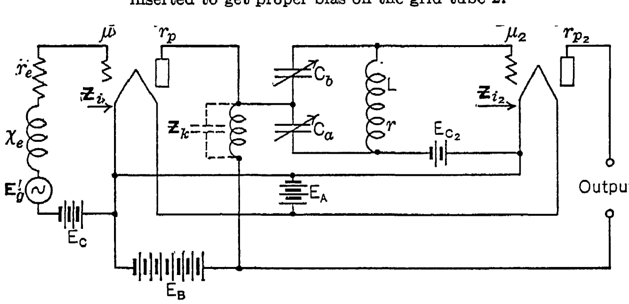

FIG. 7. Tuned Coupling. The tuned circuit is C_a–C_b–L. The coil Z_k is inserted to get proper potential on the plate of the first tube.

Other forms of tuned amplifiers are shown in Figs. 6 and 7. For the resonant frequency the amplification of the circuit of Fig. 7 is

$$\text{V.A.} = \frac{\mu}{\left(\frac{r}{z} - \frac{j\omega L}{z_{i2}}\right)(1 + j\omega C_a r_p) + \frac{j}{\omega C_a z} + \frac{j}{\omega C_a z_{i2}}} \tag{8}$$

where $z = r + j\omega L$.

Performance. Certain tube characteristics are supplied by the tube manufacturers (see Section 4) which are used to predict the performance of tubes as class A amplifiers; representative curves and tube constants will be given herein with sample calculations of performance. A typical general-purpose triode is the 56-type tube whose plate characteristics are given in Fig. 8. It will be noted that each curve of plate current against plate voltage is drawn for a given grid or bias voltage denoted as E_c. From these curves, the various constants of the tube may be calculated as explained in the section on vacuum tubes. The constants for the 56, as calculated from Fig. 8, at approximately 238 volts at the plate, 13.5 volts bias, and 5 ma plate current, are plate resistance (r_p) equals 10,000 ohms, amplification factor (μ) equals 15, and the grid plate transconductance (s_M) equals 1500 micromhos.

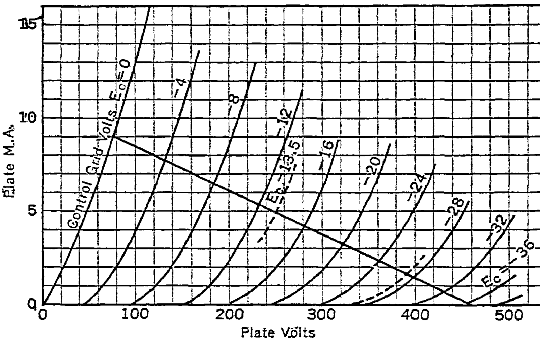

FIG. 8. Type 56, Plate Characteristics

INPUT CIRCUIT CALCULATIONS. A typical circuit for the 56 tube as a transformer-coupled audio amplifier is shown in Fig. 9 and its approximate equivalent in Fig. 10. If the tube used in Fig. 9 is the 56 type with characteristics as shown in Fig. 8, and its various constants are as indicated above, the constants of the circuit and performance of the tube may be calculated as follows:

The self bias resistor, r_1, is calculated for a 13.5-volt operating grid bias voltage with 5 ma plate current, in which case, according to the curves in Fig. 8, the voltage across the terminals marked minus and plus for plate supply should be 250 volts and the actual plate voltage will be about 236.5. The value of the resistor, r_1, is $13.5/0.005 = 2700$ ohms.

The by-pass condenser, C_1, must effectively by-pass r_1 at the lowest audio frequency desired so that the pulsating plate current through r_1 will not generate an audio voltage appreciable compared to that applied to the grid. The voltage across r_1 is out of phase with the input voltage so that the low-frequency gain may be lower than the gain at other

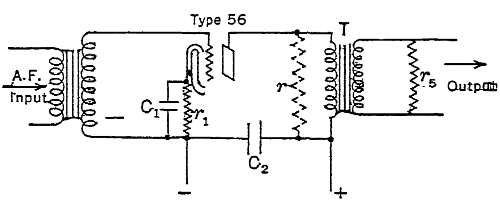

FIG. 9. Transformer-coupled Class A Amplifier

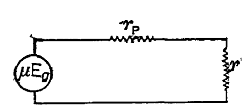

FIG. 10. Equivalent Circuit for Fig. 9

frequencies if the impedance of C_1 is large. The capacitance, C_2, across the plate supply may be the plate-supply filter condenser but, in any case, must have sufficiently low impedance at the lowest desired frequency to by-pass the plate supply effectively unless the a-c impedance of the plate supply is very low.

OUTPUT CALCULATIONS. The dotted resistance r in Fig. 9 is the equivalent impedance (as nearly unity power factor as possible) of the primary of the transformer, T, with the load resistance, r_5, transferred from the secondary into the primary. It will be noted that r is in series with the plate of the tube and may be represented by a load line drawn through the operating point at 5 ma plate current and 13.5 volts bias in Fig. 8.

The proper value for this resistance is obtained by drawing a line through the operating point and the point on the zero grid voltage curve representing the maximum desired value of the operating plate current (in this case 9 ma, since experience has shown that an 80 per cent change in plate current is a reasonable value to assume). A check along the load line as drawn indicates that, if the grid swings in a negative direction to double the grid voltage of 13.5 volts, the decrease in plate current is only 3.2 ma, approximately.

This load line represents approximately 43,000 ohms and is r as shown in Fig. 9. The approximate second harmonic under these conditions may be calculated by the following formula:

$$\left.\begin{aligned}\frac{I_{b\,\max} + I_{b\,\min} - 2I_b}{2(I_{b\,\max} - I_{b\,\min})} &= \text{per cent second harmonic approximately}\\ &= \text{5.5 per cent for 80 per cent increase in plate current as assumed above}\end{aligned}\right\} \quad (9)$$

in which I_b is the "no-signal plate current," $I_{b\,\max}$ is the peak plate current, and $I_{b\,\min}$ is the minimum plate current.

Note that if the maximum current change is equal on each side of the operating value the second harmonic is zero, since $(I_{b\,\max} - I_b) - (I_b - I_{b\,\min}) = 0$. If intermediate points are considered and it is found that equal grid-voltage increments do not cause equal plate-current increments throughout the range, higher harmonics will be present. (See p. 5-47.)

The average power output may be calculated by the following formula, which is readily derived from peak values of a-c voltages and currents.

$$\frac{(I_{b\,\max} - I_{b\,\min})(E_{b\,\max} - E_{b\,\min})}{8} = \left.\begin{array}{l}\text{power output or 0.28 watt approximately,}\\ \text{for full grid swing in the above case}\end{array}\right\} \quad (10)$$

in which $E_{b\,\max}$ is the maximum plate voltage and $E_{b\,\min}$ is the minimum plate voltage.

The theoretical maximum $I_{b\,\max}$ for the class A amplifier is $2I_b$, and the minimum $I_{b\,\min}$ is zero. The corresponding theoretical maximum $E_{b\,\max}$ is $2E_b$, and the minimum $E_{b\,\min}$ is zero.

The plate power input is expressed by the formula E_bI_b = watts input. Therefore, the plate efficiency at maximum output is

$$\text{Pl. eff.} = \frac{(I_{b\,\max} - I_{b\,\min})(E_{b\,\max} - E_{b\,\min})}{8E_bI_b} = 23 \text{ per cent} \quad (11)$$

The load resistance is

$$r = \frac{(E_{b\,\max} - E_{b\,\min})}{(I_{b\,\max} - I_{b\,\min})} = 43{,}000 \text{ ohms approximately} \quad (12)$$

The total plate voltage swing is approximately 314 volts, and the total grid swing is 27 volts, which is

$$\frac{(E_{b\,\max} - E_{b\,\min})}{(E_{c\,\max} - E_{c\,\min})} = \frac{314}{27} = 11.6 \text{ approximate actual amplification by the tube} \quad (13)$$

In the above circuit the transformer T may be designed as a voltage coupling transformer to supply a secondary load as high as 200,000 ohms or more, an output impedance which is not particularly difficult to obtain especially if a choke voltage feed is used as shown in Fig. 11, so that the d-c plate current does not go through the transformer pri-

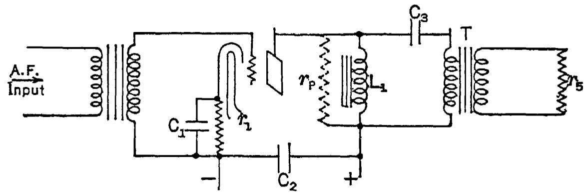

FIG. 11. Shunt Transformer-coupled Amplifier

mary. The turn ratio would be the square root of the impedance ratio or a turn ratio of the primary to secondary of at least 2.2. The total amplification of this amplifier stage including the transformer is 11.6 × 2.2 = 25.5, approximately.

The above condition is also approximately the condition for maximum power output. If the calculated distortion is too high, the grid swing may be reduced with a corresponding reduction of power output. In actual practice, the grid swing is usually very small if the amplifier is used as a voltage amplifier so that maximum voltage output is not obtained but the voltage amplification is the same; in such a case the second harmonic may be negligible (far less than 1/2 per cent).

PERFORMANCE CALCULATIONS FROM TUBE CONSTANTS. Referring to the equivalent circuit shown in Fig. 10, the voltage amplification of the combination of Fig. 9 and Fig. 8 may be calculated from the constants of the tube by means of the following formulas:

$$\text{V.A.} = \frac{\mu E_g \left(\dfrac{r}{r_p + r}\right)}{E_g} = \mu\left(\frac{r}{r_p + r}\right)$$
$$= 12.2 \text{ gain without transformer} \tag{14}$$

in which E_g is the rms grid voltage and the other constants are as defined above.

The power output for full grid swing of 13.5 volts peak or an rms value of 9.6 volts is

$$\text{P. out} = \frac{\left[E_g\mu\left(\dfrac{r}{r_p - r}\right)\right]^2}{r_p} = 0.27 \text{ watt} \tag{15}$$

It may be seen that, by using the constants of the tube in the equivalent circuit of Fig. 10, the performance calculations do not differ materially from the performance calculated from the curves in Fig. 8. The small discrepancy may be accounted for by the fact that the constants of μ and r_p used in eqs. (14) and (15) are obtained by using smaller increments of voltage and current changes than are used in eqs. (10) and (13); in other words, the effect of distortion is neglected.

It will be seen that, if the circuit shown in Fig. 9 is used, the only difference between a voltage and power amplifier is the design of the transformer, T, which in a voltage amplifier works into a high resistance and in a power amplifier works into the desired load, the turn ratio being chosen to present the same equivalent primary impedance.

If in the resistance coupled amplifier the load resistance is 43,000 ohms, the gain is the same as calculated for the above case if $r_K \gg r$. The same load line as shown in Fig. 8 may be used provided the plate supply voltage is equal to the value indicated by the intersection of the load line and the zero plate-current axis. This plate voltage is approximately 460 volts instead of the 250-volt supply for the transformer-coupled case.

POWER OUTPUT AND PLATE EFFICIENCY. In the operation of vacuum tubes as amplifiers (also as oscillators, or detectors) at low power levels it is usually desirable to get as much *output signal power* as possible from a given tube regardless of the *plate efficiency* (the ratio of the output signal power to the input plate supply power). Under such conditions there is usually one of two parameters limiting the power output, namely, the input signal voltage in amplifiers and detectors, or the plate supply potential in the case of all vacuum-tube operation.

When the input signal voltage is the limiting factor, and the tube is operating over a linear part of its characteristic (for detectors this means linear with respect to its detection characteristic—see Detectors, p. 7-76), the vacuum tube can be considered a generator with an internal resistance. Then the maximum power output occurs when the load is a pure resistance equal to the internal resistance.

Frequently the input voltage available is large enough so that for the given plate supply voltage the introduction of distortion is the limiting factor. Using the Taylor's series development of the plate current up to and including the second power term, Warner and Loughren (*Proc. I.R.E.*, Vol. 13, 709 [1925]) showed that under these conditions the maximum undistorted power output is obtained when the load was resistive and equal to twice the internal resistance. Experiment has generally shown this to be approximately correct for amplifiers using low amplification triodes in class A operation but that no such simple rule applies in high-mu triodes, tetrodes, pentodes, and class B operation of triodes. The optimum value of load resistance is usually determined experimentally and forms part of the operating data furnished by the tube manufacturer.

When vacuum tubes are operated at high power levels it is usually economically necessary to consider the plate efficiency. This is given by the formula

$$\text{Eff.} = \frac{\dfrac{1}{T}\displaystyle\int_0^T i_0 e_0\,dt}{\dfrac{E_b}{T}\displaystyle\int_0^T i\,dt} = \frac{\dfrac{-r_L}{T}\displaystyle\int_0^T i_0^2\,dt}{\dfrac{E_b}{T}\displaystyle\int_0^T i\,dt}$$

where i_0 is the component of the current in the plate circuit having the desired output frequencies and amplitudes; e_0 is the corresponding voltage drop across the load z_L, the resistance component of which is r_L; i is the instantaneous value of the plate current; E_b is the plate supply potential; and T is a complete period of i.

When the current i is given in the form

$$i = I_0 + I_1 \cos \omega t + I_2 \cos 2\omega t + \cdots$$

the plate efficiency becomes

$$\text{Eff.} = \frac{I_1^2 r_L}{2E_b I_0}$$

when the fundamental is the desired frequency of the output power.

PUSHPULL AMPLIFIER. Figure 12 represents a pushpull amplifier, which has several advantages over the single-ended amplifier. A class A pushpull amplifier does not take a pulsating current from the plate supply for the ideal condition, and in practice the variation of supply plate current is negligible. This essentially constant plate current permits the omission of the bypass condenser that is required in a single-ended class A amplifier, shown as C_1 in Fig. 9. Another advantage of the pushpull amplifier is that the d-c magnetizing current in the primary of the plate transformer is balanced out, which simplifies the plate transformer design. (See p. 6-17.)

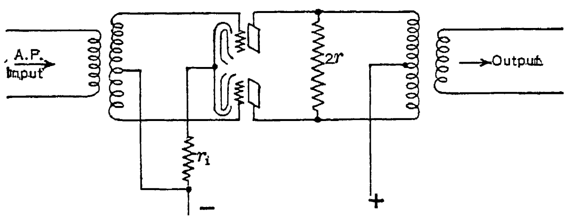

FIG. 12. Pushpull Amplifier

The equivalent circuit of the pushpull class A amplifier is shown in Fig. 13, which is similar to the circuit shown in Fig. 10, except that the resistances of both plates are in series with the load resistance. In order that the load resistance r of 43,000 ohms be obtained for the 56-type tube as discussed for the single-ended amplifier, it is necessary that the primary impedance of the loaded output transformer be 86,000 ohms, which is not very practical for voltage amplifier purposes, because of the large number of turns required in the primary. Another disadvantage of the pushpull voltage amplifier is that one-half of the total input voltage is available for each grid and the increased power output increases the output voltage into a given resistance by only approximately 40 per cent. Therefore, the actual decrease in voltage gain by using two tubes in pushpull-instead of one single-ended tube is about 20 per cent.

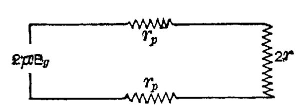

FIG. 13. Equivalent Circuit for Class A Pushpull Amplifier

The calculations of power output of the class A pushpull amplifier may be made by using eq. (10) or (15), if the results are multiplied by 2. The load resistance is calculated by multiplying eq. (12) by 2 so that the transformer primary impedance (plate to plate) is double the value obtained for a single-ended amplifier.

TRIODE VOLTAGE AMPLIFIER. The class A voltage amplifier in general uses a special high-gain type of tube instead of the general-purpose tube such as the 56. The tube characteristic desired is indicated by eqs. (13) and (14). The higher the amplification constant μ, other constants being equal, the higher will be the voltage amplification. Tubes designed primarily for voltage amplifiers of the triode type are the 240, 841, 85, 203A, and others. The general-purpose tube such as the 56 discussed in some detail also has quite extensive application as a voltage amplifier, where interstage coupling transformers are used. In general, the plate resistance of the high-amplification-factor tubes is quite high, so that such tubes are employed principally in resistance-coupled amplifiers. Because of the general use of screen-grid tubes as high-gain amplifiers the triode is becoming less common as a voltage amplifier except where coupling transformers are used.

TRIODE POWER AMPLIFIER. The above discussion applied primarily to the triode as a class A amplifier in which, in general, the grid is not driven into the positive region. With this limitation for grid excitation, it is seen from eq. (10) that the higher the plate-current swing for a given plate-voltage swing the greater will be the power output and correspondingly the greater the plate dissipation. Therefore, a power tube to operate as a class A amplifier, without positive grid swing, should be a low-plate-resistance tube with a correspondingly low amplification constant and capable of relatively high plate power dissipation. The various types of triode tubes primarily designed for the class A power output service are the 31, 45, 2A3, 842, 250, 845, 849, and 848. The type-31 tube is the small battery tube rated as 0.375 watt output; the 848 is a large water-cooled tube rated at approximately 1900 watts output as a class A amplifier.

A typical low-plate-resistance tube designed as a class A power output tube is the 2A3, the plate characteristics of which are shown in Fig. 14. Calculations similar to those made on the 56 tube indicate that about 3.5 watts output can be obtained from the 2A3 with a load resistance of 2500 ohms, a bias of 43.5 volts, a plate voltage of 250, and a plate dissipation of 15 watts at zero output. The plate dissipation decreases from full value at no signal to the full value less the output power with signal. The above 15-watt plate dissipation for the 2A3 decreases to 11.5 watts at full output.

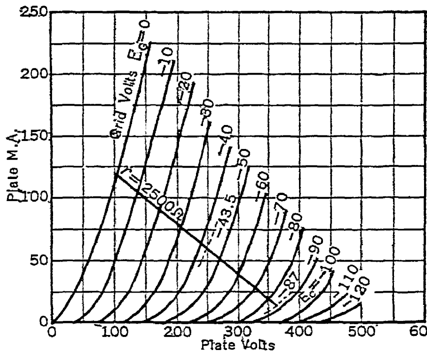

FIG. 14. Type 2A3 Plate Characteristics

PENTODE VOLTAGE AMPLIFIER. The class A pentode amplifier may be used as a voltage amplifier for audio or radio frequencies. The fundamental calculations of power output and determination of load (r) lines is essentially as discussed for the triode amplifier, but certain details of the calculations are different. One of the principal differences is that the amplification factor is much higher than the amplification obtained in practice because the plate resistance, r_p, of the tube is much higher than it is feasible to equal with a load resistance, r. Because of the very high amplification factor of pentodes as well as tetrodes with a correspondingly high plate resistance, eqs. (10), (12), and (13) are much more useful than eq. (14). The transconductance, g_m, for the pentodes and tetrodes is also quite useful in performance calculations.

Referring to the definition and means by which the transconductance was obtained (as given in Section 4), it will be noted that the condition for obtaining data for g_m calculations is that the resistance in series with the plate is zero or at least sufficiently low not to alter the observed plate-current change for a given grid-voltage change. It may be seen from the plate current characteristic of a type-57 pentode, as shown in Fig. 15, that the slope of a load resistance line drawn through the indicated operating point does not alter the plate-current change appreciably for a given grid voltage swing. This tube is used extensively for radio-frequency and audio-frequency high-gain amplifiers. Except where maximum power or voltage swing is desired, it is not necessary to use the plate-current curves to make performance calculations (except to prevent overloading), as such calculations can be readily made from the constants of the tube. For the conditions as given in Fig. 15, the transconductance at −3 volts bias is 1225 micromhos, the plate resistance is given as greater than 1.5 megohms, and the amplification factor is greater than 1500. It is obvious that, with the more or less indefinite amplification factor and plate resistance, the equations involving these constants are of little value in calculating the voltage gain in a 57 amplifier. However, since the g_m of the tube is definite within limits and the above constants are high, the plate-current change for a given signal E_g is: $E_g g_m = I_p$ and $I_p r = E_p$. Therefore, the voltage gain is

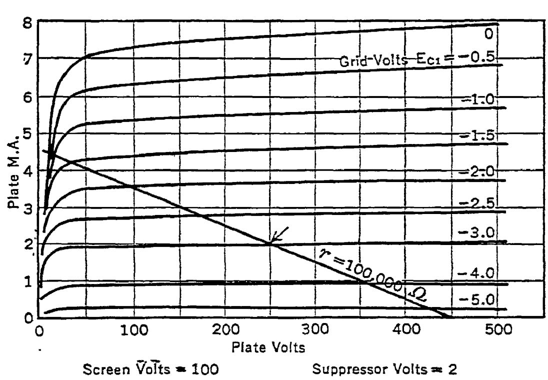

FIG. 15. Type 57, Plate Characteristics

$$\frac{E_p}{E_g} = g_m r = \text{Voltage gain} \tag{16}$$

For the assumed conditions and a load of 100,000 ohms the voltage gain is

$$1225 \times 10^{-6} \times 100{,}000 = 122.5$$

The above value of voltage amplification is approximately 6 per cent high if the plate resistance of the tube is 1.5 megohms, but such corrections are usually unnecessary unless great accuracy is required, and then it is advisable to measure the transconductance of the tube, as well as the plate resistance, at the point of actual operation. A decrease of load resistance to 50,000 ohms reduces the gain to approximately 50 per cent of the above calculated value, and the accuracy is greater because of the lower value of load resistance relative to the actual plate resistance.

In an audio amplifier it is possible to attenuate the high audio frequencies considerably if the load or coupling resistance is sufficiently high so that the shunting capacitances appreciably lower the impedance of r. These capacitances are the plate to suppressor grid capacitance of the 57 amplifier plus the capacitance of the tube or device to which the amplifier is coupled. The output capacitance of a 57-type tube as an audio amplifier is about 6.5 $\mu\mu f$, and the input capacitance to a similar following stage of amplification is about 5 $\mu\mu f$ or a total of about 12 $\mu\mu f$, the impedance of which is about 1.3 megohms at 10,000 cycles, which would not appreciably affect the above 57 amplifier with an r of 100,000 ohms, at the higher audio frequencies. As commonly used the voltage output from a 57 amplifier is so small that little non-linear distortion is introduced.

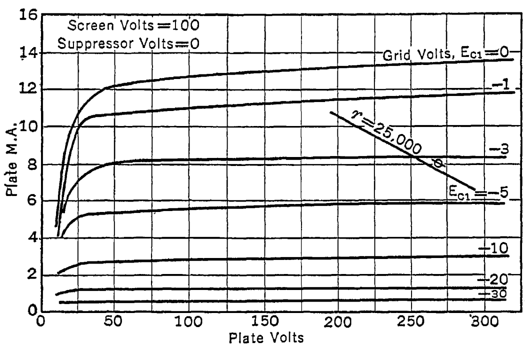

FIG. 16. Type 58, Plate Characteristics

If the tube is used as a radio-frequency amplifier, the plate impedance is obtained by a parallel-resonant, or an equivalent, circuit in series with the plate, and for known equivalent series impedance of the plate circuit the voltage gain may be calculated as indicated above. Since the tube resistance is very high, the selectivity of the amplifier for tuned output is essentially the selectivity of the tuned plate circuit.

VARIABLE-GAIN PENTODE VOLTAGE AMPLIFIER. The 57 tube just discussed is not well adapted to use as a variable-gain control tube by changes in the bias. A tube designed primarily for a bias-controlled variable-gain amplifier is known as the type-58 tube, the characteristics of which are shown in Figs. 16 and 17. Since the plate resistance of the tube is approximately 800,000 ohms or more, the gain as calculated by eq. (16) is quite accurate and the gain decreases as the negative grid-bias increases because the transconductance decreases for increased bias. The distortion in the output of this tube is greater than for the 57-type tube, and for this reason the 58-type is not generally used for an audio voltage amplifier. If the plate circuit of the 58 is tuned and the grid-voltage swing is not too great, little distortion results from the use of this tube in the radio-frequency system of a receiver. The bias may be supplied from an automatic volume-control system, the output of which supplies a bias that is proportional to the carrier value of the received signal, or may be controlled manually, or by a combination of the two. The type-58 or other tubes with the approximate exponential grid voltage vs. plate current characteristics (such as types 34, 35, 39, 78, 6C6) are almost universally employed in receivers so that a simple bias control may be used to control the sensitivity of the radio-frequency amplifier. (See Ballantine and Snow, *Proc. I.R.E.*, Vol. 18, No. 12, p. 2102 [December, 1930].) Such a system permits an automatic volume control to determine the output level to the audio system so that all stations above a predetermined level and with a given percentage of modulation will be reproduced at essentially the same volume.

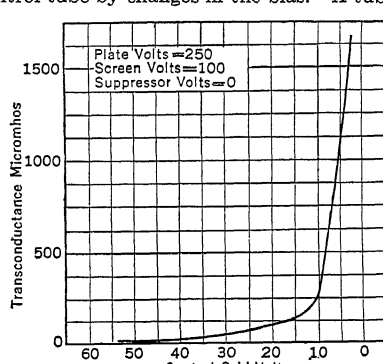

FIG. 17. Type 58, Transconductance

It will be noted that, of the tubes listed, all are pentodes except the early exponential tube, type 35. The principal reason for the pentode construction is that the plate voltage swing is not limited by the screen-grid voltage for the pentode as for the screen-grid tube.

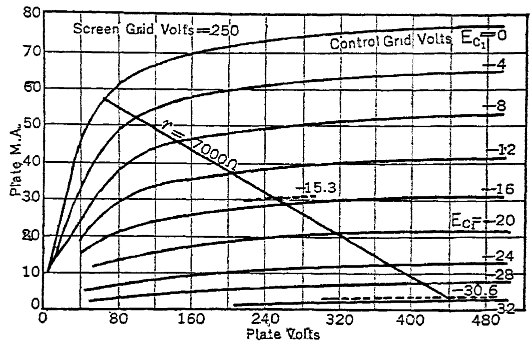

FIG. 18. Type 47, Plate Characteristics

PENTODE POWER AMPLIFIER. This latter characteristic of pentode tubes permits comparatively large power outputs from tubes designed primarily as audio power output tubes. The power pentode tubes are used principally as audio power amplifiers in radio receivers; however, the power-type pentode designed for use in transmitters is gaining favor, but not for class A amplifiers.

The first power pentode tube designed for the output system of receivers was the type 47, but it is being replaced by the indirectly heated cathode pentodes such as types 2A5, 42, and 41. The characteristics of the 47, however, are typical of the power pentodes. The plate characteristics for the 47 are shown in Fig. 18, and power-output calculations for full grid swing may be made by using eq. (10). The load line drawn through the operating bias of 15.3 volts at 250 volts on the plate and screen grid represents 7000 ohms and is approximately the load resistance for maximum power output for full grid swing and minimum distortion. A typical circuit for the pentode class A power amplifier is shown in Fig. 19, for the 47-type tube. The calculated power output according to eq. (10) is approximately 2.4 watts. Two tubes may be used in push-pull similar to Fig. 12. The desirable characteristic of the pentode tube is its power sensitivity, that is, the ratio of power output per volt of signal applied to the grid. This ratio is 3 to 4 times as large as for triodes, but the pentode power tube has several peculiar characteristics which are not particularly desirable.

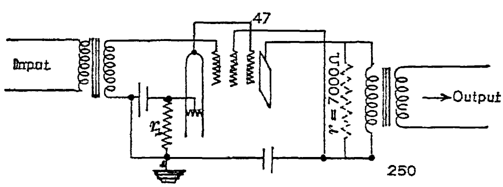

FIG. 19. Circuit for Single Type-47 Audio Amplifier

Distortion in Pentode Audio Power Amplifier. Referring to Fig. 18, it will be noted that the plate-current increase for a peak grid swing of 15.3 volts (the value of the bias) is practically equal to the plate-current decrease for the same grid-voltage swing in the negative direction along the 7000-ohm load line. Therefore, the second harmonic is essentially zero, but it can also be seen that the plate-current change per volt change in bias near the extreme swings of the bias decreases, which produces a flat-topped wave. The predominating harmonic in such a wave is the third, but other harmonics may be present, their value depending on the flatness of the top of the output wave. (See p. 5-47.) It is usually much simpler and more accurate to measure the harmonic content under actual operating conditions than it is to calculate it. All the unknown factors, such as inefficiency of output transformer and lack of proper plate supply filtering, are accounted for in the measured values; their effects are very difficult to determine and express mathematically. Experimental curves of percentage distortion of a 47 tube are shown in Fig. 20.

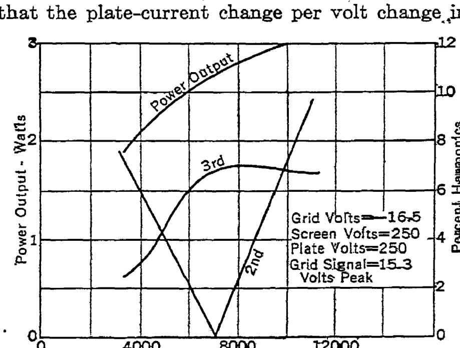

FIG. 20. Type 47, Output Characteristics

BIDIRECTIONAL AMPLIFIERS—REPEATERS. All the circuits considered above amplify in one direction only and will not pass appreciable energy in the other direction.

There are some applications, notably two-way telephony over wires, where it is desirable to amplify in either direction. (See also Section 17, p. 39.)

Figure 21 shows a schematic diagram of a circuit which amplifies signals coming from either end of the circuit, line West or East, and distributes the amplified signals equally between the two lines. Inclosed within the dotted line is a three-winding transformer; as shown in article 7, p. 6-12, if the proper circuit adjustments are made, energy coming from either line is divided by the three-winding transformer equally between the input circuit (connected across A–B) and the output circuit (inductively connected). The half entering the output circuit is dissipated as heat; but the half entering the input circuit is introduced into the grid circuit of a vacuum tube through a step-up transformer and a potentiometer. This is amplified by the tube, or tubes, and appears in the output winding of the three-winding transformer where it is again divided equally between East and West lines. Thus, although the incoming energy is twice divided, so that only one-fourth of it is utilized, the power amplification of the tube, or tubes, may easily be several hundred, so that the net result is a great increase in energy over the original.

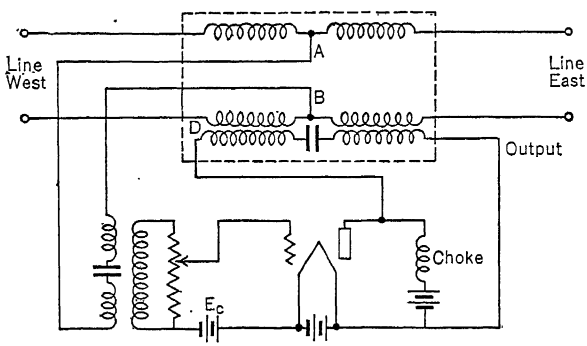

FIG. 21. Bidirectional Amplifier

The chief practical difficulty with this circuit is that the impedance of lines West and East must be identical at all frequencies, or energy will be fed by the three-winding transformer from the output to the input circuit and the tube will furnish sustained oscillations, or "sing."

To avoid the requirement of working between similar impedances a circuit such as is shown in Fig. 22 is used. Here a network of resistors, inductors, and condensers is designed to balance the external impedance on each side of the amplifier. The principle of operation is the same as above, the left-hand tube amplifying signals entering from the line West and dividing the energy between line East and the accompanying network (N).

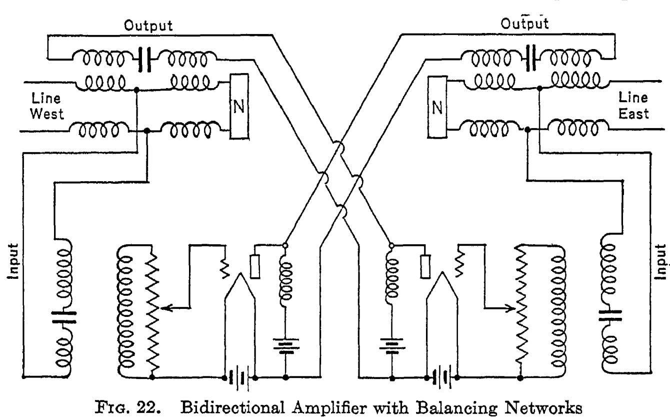

FIG. 22. Bidirectional Amplifier with Balancing Networks

Similarly, signals entering from line East are amplified by the right-hand tube and divided between line West and its network. An impedance unbalance between either line and its associated network causes some of the energy of the output circuit to be fed by the three-winding transformer into its input circuit, where it is amplified and fed into the other transformer. An unbalance here will similarly cause some of the energy to find its way back through the original path. Thus it is seen that if both lines are poorly matched by their networks the amplifier may act as an oscillator, but if either line is *perfectly* balanced by its network no sustained oscillations will be produced.

Amplifier circuits of this type are in extensive use by telephone and telegraph companies on their long lines. They are called *repeaters*.

SUMMARY FOR CLASS A AMPLIFIERS. The foregoing discussion of the class A amplifiers and the various types of tubes for particular services assumed that the grid swing or excursions were always in the negative region, and that the amplifier behaved in general according to the definition of the class A amplifier, as given at the beginning of this section on amplifiers. There are a few facts about the characteristics of class A amplifiers which should be kept in mind when designing or studying such devices; some of them are listed below.

1. The maximum voltage output of a class A amplifier measured at the plate of the tube is limited by the plate-voltage limitations of the tube and the plate load, r.
2. The maximum power output from a class A amplifier is limited by the plate dissipation at zero output and the minimum instantaneous plate voltage for peak positive grid swing to zero, at which the plate current is approximately double the steady plate-current value.
3. The load impedance into which the tube must work for maximum power output is not a simple function of the plate resistance of the tube but depends upon the two conditions above in cases where the grid swing is not limited. Power-output tubes have high bias and low plate resistance so that grid swings to zero voltage are not the controlling limitation.
4. The power output for a comparatively low and limited grid swing, that is, when limitations of 1 and 2 are not effective, is maximum when the load resistance is equal to the plate resistance of the tube. For this same grid-swing limitation, the maximum output voltage or gain approaches the amplification factor of the tube as the load resistance, r, increases toward the value of the tube plate resistance, r_p.

2. CLASS B AMPLIFIERS

GENERAL. Because of the relatively low power output of class A amplifiers and the fact that the plate dissipation is maximum for no-signal conditions, the overall efficiency of such an amplifier is very low. In applications where considerable power is desired either at radio or audio frequencies, the size of the tubes and the cost of plate power supply, per watt output for class A amplifiers, increases so rapidly that such amplifiers are not used. In the broadcast receiver it is not economical to obtain power outputs greater than about 5 or 6 watts without resorting to class B amplifiers or some combination of the class A and B amplifiers.

The grid swing in the class A amplifier is usually limited to the negative region for the entire input cycle because, in general, grid swings into the positive region result in plate-current distortion, chiefly because of the large external grid circuit impedance and limitations in plate-current swing.

According to the definition of a class B amplifier, the bias is such that the operating plate current is small, so that for the no-signal condition the plate dissipation is low. Therefore, the grid swing in general is limited only by a non-linearity of plate current and grid voltage when the grid swings positive from the operating point. Almost any three-element tube and some pentodes may be used in a class B amplifier. However, some tubes are to be preferred for reasons that will be evident after the various calculations are made from the various sample tube characteristics as shown and discussed below.

LOW-POWER AUDIO AMPLIFIERS. Since self-bias, as obtained in a pushpull circuit as shown in Fig. 12, depends upon the signal (because the *average* plate current in a class B amplifier depends upon the signal) and since there is no other convenient means for supplying fixed bias in the usual receiver, low current at zero bias is very desirable in tubes for use in class B amplifiers. The plate characteristic curves for such a tube are shown in Fig. 23, with the corresponding grid currents for various grid voltages plotted against plate voltage. Experience has indicated that a plate load resistance of about 2000 ohms for this tube with 400 volts on the plate is approximately the optimum value for power output and plate-circuit efficiency. The 2000-ohm load line is drawn through the operating point to obtain data for power-output calculations and grid-current values to determine the input resistance of the grids. Data can be obtained from this set of curves to replot curves of plate current and grid current against grid voltage, which are more useful for performance calculations than the curves in Fig. 23. Such curves are commonly called dynamic transfer characteristics.

The data for these dynamic transfer characteristics may be optionally taken directly from meter readings in a circuit such as shown in Fig. 24. Here are plotted various curves for different load resistances. Except at points near the zero bias axes, that is, for a grid swing of about 5 volts, these curves represent the dynamic performance of the 46 tube for various load resistances for one half-cycle. Another, similar tube is connected in pushpull

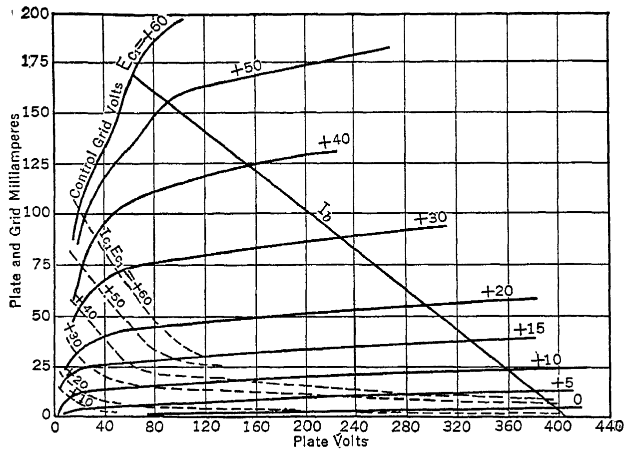

FIG. 23. Type 46, Plate Characteristics

in order to supply power for the other half-cycle. If the two tubes have similar characteristics and the pushpull input and output transformers are well balanced, the output wave will be symmetrical and only odd harmonics will be present in the output for a sinusoidal input wave.

The power-output calculations for the 46 from the curves in Fig. 24 are made like the power-output calculation for the class A amplifier, except that the plate current $I_{\max}$ (the peak plate current read from the curves) is the total change in plate current from the operating point of essentially zero plate current. Since $I_{\max}$ is the peak value of the output wave, and if little distortion is present for sinusoidal inputs, the power output for the two tubes is $I^2_{\max}r/2$. The average plate-current input for two tubes at a constant plate supply voltage, E_b, for approximately full power output is $I_{\max}2/\pi = 0.637I_{\max}$. Since the plate voltage is constant the power input to the plates of the two tubes is $0.637I_{\max}E_b$. Therefore, the plate efficiency is

$$\text{Pl. eff.} = \frac{I_{\max}r}{1.27E_b} \tag{17}$$

and the plate dissipation per tube is

$$\text{Pl. loss} = \frac{0.637I_{\max}E_b - 0.5I^2_{\max}r}{2} \tag{17a}$$

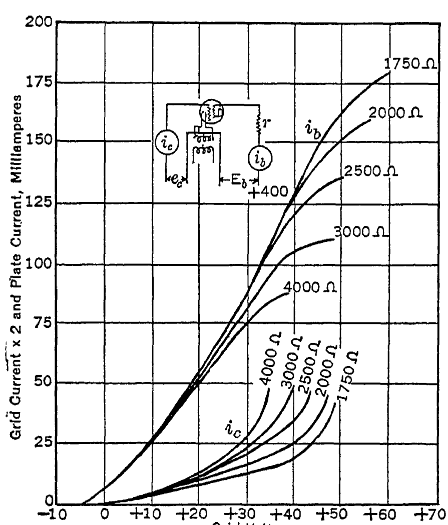

FIG. 24. Type 46, Dynamic Transfer Characteristics

The maximum theoretical efficiency is obtained when the peak a-c plate voltage is equal to the d-c plate voltage and, according to eq. (17), is 78.5 per cent.

The above equations are quite accurate at full or nearly full grid swings; the accuracy decreases with lower grid swings, the decrease in accuracy being a function of the no-signal or standby plate current. For the theoretical condition for a class B amplifier of zero plate current at no signal, they are accurate for all grid swings.

If the maximum value of plate current is taken from the curves in Fig. 24, for the 2000-ohm load, sample calculations are as follows:

$$\frac{0.150^2 \times 2000}{2} = 22.5 \text{ watts output}$$

$$\frac{0.150 \times 2000}{1.27 \times 400} = 59 \text{ per cent plate efficiency}$$

$$\frac{0.637 \times 0.150 \times 400 - \dfrac{0.150^2 \times 2000}{2}}{2} = 7.9 \text{ watts plate loss per tube}$$

It should be noted that the load resistance used is the resistance the tube works into during the half-cycle it functions so that the plate to plate equivalent load on the primary of the output transformer is $4r$.

INPUT RESISTANCE. The non-linear grid current in class B amplifiers for audio frequencies is a principal difficulty to overcome. The plate-current grid-voltage curves, as shown in Fig. 24, are for perfect regulation of grid voltage or the equivalent of zero resistance in series with the grids. An essentially zero input resistance to the grids, however, is not practical to attain, but values can be obtained which are quite low compared to the minimum instantaneous resistance of the grids of the class B amplifier tubes.

The slope of the grid-current curves in Fig. 24 at any particular grid voltage gives the instantaneous input resistance of the amplifier. The minimum value of the grid resistance occurs at a maximum grid swing of about 45 volts positive. The slope of the grid-current curve at this point represents approximately 500 ohms, while at points below 45 volts on the grid, the grid resistance is about 1600 ohms, and at near the zero axis, the resistance is still higher for each tube. However, the grid current is not zero at zero bias, so that the input resistance of the two tubes over the region at which grid current flows to each tube is the resistance of the two tubes in parallel. Therefore, to drive the grids of two 46-type tubes properly as audio amplifiers, the amplifier stage supplying voltage to the grids of the 46's works into a load resistance of approximately 4500 ohms for each tube, or a combined resistance of approximately 2250 ohms for a short period during which each tube draws grid current. When one tube ceases to draw grid current, because its grid is too negative, the input resistance rises very rapidly to approximately 4500 ohms, after which it decreases gradually to 500 ohms.

Because of this erratic change of input resistance to the 46's as class B audio amplifiers, it is very important to keep the equivalent impedance in series with each grid a minimum. The low-impedance requirement is met by using low-plate-resistance driver tubes, preferably in pushpull with a transformer *step-down* ratio as great as the plate-voltage swing of the driver tubes will permit; also the coupling transformer leakage reactance and resistance must not appreciably affect the impedance in series with the grids.

The input requirements may best be understood by referring to the circuit for a class B audio amplifier shown in Fig. 25, with the various equivalent circuit constants inserted.

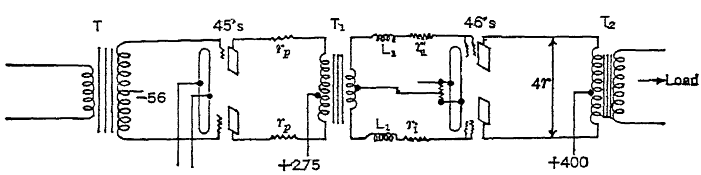

FIG. 25. Circuit and Equivalents of a Class B Audio Amplifier

The combination of tubes shown is perhaps the most practical combination for power outputs of approximately 25 watts. The transformer T is merely an interstage voltage transformer to supply audio voltage from the source to the grids of the type 45 tubes as class A amplifiers. For the grid and plate voltages as shown, the peak plate-voltage swing is approximately 165 volts each side of the operating point for load resistances of the order of 10,000 ohms, which would be a peak voltage of 330 volts on the primary of transformer T. Since according to Fig. 24 the grid swing for the 46 tube, for full output of about 25 watts, is approximately 55 volts, the ratio of the transformer T_1 is the ratio of 330 to 55 or 6 to 1, as measured from plate to plate of the driver tubes to each grid of the 46 tubes. This transformer has an impedance ratio of 36 to 1. The plate resistance, r_p, of the 45 tube is approximately 1800 ohms per tube so that the equivalent resistance in series with the primary of T_1 is $2r_p$, or 3600 ohms for the above case. Therefore, the equivalent resistance in series with the grid of each 46 tube is (in addition to transformer losses)

$$\frac{2r_p}{(\text{Turn ratio})^2} = r_1 = 100 \text{ ohms} \tag{18}$$

The actual impedance is usually about 10 per cent higher than the above calculated value because of transformer losses, but such losses are usually allowed for by assuming a grid swing about 10 per cent or more higher than the actual swing needed for a given power output. In addition to the equivalent resistance, r_1, in series with the grids of the 46 tubes, there is an equivalent inductance, L_1, which is the equivalent leakage reactance in series with one side of the secondary of transformer T_1. As explained above, the change in input resistance of the 46 tube is very rapid over certain parts of the audio cycle which results in current flow to the grids at harmonic frequencies much higher than the fundamental frequency. The frequency at which these grid currents flow may be 5 to 10 times the frequency of the fundamental, depending upon the frequency and amplitude of the signal. With currents flowing at such frequencies to the grids of the 46's, it is evident that the equivalent inductance in series with the grids due to leakage reactance of the transformer T_1 must be low in order that the grid voltage at these frequencies will be low. A high leakage reactance in the input or driver transformer manifests itself in the form of a fuzzy or a ragged output wave over certain portions of the cycle, and it may cause very high transient voltages in the plate circuit, which are responsible for many output transformer breakdowns and the tube failures.

OUTPUT CIRCUIT REQUIREMENTS. Assuming a low-impedance circuit to the grids of the 46's, which results in very little distortion of voltage supplied to the grids, there is still a source of distortion in the plate circuit because of the deviation of the plate-current curves from a straight line. This deviation is shown in Fig. 24, and if the points about the zero axis are plotted on a much larger scale and the slopes of the two plate currents added over the period during which plate current flows to each tube, it will be found that the per cent deviation is perhaps greater at zero than at any other point. In the 838 tube which was specially designed for class B operation there is appreciable plate current at no-signal condition; however, the shape of the plate-current curve is such that when two tubes are operated in pushpull the resultant output current is practically linear. This characteristic of the 46 may be seen by referring to the results of distortion measurements (Fig. 26) as made on an experimental amplifier with constants approximately as shown in Fig. 25. The non-linearity near the zero signal is distinctly shown by the rapid rise of the third harmonic at about 1-watt output, after which one tube ceases to work for most of a half-cycle, resulting in a partial balancing out of the third harmonic for certain power outputs.

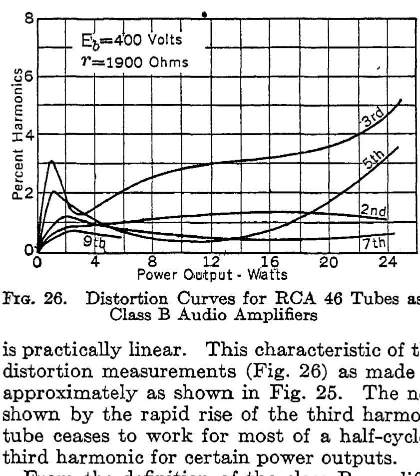

FIG. 26. Distortion Curves for RCA 46 Tubes as Class B Audio Amplifiers

From the definition of the class B amplifier, and from eq. (17), it is evident that the plate current to the class B audio amplifier tubes is approximately proportional to the grid excitation and that the efficiency increases to a maximum at full output. Referring to Fig. 24, it is seen that, if the plate voltage decreases because of poor regulation of the plate supply, the peak plate currents will not be reached as indicated by the curves. Therefore, the plate supply voltage should have good regulation and should be by-passed well for instantaneous peak plate currents. (See p. 7-108.)

The shape of the plate current curves in Fig. 24 cannot be used to calculate distortion by the simple formulas given above for the second and third harmonics. The fact that the output resistance from the driver stage is about 20 per cent of the grid resistance at near the peak swing alters the plate-current curve appreciably at the upper limits of plate current, which complicates the mathematical determination of harmonic outputs. Because of the complicated nature of the procedure in calculating harmonics, it is much easier and more accurate (for small amplifiers) to analyze the output wave, from an experimental amplifier including the driver, for harmonics by means of a reliable voltage analyzer.

LIGHT-WEIGHT CLASS B AUDIO AMPLIFIERS. Because of the high efficiency of the class B audio amplifier its use is very desirable in a battery receiver, in an automobile receiver, or where space and weight are limited. The use of small tubes for a given power output is represented by a miniature 6AU6 driving a single 1635 class B output tube. The output power from this combination is of the order of 12 to 15 watts audio power with low distortion and with very low plate drain by both the driver and output tubes.

As explained above, bias for a class B amplifier is difficult to obtain and keep constant because of the summation of grid-current and plate-current peaks that must flow through a self-bias resistor and because of the grid-current peaks if a separate bias is used. Therefore the 1635 tube was designed for zero bias at a maximum of 400 volts plate supply.

A 4000-ohm load line may be drawn through a point at zero bias and 400 volts supply to the plate on a family of published plate characteristics for the 1635. The dynamic transfer characteristics are shown in Fig. 27 for a 4000-ohm load resistance. The grid

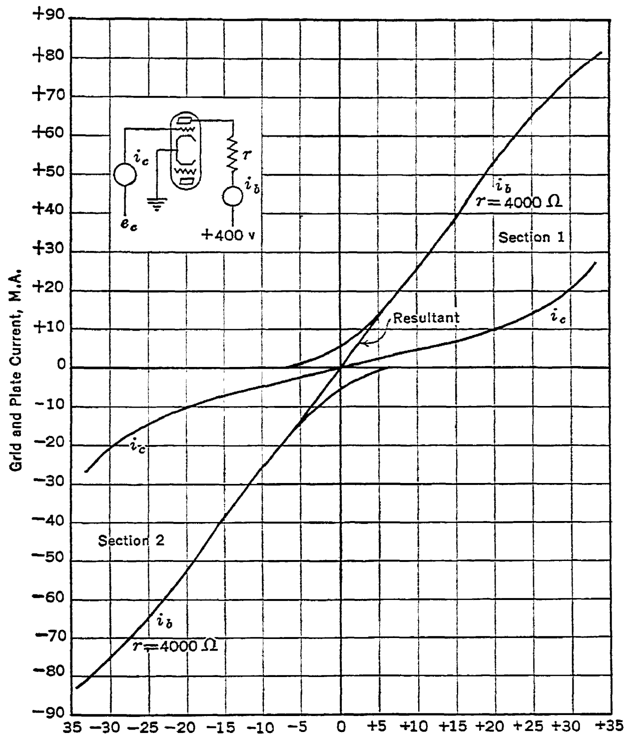

FIG. 27. Dynamic Transfer Curves for a 1635 Tube as a Class B Audio Amplifier

current vs. grid voltage is also shown in Fig. 27. A careful examination of the plate-current curve in Fig. 27 will show that the current is quite low at zero bias but trails out before cutoff similar to a variable-mu tube.

At zero bias about 6 ma plate current flows to each plate so that each plate contributes to the output. Since the plate resistance of the 1635 is high the output power from each plate is measured by plate-current deviation from its zero value through the load resistance. In pushpull operation if the plate current of one tube is increasing the other is decreasing, and since the phase of the currents is reversed in the output transformer the output current is given by the difference in plate current to the two plates. The true output-current curve is then obtained and plotted in Fig. 27 as the resultant output current. This resultant-output-current curve is more nearly linear for the 1635 tube than for other double tubes because of the special grid construction. Because of the special grids the grid current at zero bias is lower so that the sum of the grid resistance of the two tubes is higher than for other double plate tubes during the time grid current is flowing to both grids. This higher input resistance to the tube for small signal swings reduces so-called high frequency or "fuzz" type of distortion.

At a representative peak plate current of 80 ma in Fig. 27 the output is $I^2R_P/2 = 12.8$ watts. The grid peak swing is +32 volts for the above peak plate current, and the grid current is 25 ma peak. These peak grid values of current and voltage permit the driver calculations. The slope of the grid-current vs. grid-voltage curve at +30 to +32 volts represents a resistance of 500 ohms, increases to about 1500 ohms at about +6 volts on the grid, and decreases again to about 700 to 800 ohms near the zero axis because of grid current flowing to both grids. The above variation of input resistance necessitates a "stiff" driver.

The plate resistance of the 6AU6 pentode to be used as a driver is quite high so that degeneration is used to lower its output resistance. The circuit for the 6AU6 driver and the 1635 output amplifier is shown in Fig. 28.

From the published plate characteristics of the 6AU6 under the voltage conditions shown in Fig. 28 it will be seen that the bias for class A operation is about 1.5 volts at a plate current of about 7 ma. At double plate current and a signal swing to zero bias the plate swing is about 225 volts. A peak swing of about 32 volts is needed on the grids of the 1635 so that the step-down ratio of the driver transformer to each grid is about 7 to 1.

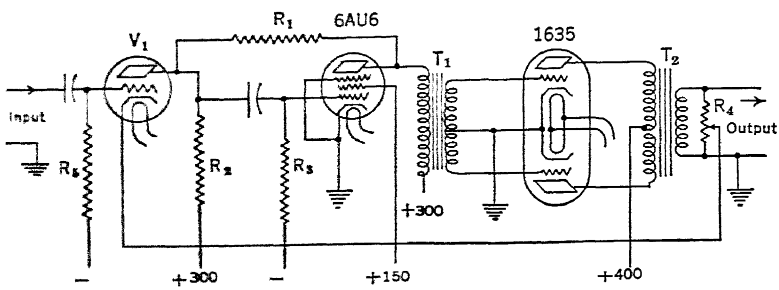

FIG. 28. Driver and Output Circuit for a 1635 Class B Audio Amplifier

The maximum current output from each side of T_1 is then 7 ma × 7 = 49 ma, which is more than ample driving capability for a needed peak grid current of 25 ma. As noted above, the variation of grid resistance or load on T_1 was 500 ohms to about 1500 ohms. The input resistance should be as low as 10 per cent of the minimum grid resistance to keep the input distortion to a low value.

The g_m of the 6AU6 is about 5000 micromhos, and, if it is assumed that 1 volt peak were applied to the plate of the 6AU6 and that 0.2 of a volt peak gets back to the grid of the 6AU6 through R_1, the effective output impedance of the 6AU6 to one side of the secondary of T_1 is:

$$\frac{1 \text{ volt}}{0.2 \times g_m} \times \frac{1}{(\text{Ratio of } T_1)^2} = \frac{1000}{49} = 20.4 \text{ ohms}$$

The effective internal resistance of the transformer, T_1, to each side of its secondary may be about 20 ohms for a good design so that the total input resistance in series with 1635 grids is about 40 ohms. This low value of resistance will effectively reduce input distortion to a low value.

Referring to Fig. 28 if the combined plate resistance of V_1, R_2, and R_3 is 50,000 ohms, R_1 in the above calculations for feedback voltage will be 200,000 ohms. Therefore, 20 per cent of the peak plate swing of 225 volts on the plate of the 6AU6 will require about 1 ma of the 6AU6 plate-current peak swing and apply 45 volts audio on the plate of the tube V_1. In this case V_1 must supply an equivalent voltage of 45 volts at its plate to balance out the feedback voltage plus a peak voltage of about 2 volts to drive the grid of the 6AU6.

For a 1635 plate load of 4000 ohms per plate the plate to plate load for T_2 is 16,000 ohms. The transformer T_1 must have low leakage reactance to prevent fuzz-type distortion as explained for T_1 in Fig. 25. A check of constants for the 6AU6 as a degenerative feedback driver for the 46's in Fig. 25 indicates that the 6AU6 is essentially as good a driver as or better than the two 45's. This indicates the effectiveness of the addition of a feedback resistor R_1 in Fig. 28.

Some degeneration may be fed back from a resistance divider, R_4, across the output of T_2 to the cathode of V_1 as shown in Fig. 28 to decrease the distortion of the system further. The distortion vs. output power of the circuit shown in Fig. 28 is shown in Fig. 29. The feedback for the overall distortion curve was an amount required to reduce the overall gain about 2 or 3 to 1.

Other sharp cutoff pentodes such as the 6SJ7 may be used as drivers. Battery tubes of the 1.4 volt series may be used in combinations to obtain high outputs for given input powers.

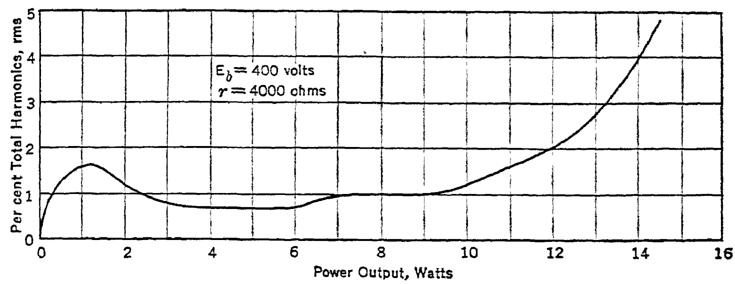

FIG. 29. Overall Distortion of the Circuit of Fig. 28 Using the 1635 as the Output Tube

MEDIUM-POWER AUDIO AMPLIFIERS. A set of curves similar to the curves in Fig. 24 is shown for the UV849 tube in Fig. 30. It will be noted from these curves that the class B operating bias is approximately -140 volts and that the instantaneous slope of the grid-current curves is positive and negative with magnitudes as low as 500 ohms. Considering the relatively high grid voltages at which these low instantaneous grid resistances occur, these tubes are hard to drive without appreciable distortion. However, two UV845-type tubes operating at full rated voltages may be used to drive these tubes successfully with an equivalent resistance of approximately 100 ohms in series with the grids of the UV849 tubes.

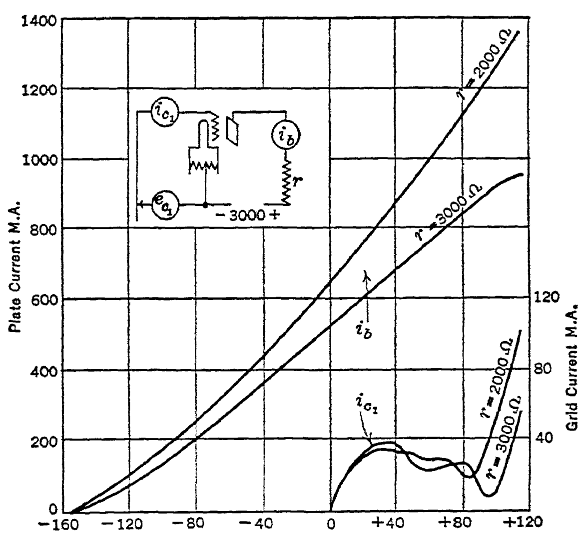

FIG. 30. Dynamic Transfer Characteristics of 849 Tube

By applying eq. (17) to calculate the various powers from data obtained from Fig. 30, it is found that the maximum power output for the 2500-ohm load line is about 1350 watts for two tubes, the plate loss is about 350 watts per tube, with a plate-circuit efficiency of approximately 65 per cent. These calculations do not take into account the transformer losses. Such audio power outputs are used principally to plate-modulate a class C radio-frequency output amplifier.

HIGH-POWER AUDIO AMPLIFIER. The 500-kw broadcasting transmitter operated at WLW in Cincinnati, Ohio, used high level modulation with a class B audio amplifier capable of approximately 325-kw audio output power. At the time this station was first operated, early in 1934, it was the world's largest broadcasting station. The class B amplifier for the above station used eight type-862, 100-kw tubes, with 12,000 volts on the plates.

As stated above, tubes other than the ones discussed may be used as class B audio amplifiers, but their particular grid characteristics must be known in order that a driver system may be properly designed. The load resistance and plate-current characteristics are also important items to consider in the design of a satisfactory class B audio amplifier.

RADIO-FREQUENCY AMPLIFIERS. The class B radio amplifier functions much the same as the class B audio amplifier as far as the grid currents and plate currents are concerned, except that the plate-current distortion may be greater with a correspondingly higher output power without serious signal distortion. This is because the second and higher harmonics are multiples of the radio frequency and are outside of the frequency range of interest. The principal difference between the two amplifiers is in the input or driver circuits and the output circuits. If the input or driver circuit is tuned, the harmonics are by-passed and do not appear on the grids, which results in a well-regulated or low-impedance driver source, as far as the fundamental frequency is concerned. As in the class B audio amplifier, the regulation of the voltage to the grids of the class B tubes depends upon the ability of the driver tube to supply the instantaneous grid currents directly.

Another factor which reduces distortion to a negligible value is the fact that the plate circuit is timed; thus it will absorb the fundamental component of the plate current and by-pass the harmonics. The power output of the class B radio amplifier may be calculated like the power output for the class B audio amplifier if somewhat greater peak currents are assumed for peak outputs. It would seem from the above that the class B radio amplifier, also known as the linear amplifier, is inherently a simple type of amplifier to design; this is true if it is desired only to obtain a power amplification of the fundamental frequency. However, it is not economical to use such an amplifier as merely a tuned amplifier for voltage or power amplification, because in such cases the class A amplifier would probably be better for voltage amplification and the class C amplifier for power amplification. The real use for the class B radio amplifier is in circuits where a low-powered modulated signal is to be amplified to a higher power level. Referring to the definition of the class B amplifier, one characteristic of the amplifier is that the output voltage is proportional to the input voltage; therefore, if a modulated radio-frequency signal is used to excite the grids of a class B radio amplifier, the output for an ideal case would be a modulated signal identical to the modulated input signal, except that it would be at a much higher power level. The increase in power level is 20 to 100 times, depending upon the degree to which the amplifier is driven.

A typical circuit for such an amplifier is shown in Fig. 31, in which the tuned input circuit $L_1C_1C_2C_3$ is so arranged that C_2 equals C_3 and each has a value with respect to

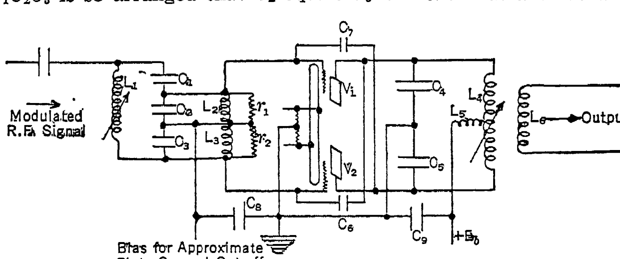

FIG. 31. Circuit for Class B Radio Amplifier

C_1 that permits the desired grid swing of the tubes, V_1 and V_2, for a given modulated signal applied to the input circuit. Inductances L_2 and L_3 are radio-frequency chokes to provide a low d-c resistance path for the grids, and r_1 and r_2 are resistors from the grids to ground to suppress undesirable oscillation. C_6 and C_7 are neutralizing condensers, and the output tuned circuit is $L_4C_4C_5$, in which C_4 and C_5 are equal. The radio-frequency choke L_5 provides a floating center tap for L_4 because the tuned circuit is center-tapped in the condenser branch. The circuit as shown is for a pushpull class B radio-frequency amplifier, but, as stated above, a single tube may be used in a circuit similar to the one discussed, by leaving out the unnecessary parts or sections of the circuit. The type of circuit shown, or its equivalent, was in common use in most broadcasting stations of 1000 watts or more. However, the present trend is toward the use of the more efficient high level modulation system. (See p. 7-74.)

Distortion. As discussed above, there is little distortion from a tuned input and tuned output amplifier as far as the fundamental radio frequency is concerned. Since the primary use of the linear amplifier is to amplify modulated signals without distortion, the linearity of the amplifier becomes a factor which determines almost entirely whether the demodulated output is distorted or not. The linearity of such an amplifier is determined by the ratio of output current, or voltage, against rms input voltage. The curves of Fig. 32 are plotted from actual experimental data obtained on two RCA 846 tubes in pushpull as a class B radio or linear amplifier with 7500 volts on plate. For a bias of -150 volts, the output tank current is approximately linear with respect to the grid-excitation voltage from zero to about 4 amp. If the amplifier is used as a radio-frequency output amplifier in which the input signal is 100 per cent modulated, the normal output

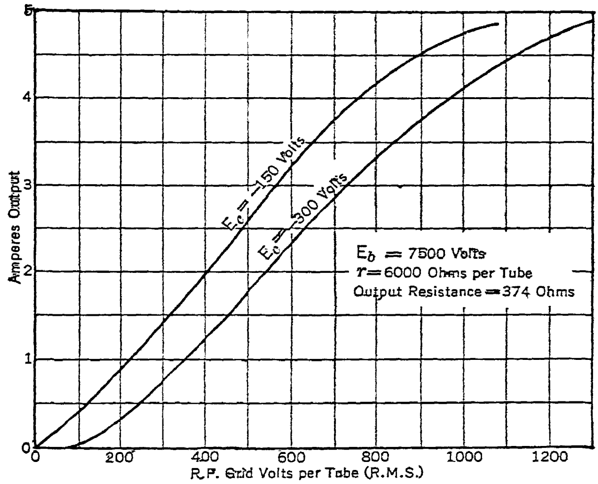

FIG. 32. Characteristics of RCA 846 as Class B R-f Amplifier

tank current would be approximately 2 amp, which corresponds to a grid excitation of 470 volts for approximately 1300 watts output. It will be noted that such high per cent modulation of the excitation voltage in this case causes a deviation from a straight line at both the upper and lower limits of swings so that the predominating harmonic in the demodulated output signal is the third. If a lower bias is used the curve would be more nearly linear from the operating point of 2 amp, but the slope at the upper end would be approximately the same resulting in a second harmonic for 100 per cent modulation.

The flattening of the output tank current near the zero axis, for the curves in Fig. 32, is due to the large bias chosen; however, the flattening of the upper end of the curve may be due to emission or space-charge limitations which limit the peak plate currents. Another factor that often contributes to the flattening of the upper end of the output tank current curve is the inability of the modulated exciter to supply the higher value of average grid current without distortion to the output tubes at the peak values of grid excitation. The driver must have low impedance to the grids of the output tubes to prevent distortion, for practically the same reasons as a low impedance is required for the input to the class B audio amplifiers.

Since the normal carrier value of output current for the class B radio amplifier is approximately one-half the peak value and occurs at one-half the peak value of grid excitation, it can be seen from eq. (17) that the efficiency of the plate circuit is relatively low. (See p. 7-17.) This efficiency is usually 20 to 30 per cent. The carrier power output is only 25 per cent of the peak power output; therefore, except in tubes where peak plate voltage or peak plate power input is limited, four times as many tubes are theoretically required for class B radio amplifiers for a given power output as are required for a class C high level modulated radio-frequency amplifier. Actually the water-cooled tubes are limited by peak plate voltage for the plate modulated class C amplifier so that the number of tubes for a class C amplifier, when these tubes are used, is approximately one-half that required for a class B radio amplifier.

SUMMARY FOR CLASS B AMPLIFIERS. Some of the more important requirements to meet in the design and operation of class B amplifiers and some of their characteristics may be summarized as follows.

1. The input system to the class B audio amplifier must have low impedance, especially if the instantaneous values of grid current change rapidly either negatively or positively. The slope of the grid-current curve or its rate of change per volt applied to the grid is the grid resistance at the point taken. The equivalent inductive reactance in series with each grid because of driver transformer leakage is a part of the impedance in series with the grids; it must be kept very low if the instantaneous values of grid resistance are low and change rapidly over the audio cycle.
2. Failure to meet the low-impedance input requirements usually results in appreciable distortion, and generally the output transformer is subjected to high peak voltages which may damage the transformer or the tubes.
3. The load resistance the tube works into is one-fourth of the calculated plate to plate impedance of the loaded output transformer. This applies to radio-frequency as well as audio-frequency amplifiers.
4. The load line for the class B amplifier for radio and audio frequencies should be as high a resistance as possible consistent with grid current peaks and space-charge limitation in order that the plate efficiency may be maximum. Somewhat higher peak plate currents may be assumed for the class B radio amplifier, because of the tuned plate circuit.
5. The class B audio amplifier is the most efficient type of amplifier for audio frequencies, and may attain a plate efficiency of 65 to 70 per cent at full output power for some of the larger tubes.
6. The class B radio amplifier has poor plate efficiency, which is usually 20 to 30 per cent, so that a relatively high tube power capacity is required for a given output.
7. The class B radio amplifier also requires a well-regulated or low-impedance driving source, but the requirements are not as strict as the driver requirements of the class B audio amplifier, because the radio amplifier may have a tuned input circuit.
8. The plate supply for the class B audio amplifier must have good regulation, especially if tubes with high bias are used. The plate supply regulation is not so important with the class B radio amplifier because the average plate current is essentially constant. Sufficient plate supply by-pass capacitance is necessary in either amplifier to maintain constant plate voltage over the audio cycle.

3. CLASS C AMPLIFIERS

GENERAL. The class C amplifier by definition is an amplifier that is biased considerably beyond plate current cutoff, so that plate current flows for a period less than 180 electrical degrees, during the time the grid swings in a positive direction from its normal value of bias potential. In general, the grid is driven to the point of saturation, that is, to a point at which the output voltage is no longer proportional to input voltage. Under this condition the efficiency of the amplifier is approximately maximum for any given plate-circuit conditions, the output voltage is proportional to the d-c plate voltage, and the output power is proportional to the square of the d-c plate voltage.

Since, in general, appreciable power is required to drive the class C amplifier because of the relatively high positive grid swings, this type of amplifier is essentially a power-amplifier device. Because of the distorted plate current that flows during only a part of a half-cycle it is necessary to tune the output or plate circuit of the amplifier if an undistorted output wave is desired. Therefore, the class C amplifier is essentially a single-frequency amplifier and is used as the output device for radio telegraphy or high level modulated telephony transmitters.

CIRCUIT CALCULATIONS. Since the class C amplifier can be used only as a tuned plate amplifier except where distortion of the output wave is permitted, it is obvious that the application of this amplifier is much more limited than the applications of the class A or class B amplifiers. In the class C amplifier it is difficult to predict the performance of a tube from its static characteristics. As long as the plate circuit load, r, has a sufficiently low value to limit the minimum instantaneous plate voltage to a value such that the plate current is essentially half sine waves, the power output and other characteristics of the circuit and tube may be calculated in much the same manner as for the class B audio amplifier. However, under these conditions, the plate-circuit efficiency is usually less than 65 per cent. When the load resistance is high the minimum instantaneous plate voltage may reach or approach zero, so that essentially no plate current can flow at the instant, because the plate voltage is near zero.

To illustrate better the above features of the class C amplifiers as well as the general circuit features, it is well to discuss the typical class C amplifier circuit such as shown in Fig. 33. The proper constants to use in the circuit depend upon the tube used, general class of service, and the values of maximum grid and plate currents allowed. For the 204A tube the maximum allowed constants are: d-c plate voltage, 2000 volts; d-c plate current, 275 ma; plate dissipation, 167 watts; d-c grid current, 80 ma.

If a modulation factor of 1 is applied to the plate voltage, it is evident that at peak upward modulation the instantaneous plate voltage will be 4000 volts. In order that plate current cutoff may be obtained at 4000 volts on the plate, so that the tube may continue to operate as a class C amplifier at this voltage, the bias required is approximately −200 volts, but a bias somewhat beyond plate-current cutoff, such as −250 volts, should be used. Therefore, since the allowable direct current through the bias resistor, r_1, of Fig. 33, is a maximum of 80 ma, a voltage drop of 250 volts requires a resistance of 3125 ohms for r_1. The power dissipated in r_1 is approximately 20 watts, and the power dissipated on the grid of the tube is comparatively small because of the low resistance of the grid when the grid current is large.

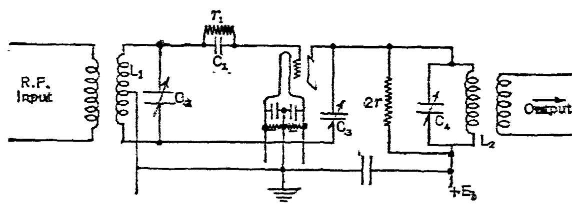

FIG. 33. Typical Circuit for Class C Amplifier

If it is assumed that one-third of the bias power is dissipated on the grid, the total power required of the r-f input circuit is approximately 30 watts.

This power must be supplied by the exciter amplifier, and the loss in the resistor r_1 cannot be supplied by means of a separate voltage supply in the hope that the exciter is required to supply the grid losses only. The grid-leak method of supplying bias as shown is a self-biasing arrangement and consumes no power from the plate supply. The one disadvantage of this method of supplying grid voltage is that if the excitation is lost the class C tubes have no bias, so that, in the case of the 204A, the resulting plate current would cause excessive plate dissipation. This difficulty may be removed by using a combination of a fixed bias (or biasing resistor in the cathode to negative plate supply lead) to limit the plate current if the excitation is lost and the additional bias supplied by a leak system as shown.

The input circuit to the tube is tuned and the inductance, L_1, is center-tapped in order that the amplifier may be neutralized by means of the condenser C_3. The plate circuit is tuned by means of C_4 and L_2, which in turn is coupled to an output circuit. The output circuit reflects, to the C_4L_2 circuit, an equivalent resistance of $2r$ across the tuned circuit. Therefore, r is the approximate resistance the tube works into during the time plate current flows.

POWER CALCULATIONS. The efficiency of the plate circuit of the class C amplifier can be estimated quite accurately if the peak a-c voltage across the tank circuit C_4L_2 is measured and used in eq. (17), as for the class B amplifier, provided the plate current is approximately one-half sine wave or that the fundamental component of the current is very large compared to the harmonic components. For this case it will be seen that the expression $I_{max}\,r$ is in reality the peak a-c voltage measured across the plate tank circuit in which I_{max} is the peak value of the fundamental component of plate current and r is the value of resistance the tube works into during the time plate current flows. The values of I_{max} and r are more or less fictitious, but their effective product is approximately the measured peak plate voltage.

Referring to the ratings on the 204A as given above, the permissible input plate power is 550 watts with only 167 watts plate dissipation, which requires a plate efficiency of approximately 70 per cent. Therefore, from eq. (17), it is found that the peak voltage across the tank circuit is 1778 volts. This peak voltage leaves only 222 volts on the plate to cause the peak plate current to flow. The power output for the above power input and plate loss is 383 watts, and if the peak plate voltage swing is 1778 volts, as calculated above, the approximate value of $2r$ is found to be 4150 ohms, which is the equivalent load resistance across the plate tank circuit, and the resistance the tube works into is r, or approximately 2075 ohms. The peak value of the fundamental component of plate current, as found from the expression for peak a-c plate voltage, is 860 ma. It is doubtful if this value of plate current flows at the instant the plate voltage reaches a minimum value of 222 volts. However, plate-circuit efficiencies of 70 per cent are easily attained, so that, even though the actual plate current may be considerably below 860 ma at the instant the plate voltage is 222 volts, the peak value of the fundamental component may be 860 ma without sufficient plate-current distortion to affect the plate loss seriously.

Experience has shown, however, in experimental class C amplifiers that approximately 70 to 75 per cent plate-circuit efficiency, for a circuit as shown in Fig. 33, is the limit of efficiency, because the actual plate current for higher load resistances deviates so far from a half sine wave of current at higher peak values of a-c plate voltage that the plate-current harmonic losses increase to keep the plate efficiency at a more or less constant value, in spite of the fact that the measured peak a-c plate voltage increases.

SPECIAL FILTER FOR HIGH EFFICIENCY. Equation (17) indicates that if an essentially half sine wave of plate current can be caused to flow to the plate the efficiency may be caused to increase as the peak tank voltage increases.

When the peak tank voltage approaches the plate voltage the efficiency by eq. (17) approaches 78.5 per cent. If the peak plate voltage could reach 1.27 times the d-c plate voltage, the efficiency would be 100 per cent, provided that the plate current is essentially a half sine wave and the plate resistance of the tube during the time current flows is zero. This 100 per cent efficiency condition is impossible, of course, but the limit of efficiency is seen to be 100 per cent, because the plate circuit is tuned and filters may be inserted in series with the plate to prevent appreciable flow of harmonic plate currents. Such a filter circuit is shown in Fig. 34. The inductance L_3 is comparatively large and offers a high impedance to the fundamental and harmonic plate currents. The primary function of L_3 is to provide a path for d-c plate current but to offer a high impedance to all a-c components of the plate current. The inductance L_4 and capacitance C_5 are tuned to series resonance for the fundamental frequency of the circuits. Therefore, the band-pass filter offers low impedance to the fundamental component of plate current but is designed to offer high impedance to harmonic components of the plate current.

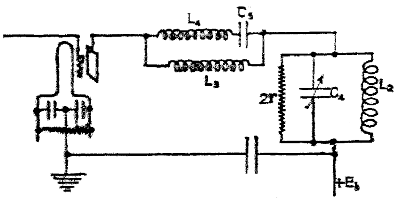

FIG. 34. Circuit for Increased Efficiency of Class C Amplifier

The value of the more or less fictitious plate resistance is a function of the tube and its excitation, and it may be calculated if all the constants of the tube and circuits are known. However, an apparent resistance of the tube may be easily calculated from the plate efficiency. This is done by assuming that the apparent load resistance is in series with an apparent plate resistance that will give the measured or calculated plate-circuit efficiency.

Such a formula is given below:

$$\frac{2r}{\text{Eff.}} - 2r = r_{ap} \text{ apparent plate resistance} \qquad (19)$$

in which $2r$ is the equivalent resistance in parallel with the tank circuit due to the load connected to the class C amplifier. Since the tube functions for approximately one-half the time, the actual effective resistance of the tube is approximately one-half of the apparent resistance r_{ap}, and the load the plate works into is one-half the equivalent load resistance or r. The load resistance r as calculated for the 204A at rated conditions as given above is 2075 ohms, and the calculated efficiency is 70 per cent. Substituting these values in formula (19), the effective resistance of the 204A is about 890 ohms.

If the harmonic components of the plate current are to be effectively reduced, the impedance of the circuit $L_3L_4C_5$, when tuned to the fundamental frequency, must be 4 or 5 times the approximate effective resistance of the tube at the second harmonic of the fundamental frequency. The impedance to higher harmonics, of course, will be still higher. Therefore, a rough approximation of what the impedance of the filter should be at the second harmonic is equal to the normal effective resistance across the output tank circuit at full power output of the tube.

Such impedance at the second harmonic frequency necessitates a comparatively large L to C ratio for the series tuned circuit L_4C_5. Since the a-c component of plate current flows through this series tuned circuit, the voltage across L_4 and C_5 reaches quite high values at the fundamental frequency, and the voltage across L_3 at all the harmonic frequencies is comparatively high. However, the system permits approximately only half sine waves of plate current at the fundamental frequency so that high efficiency can be achieved.

This type of filter has been successfully used to increase materially the efficiency of a class C amplifier in the laboratory, and was successfully applied to at least one broadcasting station, although the circuit has not been used extensively in transmitters to date. The effect of the filter on plate loss, power output, and efficiency of a laboratory test on a

204A is given in Fig. 35. It will be noted that for low load resistances, that is, resistances that limit peak a-c plate voltages to values appreciably below the d-c supply voltage, the filter adds little if any to the efficiency of the plate circuit. This is due to the fact that heavy loads cause essentially one-half sine waves of plate current, so that there are practically no harmonic components of plate current to reduce.

The results of the experimental data as plotted in Fig. 35 indicate that the efficiency of a class C amplifier without a filter is essentially constant over practically all the load range that might be used. The 204A tube, with which the data for the above curves were taken, was operated at approximately optimum grid excitation so that the values read from the curves represent approximately the best performance of the tube. Any loss in the filter for the curves in Fig. 35 is included as plate loss, so that the plate efficiency is actually greater than shown when the filter was used.

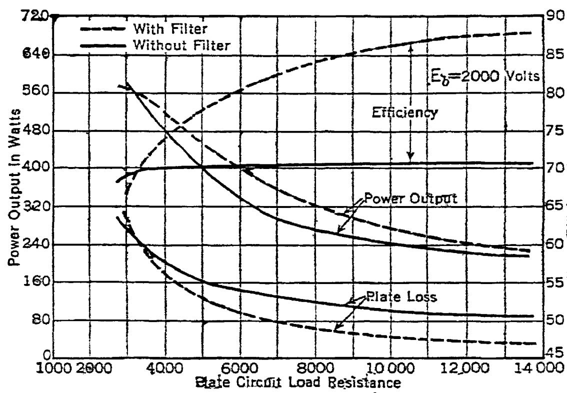

Fig. 35. Performance of RCA 204A as Class C Amplifier

Oscillograms of the actual plate current in a low-frequency class C amplifier were made on an experimental amplifier; they substantiate the above explanation of the behavior of the filter and indicate quite definitely that the plate current to the tube at most practical load resistances is a double peaked affair, whereas with the filter the plate current is essentially one-half of a sine wave. As a result of the peaked condition of the plate current without a filter, the peak emission required from the filament of the tube in a class C amplifier is 6 to 12 times the d-c value; when a filter is used the peak emission required is one-third to one-fifth of the peak without the filter. The reduced peak plate current requirement when the filter is used is a decided benefit.

Although the applications of the class C amplifier to radio devices are limited in number, it is the most efficient type of vacuum-tube amplifier known. When the class C amplifier is used as the output system for a radiophone transmitter, in which a class B audio amplifier is used to modulate the plate supply to the class C amplifier, a radiophone transmitting station is obtained that has a greater overall efficiency than any other type of transmitter now in general use.

SUMMARY FOR CLASS C AMPLIFIERS. Some of the more important circuit requirements of the class C amplifier as well as some of the more important operating points are summarized below:

1. If full output is to be obtained from the class C amplifier, the grid excitation should be sufficient to obtain essentially full permissible d-c grid current at the recommended bias.

2. The grid excitation for a plate-modulated class C amplifier must be sufficient to cause a linear relation between the plate voltage and output voltage.

3. In a plate-modulated class C amplifier, it must be remembered that the peak plate voltage due to modulation peaks is double the plate voltage for normal carrier, which in turn doubles the average plate current and also the peak current corresponding to a power four times the carrier power. Therefore, it is necessary to determine whether the tubes used in such an amplifier are capable of withstanding the peak d-c plate voltage over an audio cycle and whether the emission of the tube is ample to meet the peak-plate-current conditions.

4. Failure to meet the peak-plate-current condition in item 3, because of emission limitation or insufficient excitation, results in a second harmonic in the detected carrier output. Failure to meet the requirements in item 3 only reduces the power output and efficiency in the case of class C amplifiers for telegraphy.

5. The bias for a class C amplifier must be beyond plate-current cutoff at the highest instantaneous d-c plate voltage. For 100 per cent modulation the bias should be 2.5 to 3 times the bias for plate current cutoff at normal plate voltage. Excessive bias usually results in higher excitation power with little gain in efficiency.

6. The plate dissipation of a tube in a class C amplifier is determined entirely by the plate supply voltage and the load resistance for normal class C operation of the tube, and the value of load resistance has essentially no relation to the plate resistance of the tube.

7. The maximum plate efficiency of a class C amplifier is approximately 70 to 75 per cent for all practical load resistances. This efficiency may be raised to 80 or 90 per cent by using somewhat higher resistance plate loads if a band-pass filter is used in series with the plate.

8. The band-pass filter also reduces the peak-plate-current requirements, which tends to reduce distortion at high percentage modulation.

9. The audio power required to modulate the plate circuit is 50 per cent of the amplifier input plate power; therefore, any increase in plate efficiency reduces the modulator power required.

4. REGENERATION AND ITS PREVENTION

CONDITIONS FOR REGENERATION. In each of the theoretical amplification equations (eqs. [4], [6], etc.) the internal input impedance z_{i2} appears. When r_{i2} is a positive quantity the greatest amplification will be obtained by making the internal input impedance as great as possible. However, it is possible for r_{i2} to have a negative value (p. 5-49) when the external plate impedance of the succeeding tube is inductive. In this case the conditions under which maximum amplification will be obtained are quite different.

If r_i is negative and less than twice the magnitude of the resistance presented to the grid filament terminals by the rest of the input circuit, it is possible for the amplification to be greater than the value obtained when the internal input impedance is infinite, for the plate current of a single tube in terms of the impressed voltage is (see eq. [1], p. 7-03)

$$i_{pa} = \frac{\mu e'_g(r_i + jx_i)}{r_i + r_e + j(x_i + x_e)}\left[\times \frac{z}{r_p + z}\right] \tag{20}$$

and the absolute value is

$$i_{pa} = \frac{\mu e'_g\sqrt{r_i^2 + x_i^2}}{\sqrt{(r_i + r_e)^2 + (x_i + x_e)^2}}\,\frac{\sqrt{r^2 + x^2}}{\sqrt{(r + r_p)^2 + x^2}} \tag{20a}$$

If either r_i or x_i is infinite, the first factor reduces to $\mu e'_g$, but if r_i is negative and less than twice the magnitude of r_e (and x_i and x_e are of opposite sign and their sum less than x_i) the first factor will be greater than $\mu e'_g$. The tube is then said to be *regenerating*. In particular when the denominator is zero the amplification will be infinite and the tube will *oscillate;* that is, plate current of a particular frequency will flow even when there is no externally impressed alternating voltage on the grid.

In an impedance-capacitance coupled amplifier (eq. [6], p. 7-04) regeneration occurs when

$$0 > r_{i2}/z_{i2}^2 > 2(r/z^2 + 1/r_p)$$

When transformer-coupled amplification is used and the circuit is properly tuned (eq. [7b]) regeneration occurs when $0 > r_{i2} > 2r_4$, and oscillation when $r_{i2} = -r_4$.

The *equivalent negative resistance* of the input circuit is caused by the plate voltage electrostatically inducing a voltage between the grid and filament which has a component in phase with the impressed grid voltage. This will occur only when the plate load is inductive. (See p. 5-49.) A similar voltage impressed on the grid by any other means would, of course, have the same effect. (See Regeneration, Theory and Experiment, by Peterson, Kreer, and Ware, *Proc. I.R.E.*, October, 1935.) Circuits are frequently designed so that part of the energy in the plate circuit is "fed back" to the grid circuit to increase the amplification. When the feedback is inductive through a movable coil, this coil is called the *tickler coil*.

EFFECTS OF REGENERATION. The increased amplification obtained as a result of regeneration is sometimes used to increase gain, particularly where a single frequency is being amplified. Since a regenerative circuit usually behaves like a very sharply tuned circuit it is not useful when a broad band of frequencies must be amplified.

Regeneration results in a decrease in the effective input resistance of the amplifier and so decreases the non-regenerative amplification obtainable from the tube.

As a rule most difficulty is experienced at radio frequencies. Even if regeneration is prevented at the working frequency of the amplifier, there may be considerable feedback at higher frequencies: if a resonant path exists at one of these high frequencies a *parasitic self-oscillation* may begin. This may cause the amplifier to cease functioning as an amplifier, and unless some protective device limits the plate current the tubes may be overheated very quickly.

Another type of parasitic oscillation may exist in the pushpull circuit shown in Fig. 31; in which the input circuit has a certain impedance from ground to grids, because of the leakage in the center-tapped grid and plate inductances. This condition effectively places the pushpull tubes in parallel with an input and output circuit with the neutralizing condensers ineffective. If the input and output circuits have sufficiently high impedance (which may be comparatively low for high-power tubes) parasitic oscillations will result. However, it should be noted that r_1 and r_2 in Fig. 31 are connected from their respective grids to ground so that the resistors are still effective in suppressing parallel parasitic oscillation of the tubes. If the corresponding value of resistance in r_1 and r_2 is placed across the grids without the r-f ground at the center point, parallel parasitic oscillation of the tubes may exist because the grids would be at essentially the same potential so that the resistances would be ineffective.

This type of parasitic oscillation is apparently responsible for the self-oscillation of most pushpull audio amplifiers.

PREVENTION OF OSCILLATION. Regeneration to the point of oscillation may be prevented in several ways. It is often accomplished by the introduction of power-absorbing resistors into various parts of the amplifier circuit, but these invariably increase the losses in the circuit and so are objectionable. Another possible method is to decrease the impedance of the input circuit, but this is frequently impracticable without too great decrease in amplification.

Parasitic oscillations may sometimes be prevented by so changing either the plate or grid circuit that the resonant frequencies of the one have no counterpart in the other. There is then no complete resonant path at any frequency. In general, if the leads to the grid are short, and a small r-f choke is inserted in series with the plate to increase the effective length of the plate leads, there will be no common resonant frequency. If the circuits cannot be so unbalanced resistances must be used, such as are shown in Fig. 31.

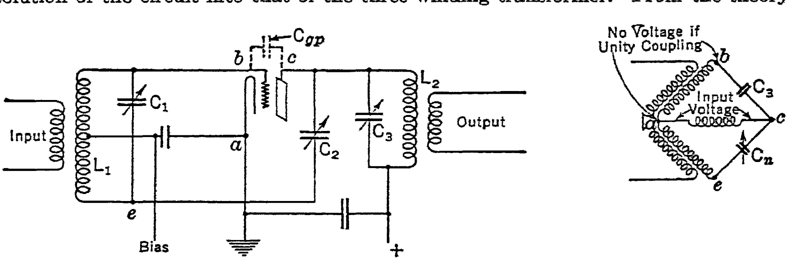
The most effective cure for parasitic oscillation of pushpull audio amplifiers is to unbalance the input and output circuits by placing a resistor or small condenser across one side of the input or output transformers. In general, the value of impedance required to suppress the undesired oscillation will not noticeably affect the frequency characteristic of the amplifier.

Improvement in shielding between stages will sometimes eliminate enough of the feedback to make the circuit stable, or the plate and grid circuits may be moved apart if practicable. Shielding for pentode or tetrode r-f amplifiers is always necessary. Shielding an audio amplifier is usually not necessary with proper placement of the various tubes and transformers for minimum feedback. However, it may be necessary to use elaborate means to prevent stray pick-up to the input transformer. In general, a magnetic shield for audio frequencies is better than a copper shield, but the copper is better at radio frequencies.

Where the feedback is due to the grid-plate capacitance, this capacitance may be eliminated by electrostatically shielding the plate from the grid. This has been done in the tetrode and pentode. It makes possible the extremely high amplification factors obtainable with these tubes.

NEUTRALIZATION. When it is impossible to eliminate the fed-back voltage it is still possible to cancel its effect by introducing an equal and opposite voltage. Circuits to accomplish this are based on the impedance bridge principle or on the three-winding transformer. (See p. 6-12.)

The first method for *neutralizing* the grid-plate capacitance was that of Rice shown in Fig. 36. Diagram A of this figure is a schematic sketch of connections; diagram B is the resolution of the circuit into that of the three-winding transformer. From the theory of

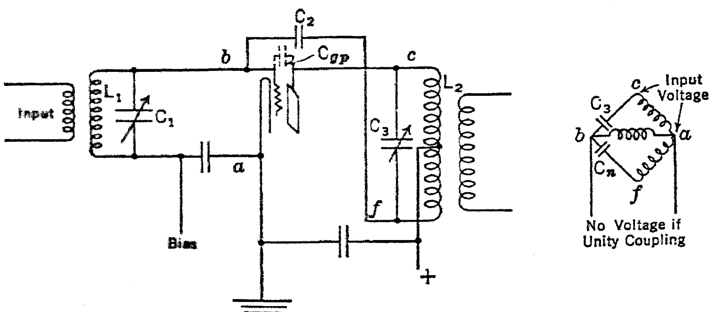


A. Schematic Diagram *B*. Equivalent Circuit

FIG. 36. Rice System for Neutralization. The tuning and bypass capacitors shown in the circuit diagram on the left are omitted from the equivalent three-winding transformer diagram on the right.

the three-winding transformer any voltage induced in the coil *a-c* will cause no voltage drop across *b-a-e* (except that due to incidental resistance of the coils) if the value of C_n is properly chosen and the coupling between *b-a* and *a-e* is unity. In practice the condenser (C_n) is made variable to permit its proper adjustment and is called the neutralizing condenser. The disadvantages of the Rice method lie in the fact that part of the input voltage across *a-e* is lost since it is not impressed on the grid, and that neither side of the neutralizing condenser can be grounded.

A modification of the Rice method is shown in Fig. 37, *A* being a schematic diagram of connections. Diagram *B* shows that this circuit can also be resolved into a three-winding transformer circuit. From the theory there will be a value of C_n for which the voltage across *b-a* will be very low, approaching zero as the resistance of *c-a-f* decreases. This system is not so useful for power amplifiers as the Rice system; the plate circuit of the latter can be more favorably loaded because the entire plate coil is in the plate circuit.



A. Schematic Diagram *B*. Equivalent Circuit

FIG. 37. Modified Rice System for Neutralization. The tuning and bypass capacitors shown in the circuit diagram on the left are omitted from the equivalent three-winding diagram on the right.

Both these methods require that for perfect neutralization the coefficient of coupling be unity and that the incidental resistances be zero; hence perfect neutralization can be only approached.

A pushpull r-f amplifier can be neutralized, as shown in Fig. 31, by means of the condensers C_6 and C_7, the value of which is equal to the grid-plate capacitance of the tubes for symmetrical input and output circuits.

In general, shielding of the input and output circuits of a capacitance-neutralized amplifier need not be so complete or effective to prevent feedback as for the screen-grid tube amplifier, because some stray magnetic or capacitance feedback can be effectively compensated for by the proper adjustment of the neutralizing condensers for minimum feedback. A common and convenient method to adjust the neutralizing capacitance properly is to apply a signal to the grid of the amplifier to be neutralized with the tube in place and the filament lighted but without plate voltage. An r-f galvanometer is placed in the plate tank circuit, and the neutralizing capacitances are adjusted for zero or minimum galvanometer deflection. Precaution against excessive currents through the galvanometer must be taken for the initial adjustment of the neutralizing condensers, or other methods of indicating a tank voltage may be used.

If the amplifier to be neutralized is a plate-modulated class C amplifier the simplest and quickest method for neutralizing is to overmodulate the amplifier and adjust the neutralizing condenser until the instantaneous value of carrier will be zero at the peaks of downward modulation. A cathode-ray oscillograph may be used as an indicator for the adjustment.

SPECIAL-PURPOSE AMPLIFIERS

By E. L. Clark

A special-purpose amplifier, as the name implies, is a particular type of vacuum-tube amplifier designed for a definite purpose. Such amplifiers are usually of the capacitance, impedance-coupled circuit type, as differentiated from tuned and mutually coupled amplifiers.

A wide-band amplifier is an amplifier that covers a wide frequency spectrum, such as is used for a television video amplifier. In most cases, the wide-band amplifier operates as a class A amplifier with plate current flowing for 360 electrical degrees. A wide-band amplifier is characterized by low gain; for a given tube the gain multiplied by the band width is a constant.

A cathode follower is an amplifier which has its output load in the cathode circuit of a vacuum tube. The characteristics of a cathode follower are: reduced input capacitance, increased input resistance, reduced output impedance, a gain of less than 1, and no voltage inversion. The cathode follower may be used as an impedance matching device, without the use of a transformer.

A grounded-grid amplifier is an amplifier that has its grid grounded, and the input signal applied to the cathode. The output circuit is in the plate, in the usual manner. The characteristics of a grounded-grid amplifier are: low input impedance, low input-to-output capacitance due to the shielding action of the grounded grid, and no voltage inversion.

An in-phase amplifier is one in which the polarity of the output signal is the same as that of the input signal. This is of no importance in sine-wave work. However, for pulse work and for television video amplifiers, the polarity of the amplified signal is of great importance.

A negative feedback amplifier is an amplifier in which some of the output signal is fed back to the input to modify the output. There are two general types of feedback amplifiers, the voltage-feedback and the current-feedback types. Both are characterized by a reduction in gain. However, the voltage-feedback type gives an apparent decrease in plate resistance. Both types of feedback give a reduction in distortion.

A one-shot amplifier is an amplifier which, after responding to an input pulse, will not respond to a second pulse until a given time has elapsed. This amplifier is similar to a multivibrator, and it requires two tubes. The characteristic of a one-shot amplifier is that, after a given input level has been reached, the output is a sudden sharp pulse which cannot be immediately repeated, a definite time interval being required before a second pulse can be obtained.

A pulse amplifier is an amplifier that is designed to handle a pulse type of input signal. Pulse signals are of two general types: positive pulses and negative pulses. The pulse amplifier must be designed for the polarity of pulse to obtain the optimum performance. The band width of the pulse amplifier must also be adjusted to the type of pulse being handled if the pulse shape is not to be degraded and if maximum gain is to be obtained.

The characteristic of a pulse amplifier intended to handle positive pulses requires that it be biased nearly to cutoff and that it shall approach class B operation and efficiency. However, to handle negative pulses the vacuum-tube bias must be near zero, and a heavy plate current is drawn except when the pulse signal is applied. This results in low efficiency for a negative pulse amplifier.

5. WIDE-BAND AMPLIFIERS

The wide-band amplifier is used when the frequency response must be extended beyond about 15 kc. It finds its chief application as a video amplifier in television equipment. However, it is finding other uses such as in radar and pulse work. In order better to understand the frequency response limitations of an r-c coupled amplifier, see Fig. 1. This is a curve of output voltage vs. frequency, of a typical amplifier stage, as shown in Fig. 2. The frequencies $5f_1$ and f_2 are considered the useful limits of the wide-band amplifier. This is somewhat empirical, but practice has shown it to be desirable in order to reduce the low-frequency phase shift (see p. 7-46). If many cascaded stages are used it may be desirable to take $10f_1$ instead of $5f_1$ as the low-frequency limit of the amplifier.

HIGH-FREQUENCY RESPONSE. The high-frequency range will be defined as that region lying above about 1 kc. The simplest form of wide-band amplifier is that shown in Fig. 2 with a low value of plate resistor (r_L). In general, pentodes are used for wide-band amplifiers, for two reasons. First, the Miller capacitance effect is negligible; second, they are made with a higher mutual conductance (g_m) than triodes. The general formulas for a class A amplifier, eqs. (1), (1a), and (2) (p. 7-03), also cover wide-band amplifiers. However, the value of Z is of interest and governs the gain and band width of the amplifier. In Fig. 2, C_T is the total shunting capacitance, composed of the stray circuit capacitance, the output capacitance of V_1, and the input capacitance of V_2 (which may be partly composed of Miller capacitance in triodes). Let the resistance r_0 represent the resulting

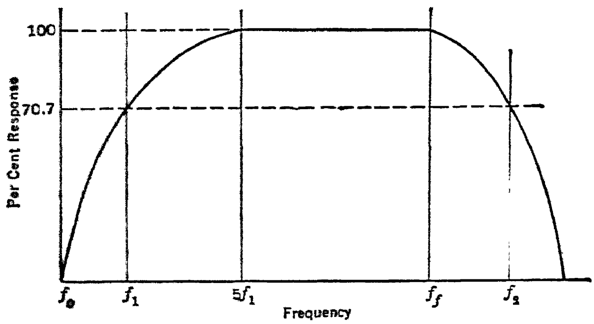

FIG. 1. Amplifier Response Curve

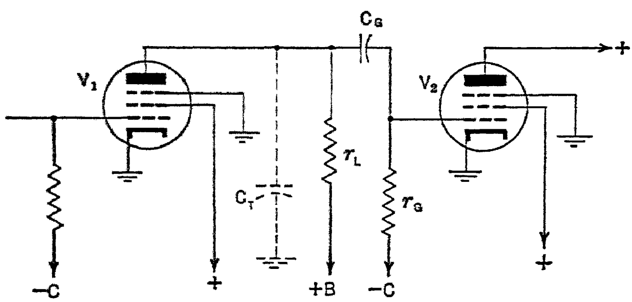

FIG. 2. Uncompensated Amplifier Stage

parallel resistance of the plate resistor r_L and the grid resistor r_g. The absolute value of Z is given by

$$Z = \frac{r_0 x_{C_T}}{\sqrt{r_0^2 + x_{C_T}^2}} \tag{1}$$

At the frequency f_2 which makes the capacitance reactance x_{ct} equal to r_0, the response will be down to 70.7 per cent of the maximum response. This gives a means of determining the value of C_T.

$$C_T = \frac{1}{2\pi f_2 r_0} \tag{2}$$

As the plate resistor r_L is usually much smaller than r_g, the effect of r_g is usually negligible.

Using g_m, the mutual conductance of the vacuum tube, the gain of the stage is

$$\text{Gain } A = \frac{g_m r_p Z}{r_p + Z} \tag{3}$$

However, for wide-band amplifiers using pentodes, r_p is much greater than Z, therefore r_p can usually be disregarded, and the gain then becomes

$$\text{Gain } A = g_m Z \tag{4}$$

The maximum gain of the flat portion of the curve of Fig. 1 is simply $g_m r_L$.

The phase angle (ϕ) is

$$\phi = \tan^{-1} \frac{r_L}{x_{C_T}} \tag{5}$$

for parallel resistance and capacitance as shown in Fig. 2 which represents a time delay of

$$\frac{0.035}{f_2} \text{ seconds} \tag{6}$$

For an uncompensated amplifier: Fig. 3 gives the value of r_L for various values of shunt capacitance C_T, at the frequency f_2. The response will be down to 70.7 per cent of the flat portion of the curve at frequency f_2 when using a plate load r_L as determined from Fig. 3.

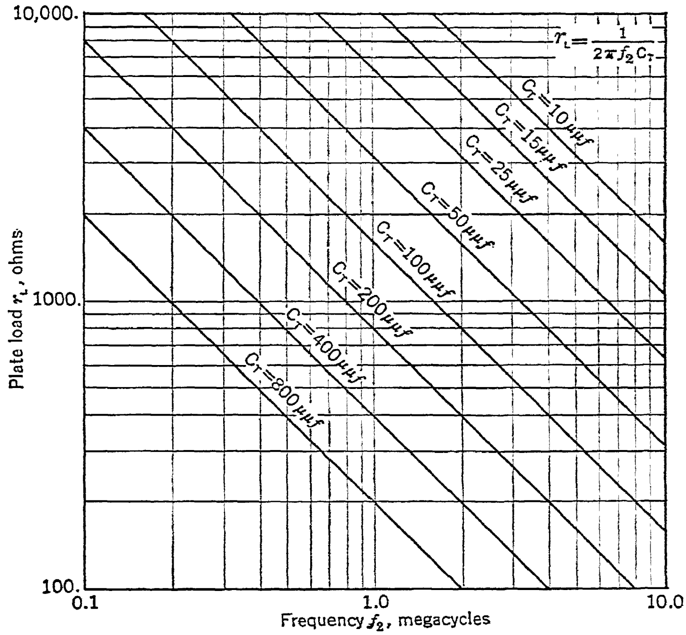

FIG. 3. Plate Load (r_L) in Terms of Frequency (f_2) and Total Capacitance (C_T) for an Uncompensated or Shunt Peaked Amplifier

SHUNT PEAKING. In Fig. 4 is shown the schematic of an amplifier stage using shunt peaking. As previously described, C_t is the total shunting capacitance. The gain for this amplifier is given by eq. (4). The value of Z is

$$Z = X_{C_T}\sqrt{\frac{r_L^2 + x_L^2}{r_L^2 + (x_L - x_{C_T})^2}} \tag{7}$$

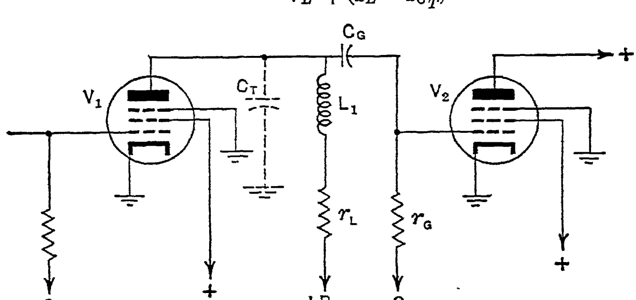

FIG. 4. Circuit for a Shunt Peaked Amplifier Stage

If an inductance L_1 is chosen so that $x_{L1} = \frac{1}{2} x_{C_T}$ at f_2, the resulting impedance Z will be equal to r_L. This means that the response will be flat to frequency f_2 instead of being

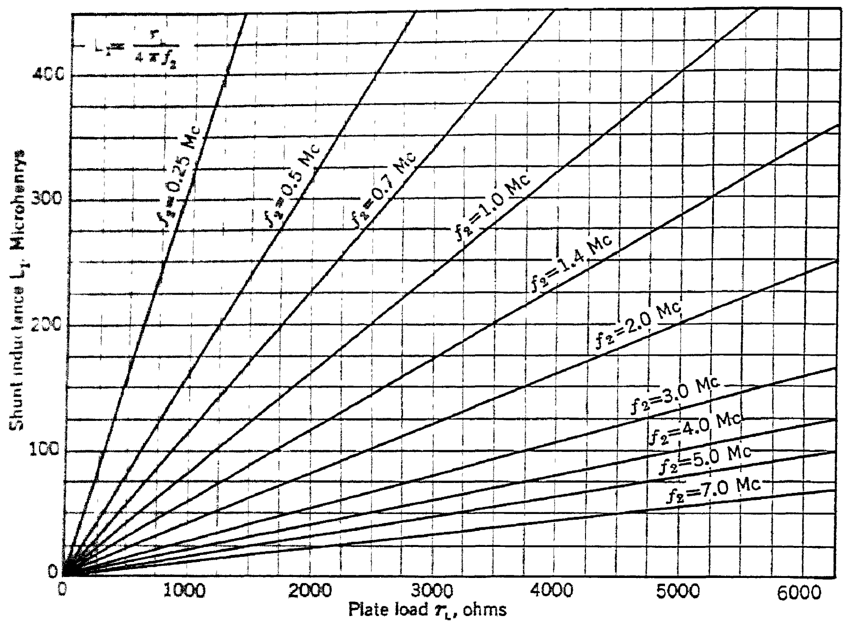

FIG. 5. Shunt Inductance (L_1) in Terms of Frequency (f_2) and Plate Load (r_L) for a Shunt Peaked Amplifier

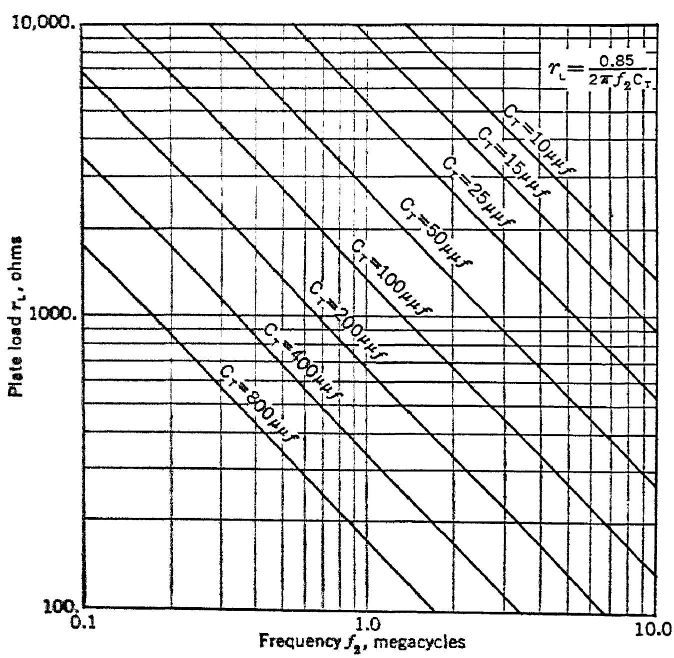

FIG. 6. Plate Load (r_L) in Terms of Frequency (f_2) and Total Capacitance (C_T) for a Shunt Peaked Amplifier, with Corrected Phase and Amplitude Characteristics

down to 70.7 per cent as in the uncompensated amplifier. The values are

$$r_L = \frac{1}{2\pi f_2 C_t} \tag{8}$$

$$L_1 = \frac{r_L}{4\pi f_2} \tag{9}$$

$$\text{Gain } A = g_m r_L \tag{10}$$

The time delay is no greater than $0.023/f_2$ seconds.

Figure 5 gives the value of inductance L_1, for various frequencies f_2, and load resistance r_L for use in a shunt peaked amplifier.

A shunt peaked amplifier can be designed quickly by the use of Fig. 3 and Fig. 5. Knowing what frequency f_2 is needed (say 3.0 megacycles), determine the value of C_t; 40 $\mu\mu f$ is

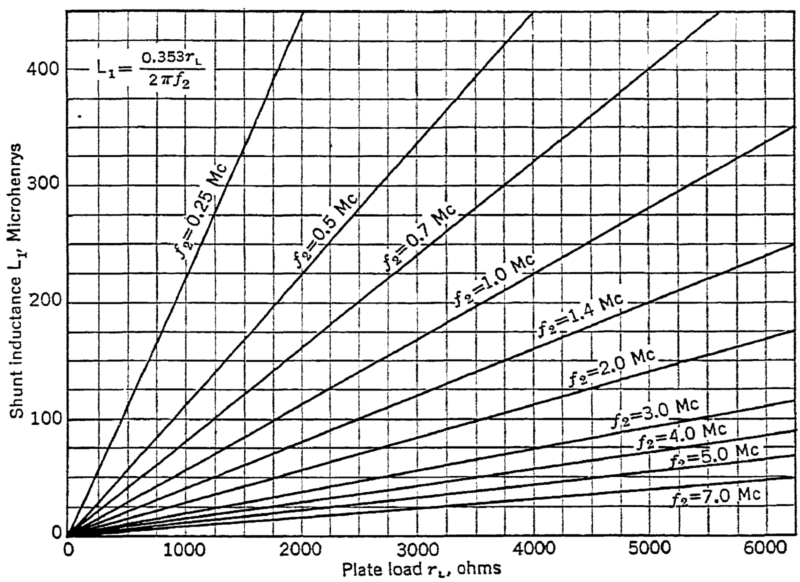

FIG. 7. Shunt Inductance (L_1) in Terms of Frequency (f_2) and Plate Load Resistance (r_L) for a Shunt Peaked Amplifier with Corrected Phase and Amplitude Characteristics

a good estimate. Then from Fig. 3 find r_L to be 1330 ohms. Now from Fig. 5 at 3 megacycles and 1330 ohms, L_1 is found to be 35.2 microhenrys. The stage gain will be 1330 times the mutual conductance g_m of the tube in mhos.

For multistage wide-band amplifiers where the best phase and amplitude characteristics are needed, slight revisions in eqs. (8) and (9), as shown by Freeman and Schantz, will give almost perfect results up to frequency f_2

$$r_L = \frac{0.85}{2\pi f_2 C_t} \tag{11}$$

$$L_1 = \frac{0.353 r_L}{2\pi f_2} \tag{12}$$

Equations (11) and (12) are plotted in Fig. 6 and Fig. 7 to facilitate the design of such an amplifier.

SERIES PEAKING. Figure 8 is the schematic diagram of a series peaked amplifier. It can be seen from Fig. 8 that the capacitance is split by the inductance L_2. This results in the vacuum tube V_1 working into a smaller capacitance than in the previous case of shunt peaking, with the results that more gain is obtained. For proper operation the ratio of $C_1/C_2 = 1/2$. If $C_1/C_2 = 2$ the plate load resistor r_L must be put on the other side of the series inductance L_2. The rule is to keep the plate load resistance r_L on the low-

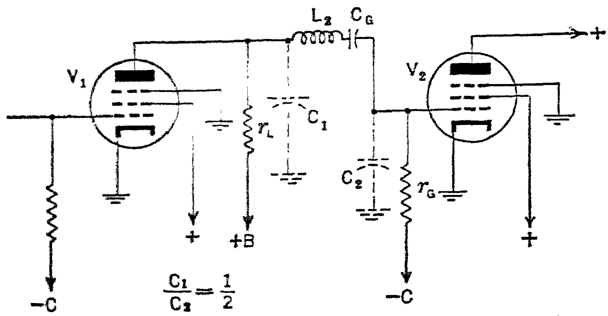

FIG. 8. Circuit for a Series Peaked Amplifier when $C_1/C_2 = 1/2$

capacitance side of the series inductance L_2. The value of r_L for series peaking is given by

$$r_L = \frac{1}{4\pi C_1 f_2} \tag{13}$$

where $C_1/C_2 = 1/2$. In most cases, however, it is more convenient to use C_T, the sum of C_1, C_2, and strays, since C_T can be determined more accurately than C_1. In terms of C_T, r_L is given by

$$r_L = \frac{1.5}{2\pi f_2 C_T} \tag{14}$$

If the series inductance L_2 is chosen to resonate with C_1 at a frequency of $f_2\sqrt{2}$, the response will be flat to frequency f_2. The value of the series inductance L_2 is given by

$$L_2 = \frac{1}{8\pi^2 f_2^2 C_1} \tag{15}$$

or, in terms of C_T, $L_2 = 667 C_T r_L^2$.

Substituting the value of C_T from eq. (14)

$$L_2 = \frac{r_L}{2\pi f_2} \tag{16}$$

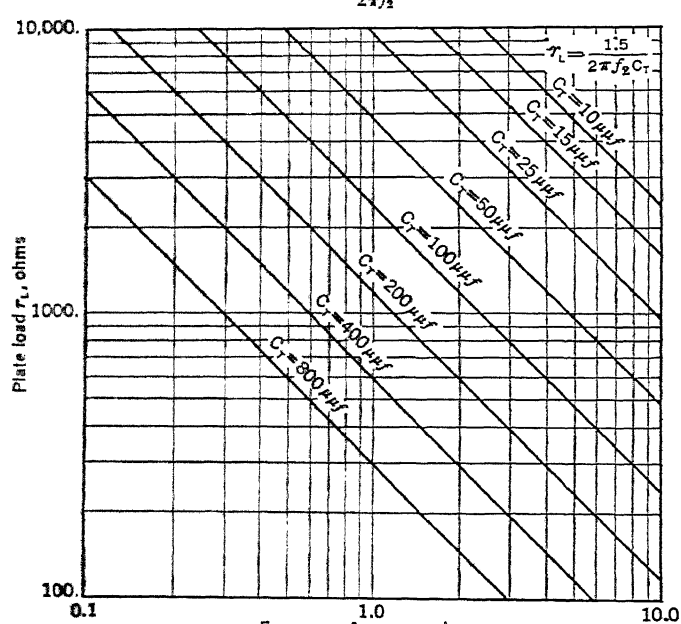

FIG. 9. Plate Load (r_L) in Terms of Frequency (f_2) and Total Capacitance (C_T) for a Series Peaked Amplifier Stage

The phase delay is a rather complicated function in the series peaking circuit, but in general, as Seeley and Kimball have shown, the time delay up to the frequency f_2 is constant within a variation of $0.0113/f_2$ seconds. This is roughly one-half the variation in

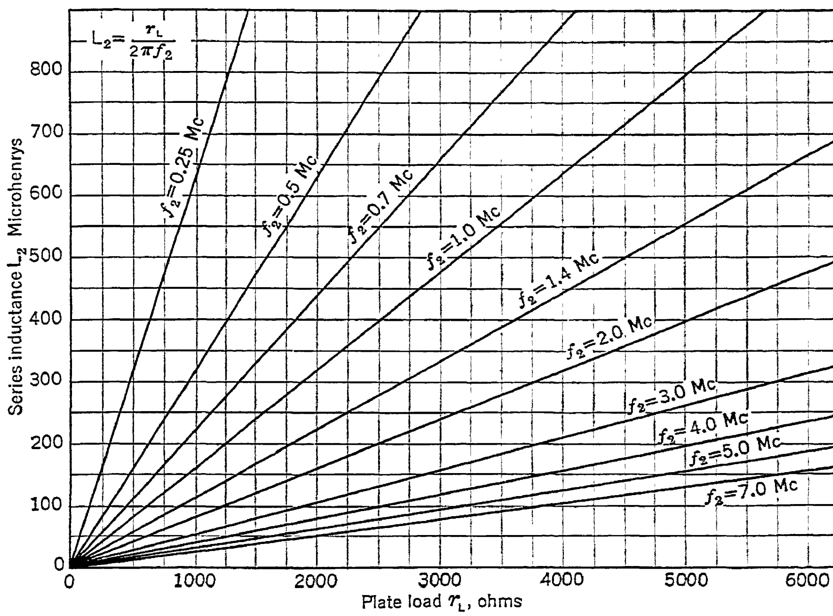

FIG. 10. Series Inductance (L_2) in Terms of Frequency (f_2) and Plate Load (r_L) for a Series Peaked Amplifier Stage

phase delay experienced with shunt peaking. The gain of a series peaked amplifier is given by eq. (10), using the value of r_L as obtained from eq. (14).

To facilitate the design of a series peaked amplifier eq. (14) is plotted in Fig. 9 and eq. (16) is plotted in Fig. 10. The curves of Fig. 9 and 10 are to be used as described in *shunt peaking*.

COMBINATION OF SHUNT AND SERIES PEAKING. As might be expected, the advantages of shunt and series peaking can be combined to increase the gain further.

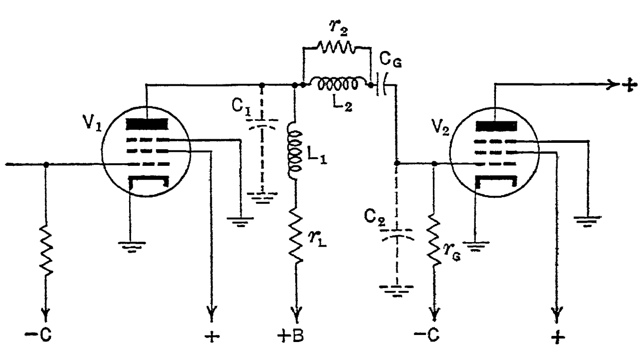

FIG. 11. Circuit for a Combined Shunt and Series Peaked Amplifier Stage

The series inductance L_2 separates the output capacitance C_1 and the input capacitance C_2, while the shunt inductance L_1 compensates for the output capacitance C_1. The circuit is shown in Fig. 11.

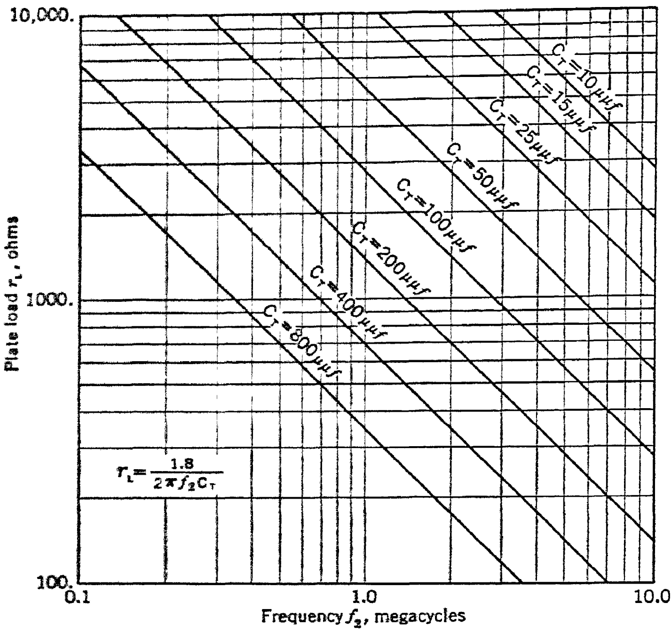

FIG. 12. **Plate Load** (r_L) in Terms of Frequency (f_2) and Total Capacitanec (C_T) for a Combined Shunt-series Peaked Amplifier Stage

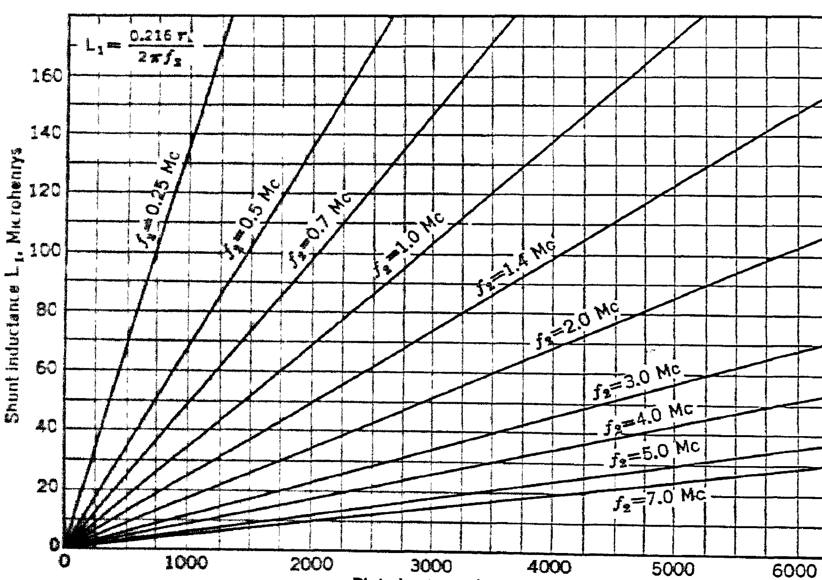

FIG. 13. **Shunt Inductance** (L_1) in Terms of Frequency (f_2) and Plate Load Resistance (r_L) for a Combined Shunt-series Peaked Amplifier Stage

Again, as in series peaking, the ratio of $C_1/C_2 = {}^1/_2$ for proper operation.

$$r_L = \frac{1.8}{2\pi f_2 C_T} \tag{17}$$

$$L_1 = 0.12 C_T r_L^2 \tag{18}$$

$$L_2 = 0.52 C_T r_L^2 \tag{19}$$

If the value of C_T from eq. (17) is substituted in eq. (18) and (19), they become

$$L_1 = \frac{0.216 r_L}{2\pi f_2} \tag{20}$$

$$L_2 = \frac{0.936 r_L}{2\pi f_2} \tag{21}$$

The gain of a combined peaked amplifier is given by eq. (10) using the value of r_L as obtained from eq. (17).

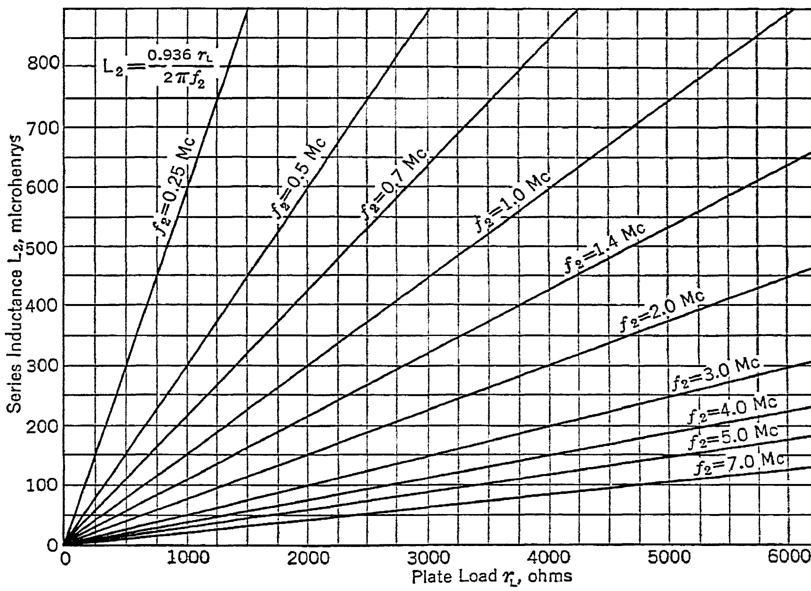

FIG. 14. Series Inductance (L_2) in Terms of Frequency (f_2) and Plate Load Resistance (r_L) for a Combined Shunt-series Peaked Amplifier Stage

The phase-delay expression becomes more complicated in this type of peaking, but it does not exceed $0.015/f_2$ seconds, up to f_2.

If the Q of L_2 is too high, a high-frequency peak will be experienced just before f_2 is reached. The resistance r_2 shunting L_2 is to lower the Q of the inductance L_2 and prevent the formation of a peak in the response curve. The value of resistance r_2 may vary from 5 to 10 times the load resistance r_L.

Equations (17), (20), and (21) are plotted in curves, Figs. 12, 13, and 14, to expedite the design of a combined shunt-series peaked amplifier.

CONSTANT-*K*-TYPE FILTER COUPLING NETWORK. The schematic diagram, Fig. 15, shows a wide-band amplifier of the constant-K, low-pass filter type. This circuit appears at first glance like the combined shunt-series peaking network; however, its constants are based on standard constant-K low-pass filter equations, as follows: $L_2 = \dfrac{r}{\pi f_2}$ and $C_2 = \dfrac{1}{\pi f_2 r}$. In forms to apply to the circuit of Fig. 15 these become:

$$r_L = \frac{1}{\pi f_2 C_2} \tag{22}$$

$$L_2 = r_L^2 C_2 = \frac{r_L}{\pi f_2} \tag{23}$$

$$L_1 = \frac{L_2}{2} \tag{24}$$

and r_2 = 5 to 10 times r_L. The stage gain is still given by eq. (10) using the value of r_L from eq. (22). This indicates higher gain than any of the other high peaking systems. This is true; however, one factor has been ignored in all the foregoing systems, namely, distributed capacitance. Only the distributed capacitance C_d across the series coil as

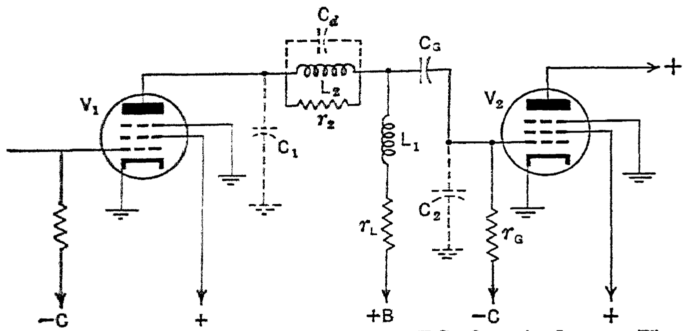

FIG. 15. Circuit for a Wide-band Amplifier with a Constant-K Configuration Low-pass Filter-coupling Network

shown in Fig. 15 has much effect. This capacitance, however, changes the seeming constant-K low-pass filter coupling network into an M-derived filter section. In most wide-band amplifiers the frequencies encountered are high enough so that this effect cannot be ignored. In changing from a constant-K to an M-derived low-pass filter, there are two ways to keep a given pass band: to reduce the shunting capacitance, or to reduce the characteristic impedance. As the capacitance cannot be reduced, the only course is to reduce the load resistance r_L, thus lowering the gain. The equations, taking this distributed capacitance C_d into consideration, are as follows:

$$M = \sqrt{1 + \left(\frac{C_d}{C_1}\right)^2} - \frac{C_d}{C_1} \tag{25}$$

$$r_L = \frac{M}{\pi f_2 C_2} \tag{26}$$

$$L_2 = r_L{}^2 C_2 = \frac{M r_L}{\pi f_2} \tag{27}$$

Also $L_1 = 0.8L_2$ approximately, and r_2 = 5 to 10 times r_L.

Equation (28) gives the frequency of infinite attenuation which should be kept well outside the pass band to prevent excessive phase shift.

$$f\infty = \frac{1}{\pi\sqrt{2L_2C_1(1 - M^2)}} \tag{28}$$

Under normal conditions the phase shift is about the same as for the combined shunt and series peaking system.

Equation (25) is plotted in Fig. 16, which gives the values of M in terms of the output

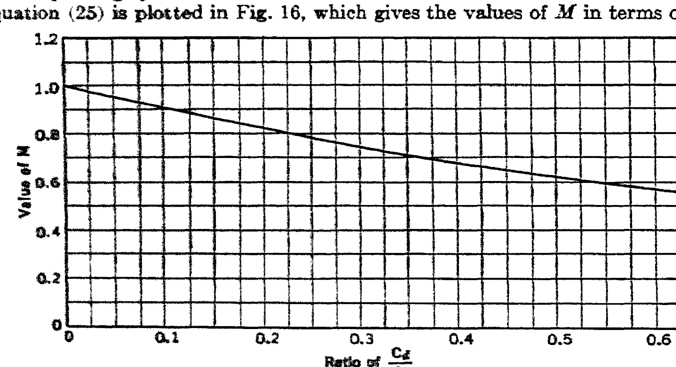

FIG. 16. Value of M as Produced by the Distributed Capacitance (C_d) of the Series Peaking Coil (L_2) and the Output Capacitance (C_1) of V_1 (Fig. 15)

capacitance C_1 and the distributed capacitance C_d of the series inductance L_2. The curve in Fig. 17 shows the effect of M on the load resistance r_L and the series inductance L_2. As the stage gain is directly proportional to the load resistance r_L, the importance of keeping the distributed capacitance C_d as low as possible is apparent.

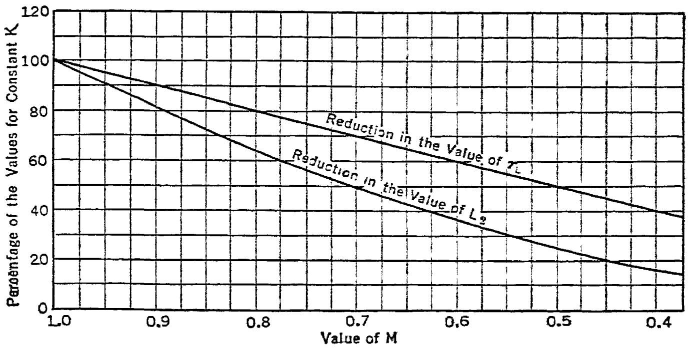

FIG. 17. The Effect of M on the Plate Load (r_L) and the Series Peaking Inductance (L_2)

Equations (22), (23), and (24) are plotted in the form of curves in Figs. 18 and 19 to be used for designing wide-band amplifiers of the constant-K configuration. Knowing the top frequency f_2 (say 3 megacycles), determine the value of C_2; 25 $\mu\mu$f is a good estimate. Then from Fig. 18 find r_L to be 4240 ohms. Now from Fig. 19 at 3 megacycles and 4240 ohms find L_2 = 448 microhenrys, and L_1 = 224. However, the distributed capacitance of L_2 must be considered. It may be about 4 $\mu\mu$f while C_1 may be approximately 16 $\mu\mu$f.

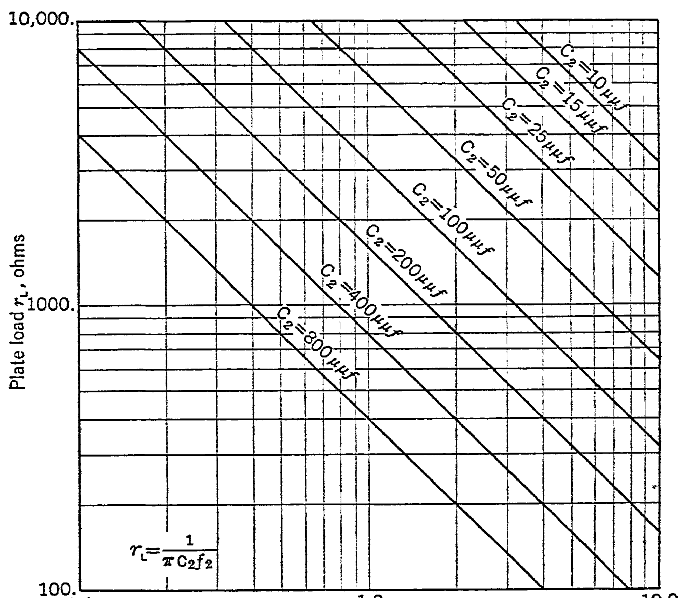

FIG. 18. Plate Load Resistance (r_L) in Terms of Frequency (f_2) and Input Capacitance (C_2) for a Constant-K Type Low-pass Coupling Network

This gives a ratio for C_d/C_1 of 0.25; referring to curve Fig. 16 M is found to be 0.78. Referring to Fig. 17 at the point M = 0.78 the value of r_L will be 78 per cent of that for a constant-K network and the value of L_2 will be 60.8 per cent of that for a constant-K network. These factors modify the value obtained above, r_L becomes 3300 ohms, and L_2

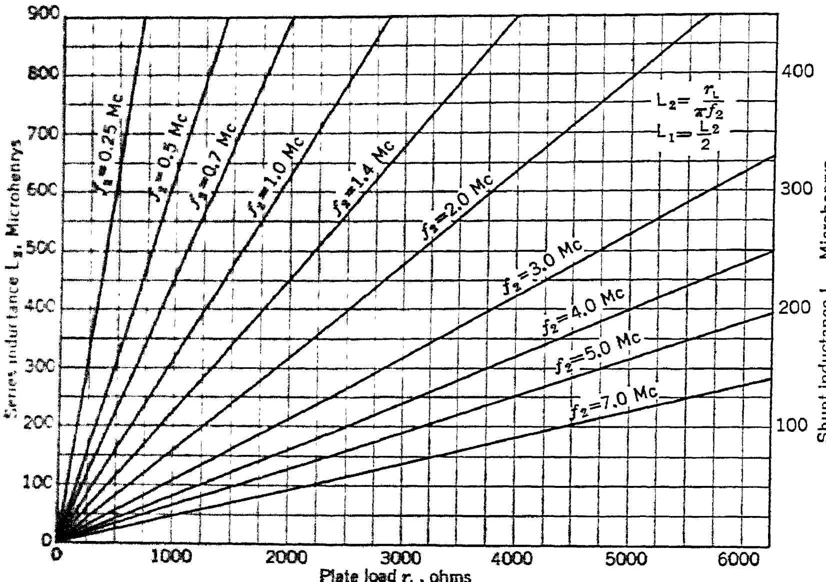

FIG. 19 Shunt and Series Inductances (L_1) and (L_2) in Terms of Plate Load Resistance (r_L) and Frequency (f_2) for a Constant-K Type Low-pass Filter-coupling Network

becomes 272 microhenrys. From the above derivation L_1 = 218 microhenrys, which is approximately that obtained from Fig. 19. The shunting resistor r_2 would have a value somewhere between 15,000 ohms and 33,000 ohms, depending upon the Q of the peaking coil (L_2). Its exact value would have to be determined by test.

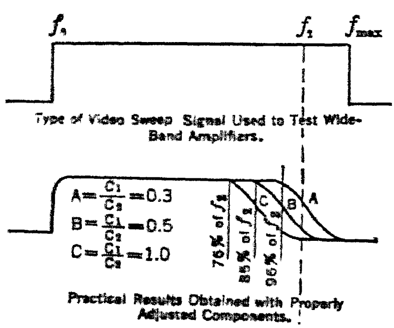

FIG. 20. Practical Results Obtained with Properly Adjusted Components (Constant-K Type)

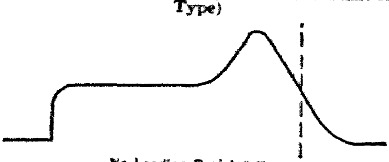

FIG. 21. Curve Shape Obtained When No Loading Resistor (r_2) Is Used

FIG. 22. Curve Shape Obtained When the Loading Resistor (r_2) Is Too Large

FIG. 23. Curve Shape Obtained When the Loading Resistor (r_2) Is Too Small

FIG. 24. Curve Shape Obtained When the Plate Load Resistor (r_L) Is Too Large

In practice the wide-band amplifier is built as designed, and then tested by means of a video sweep of constant amplitude from zero to possibly 10 megacycles. This signal is applied to the grid of the wide-band amplifier. The output of the second stage V_2 is observed across a very low plate resistance, possibly 100 ohms. Figure 20 shows the response of the wide-band amplifier of the constant-K configuration when all its components are adjusted properly. Figures 21 to 28 inclusive give the response obtained with various components that have incorrect values.

FIG. 25. Curve Shape Obtained When the Plate Load Resistor (r_L) Is Too Small

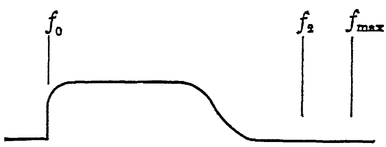

FIG. 26. Curve Shape Obtained When the Series Peaking Coil (L_2) Is Too Large

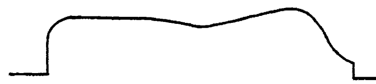

FIG. 27. Curve Shape Obtained When the Series Peaking Coil (L_2) Is Too Small

FIG. 28. Curve Shape Obtained When the Shunt Peaking Coil (L_1) Is Incorrect

Multistage wide-band amplifiers using pentodes or beam power tubes offer no particular difficulty. However, if a multistage triode amplifier is to be designed, trouble will be encountered if peaking is used in the grid circuit and plate circuit of the same tube, as it may result in a tuned-grid, tuned-plate oscillator.

FIGURE OF MERIT FOR WIDE-BAND AMPLIFIER TUBES. The capability of a vacuum tube to amplify at high frequencies depends not only upon its mutual conductance but also upon its input and output capacitances. It is these capacitances, in addition to the stray capacitance, that limits the value of plate resistance r_L that can be used. The "Miller" capacitance effect is the chief reason triodes are not satisfactory as wide-band amplifiers.

Considering these factors, eq. (29) gives an acceptable figure of merit (F.M.) for wide-band amplifiers.

$$\text{F.M.} = \frac{g_m}{C_{gk} + C_{pk} + C_{gp}(1 + A)} \tag{29}$$

Equation (29) is applicable to either triodes or pentodes; for pentodes and beam power tubes C_{gp} is so small that the last term may be ignored, hence:

$$\text{F.M.} = \frac{g_m}{C_{\text{in}} + C_{\text{out}}} \tag{30}$$

Table 1 gives a list of vacuum tubes with their corresponding figure of merit.

Table 1. List of Vacuum Tubes Applicable to Wide-band Amplifier Service, and Their Figure of Merit

Tube Type	Input Capacitance, $\mu\mu$f	Output Capacitance, $\mu\mu$f	G_m	F.M.
6AK5	4.0	2.8	5,100	750

COMPARISON OF HIGH-FREQUENCY COMPENSATION METHODS. Table 2 gives the essential design data for high-frequency compensation of wide-band amplifiers. The last three types listed as "practical results" give data obtained by measuring the constant-K network response, with different ratios of C_1/C_2. As the distributed capacitance C_d cannot be eliminated, it must be considered as producing an M-derived low-pass filter network.

Table 2. Summary of Wide-band Amplifier Formulas

Type	r_L	L_2	L_1	Relative Gain at f_2	M
Uncompensated	$\frac{1}{2\pi f_2 C_T}$	....	....	0.707	....

Gain $= r_L G_M$

LOW-FREQUENCY RESPONSE. Low-frequency attenuation or low-frequency amplitude distortion and phase shift may be introduced in any one of four places, or a combination of the four. They are (1) cathode resistor and by-pass condenser; (2) grid condenser-resistor coupling network; (3) screen supply resistor and by-pass; (4) the internal impedance of the B power supply.

EFFECT OF A CATHODE RESISTOR AND BY-PASS. One method of obtaining a negative bias on the grid of a vacuum-tube amplifier is to include a resistor r_k in series with the cathode to ground; to prevent loss of gain, this resistor r_k is shunted by a capacitor C_k. See Fig. 29. The effect of this bias network $r_k C_k$ on the low-frequency response is caused by the fact that, the lower the frequency, the higher the capacitive reactance of C_k and the less its shunting effect on r_k. This results in cathode degeneration with an accompanying loss in gain. The gain of such an amplifier stage is given by:

$$\text{Gain } A = \frac{g_m r_L}{1 + \frac{r_L}{r_p} + Z_k\left(\frac{1}{r_p} + g_m\right)} \tag{31}$$

The cathode circuit impedance Z_k, is given by

$$Z_k = \frac{r_k/(2\pi f C_k)}{\sqrt{r_k^2 + (1/2\pi f C_k)^2}} \tag{32}$$

Equation (31) is a general formula. For a wide-band amplifier the tube is usually of the pentode type, in which case $r_p \gg r_L$, and $r_p \gg 1.0$, so r_L/r_p and $1/r_p$ may be disregarded, and eq. (31) becomes:

$$\text{Gain } A = \frac{g_m r_L}{1 + g_m Z_k} \tag{33}$$

To prevent loss of gain at the lowest frequency, Z_k must remain essentially constant. In practice this may mean hundreds of microfarads for C_k, especially if r_k is low. It is possible to compensate for the loss of gain due to cathode degeneration by a plate filter r_FC_F in the plate circuit of the amplifier stage (Fig. 29). The conditions that must be

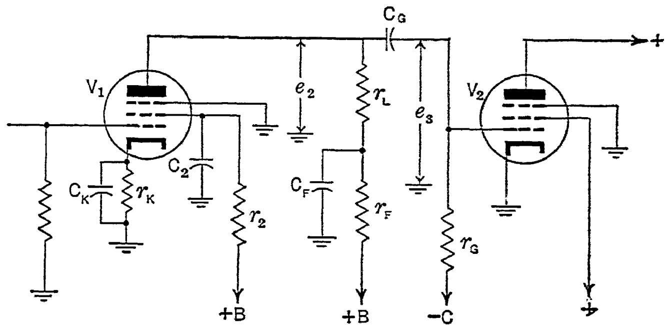

FIG. 29. Amplifier Stage Considering Low-frequency Response Only

met to compensate for the r_kC_k network are: $r_kC_k = r_FC_F$, $r_F/r_k = r_Lg_m$, and $C_k/C_F = r_Lg_m$, from which the values of r_F and C_F are obtained

$$r_F = g_m r_L r_k \tag{34}$$

and

$$C_F = \frac{C_k}{g_m r_L} \tag{35}$$

THE EFFECT OF THE GRID COUPLING CAPACITOR-RESISTOR. With a grid coupling condenser C_G and resistor r_g, Fig. 29, the voltage e_3 impressed on the grid of V_2 will decrease, as the frequency decreases, assuming e_2 to remain constant. The ratio e_3/e_2 is given by

$$\frac{e_3}{e_2} = \frac{r_G}{\sqrt{r_G^2 + (1/2\,\pi f C_G)^2}} \tag{36}$$

At the frequency that makes the capacitive reactance $1/\omega C_G$ equal to the grid resistance r_G, the response e_3/e_2 will be 70.7 per cent of that at mid-range frequency, and the phase shift will be

$$\tan^{-1}\frac{X_{C_G}}{r_G} = 45 \text{ deg} \tag{37}$$

The grid resistor r_G should be made as large as possible; its value, however, is limited by the tube manufacturer to a maximum for a given tube type. For a given low-frequency response the value of C_G may have to be so large that there is danger of ruining the high-frequency response by increased stray capacitance to ground. In practice the value of C_G would be 0.05 to 0.10 μf, and r_G would be the manufacturer's maximum value for the tube type being used. If these values do not give a response at the lowest frequency of $5f_1$ as indicated on Fig. 1, compensation is needed.

Equations (36) and (37) are plotted in the form of curves in Fig. 30. This gives an easy means of determining low-frequency response before compensation. The plate filter C_Fr_F, Fig. 29, can be so proportioned that the voltage rise across r_LC_F as the frequency decreases can just compensate for the voltage loss across C_G, thus producing flat response. Also the phase angles are such as to compensate. To achieve this compensation the time constants of the plate-filter circuit and grid circuit must be equal, that is, $r_GC_G = r_LC_F$, from which

$$C_F = \frac{r_GC_G}{r_L} \tag{38}$$

and

$$r_F = \frac{10}{2\pi f C_F} \tag{39}$$

where f is the lowest frequency to be compensated to full response. These equations are based on the fact that the pentode amplifier is a constant current device within the range of operation. The value of r_F should not be made so high that the amplifier plate voltage falls appreciably below its screen voltage, or trouble may result from too high a screen dissipation.

Usually it is preferable to make the cathode circuit such that no compensation is needed at the lowest frequency required. Then compensate the grid coupling network in the plate circuit by means of the plate filter. It must be remembered that the plate filter compensation will take care of only the loss of lows at one point. *Do not try to compensate for two losses by a single compensation;* it cannot be done.

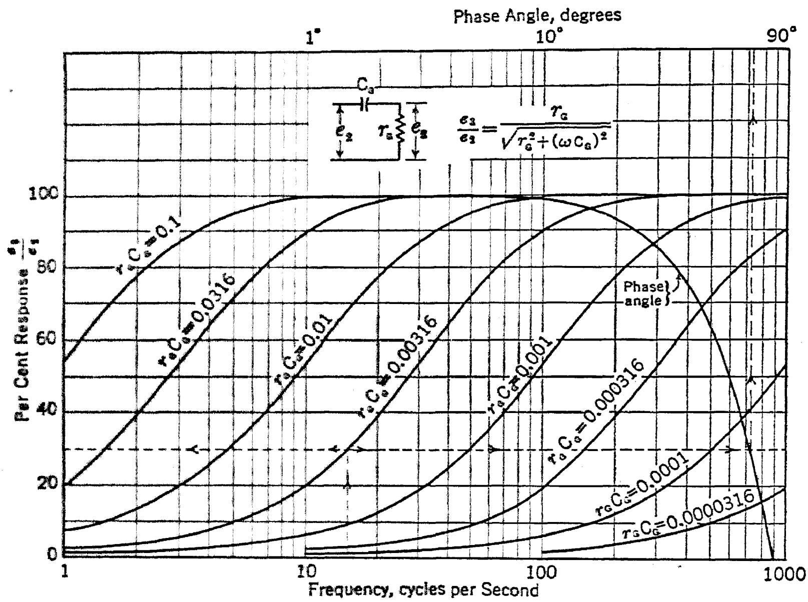

FIG. 30. Curve, Giving the Low-frequency Response Obtained, and the Low-frequency Phase Shift, with Different (r_GC_G) Grid Coupling Network

THE EFFECT OF THE SCREEN BY-PASS. The effect of r_2C_2 (Fig. 29) is similar to that which results from cathode degeneration mentioned previously. However, the screen current is only about 10 per cent of the plate current, and the screen-plate mutual conductance is only about 12 per cent of the control grid or cathode-to-plate mutual conductance, and so the effect is much smaller.

If the time constant of r_2C_2 is made at least 4 times as long as the period of the lowest frequency it is desired to pass, the effect will be negligible. The value of r_2 is determined by the voltage requirements for the particular tube being used; then the value of C_2 is given by:

$$C_2 = \frac{4}{r_2 f} \tag{40}$$

THE EFFECT OF THE INTERNAL IMPEDANCE OF THE POWER SUPPLY. The power supply internal impedance Z_b is essentially the reactance of the output filter condenser. This reactance becomes common for all amplifier stages and may result in the loss of low-frequency response or in low-frequency motor-boating, depending upon the number of stages, the response, and the gain of the system.

It has been found that the capacitive reactance x_c of the final filter condenser in the power supply system, at the lowest frequency encountered, should be no greater than 10 per cent of the effective full load resistance to prevent common coupling through the B supply. The value of the final filter capacitance is then given by:

$$C = \frac{10}{2\pi f r} \tag{41}$$

where r is the effective load resistance which is given by:

$$r = \frac{E_b}{I_b} \tag{42}$$

where E_b and I_b are the B voltage and B current of the B supply.

In general, when designed for low-frequency response, the cathode circuit is by-passed with a capacitor of sufficient size to prevent cathode degeneration at the lowest frequency encountered, or the cathode is grounded and negative bias is supplied to the grid. The screen circuit is adequately by-passed so that no loss of lows results, and the B supply impedance is made sufficiently low to prevent trouble. This leaves only the effect of the grid capacitor-resistor network which must be compensated. This compensation is done in the plate circuit of tube V_1 driving the grid of V_2, as previously explained.

6. CATHODE FOLLOWERS

The name "cathode follower" is given to an amplifier stage when the load, or the major portion of the load, is in the cathode circuit instead of in the plate circuit. Figure 31 shows such an amplifier stage.

This type of operation is called a cathode follower because the cathode tends to follow the grid in voltage as signal is applied, thus reducing the actual grid to cathode voltage

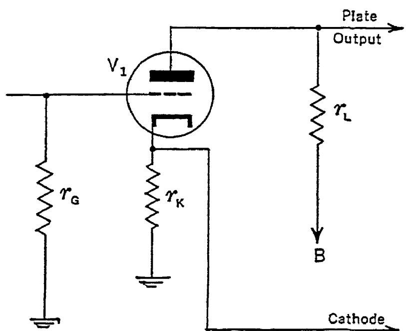

FIG. 31. Cathode-follower Stage General Case, with Resistance in Both the Plate and the Cathode Circuits

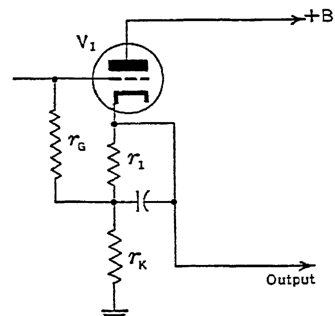

FIG. 32. Cathode-follower Arranged for Proper Bias by Returning the Grid Resistor to a Tap on the Cathode Resistor

below that of the applied signal. This type of circuit finds its widest use as an impedance-changing device. It is used extensively in connection with wide-band amplifiers to match a line where a transformer would be impractical.

Cathode followers usually use triodes, since high gain cannot be realized and since the shunt capacitance of a pentode is high, including screen-to-plate and screen by-pass capacitance as well as the usual cathode capacitance.

Cathode followers have many characteristics not found in amplifiers of other types: (1) output from the cathode circuit, (2) voltage gain to the cathode of less than 1, (3) reduction of input capacitance, (4) increase in input resistance, (5) low output impedance, (6) increase in effective plate impedance, (7) no change in polarity of output signal, and (8) use as a phase splitter with load in both cathode and plate.

When a tube is operated as a cathode follower, the circuit should be so arranged as to supply the proper negative bias for the type of tube being used. If the circuit is as shown in Fig. 31, the Ir drop across the cathode resistor r_k should be such as to provide the proper bias for class A operation. When a high value of cathode resistor is needed, the arrangement shown in Fig. 32 should be used. The Ir drop across the resistor r_1 should provide the proper negative bias for class A operation. If the cathode resistor is so low in value that sufficient negative bias is not developed, an external negative voltage must be supplied to the grid to produce proper class A operation.

In the general case (Fig. 31) the gain to the cathode is always less than 1 and is:

$$\text{Gain } A = \frac{g_m r_k}{1 + (r_L/r_p) + r_k[(1/r_p) + g_m]} \tag{43}$$

If the plate resistor is zero (Fig. 32), eq. (43) becomes

$$\text{Gain } A = \frac{g_m r_k}{1 + r_k[(1/r_p) + g_m]} \tag{44}$$

When the cathode load is not a pure resistance, r_k is replaced by Z_k, which is the absolute value of impedance at the frequency of interest.

For pentode operation $r_p \gg r_L \gg 1$, and so the gain to the cathode becomes

$$\text{Gain } A = \frac{g_m r_k}{1 + r_k g_m} \tag{45}$$

The effective input capacitance of a cathode follower is given by

$$C_{\text{eff}} = C_{gk}\left(1 - \frac{g_m r_k}{1 + r_k[(1/r_p) + g_m]}\right) + C_{gp}\left(\frac{g_m r_L}{1 + (r_L/r_p) + r_k[(1/r_p) + g_m]}\right) \tag{46}$$

When the plate resistor is zero, eq. (46) becomes:

$$C_{\text{eff}} = C_{gk}\left(1 - \frac{g_m r_k}{1 + r_k[(1/r_p) + g_m]}\right) + C_{gp} \tag{47}$$

The effective input resistance is given by:

$$r_{\text{eff}} = \frac{r_g}{1 - \dfrac{g_m r_k}{1 + (r_L/r_p) + r_k[(1/r_p) + g_m]}} \tag{48}$$

The effective output impedance r_0 of a cathode follower, for the general case, is given by:

$$r_0 = \frac{(r_L/r_p) + 1}{(1/r_p) + g_m} \tag{49}$$

Equation (49) is for the tube alone and does not include the effect of the cathode resistor r_k which is in shunt with r_0. The resulting impedance Z_1 is given by:

$$Z_1 = \frac{r_0 r_k}{r_0 + r_k} \tag{50}$$

When the plate resistor r_L is zero, eq. (49) becomes:

$$r_0 = \frac{1}{(1/r_p) + g_m} \tag{51}$$

In a pentode $r_p \gg 1$, and so $r_0 = 1/g_m$.

In some cases it may be more desirable to have Z_1 the effective output impedance of a cathode follower in a single equation rather than first to calculate r_0 and then Z_1. The general case for Z_1 directly is

$$Z_1 = \frac{r_L + r_p}{1 + r_p[g_m + (1/r_k)] + (r_L/r_k)} \tag{52}$$

When r_L is zero, eq. (52) becomes:

$$Z_1 = \frac{1}{(1/r_k) + (1/r_p) + g_m} \tag{53}$$

LINE MATCHING. It is often necessary to couple into a line, matching its characteristic impedance. For audio frequencies this can be done with a matching output transformer, but for wide-band amplifier work such a transformer is not readily available. A cathode follower can be used for such service.

When the characteristic impedance Z of the line to be matched is less than r_0 for the tube to be used the value of the cathode resistor r_k needed to match can be found from eq. (54); the circuit is shown in Fig. 33.

$$r_k = \frac{Z r_p}{r_p - Z(1 + g_m r_p)} \tag{54}$$

When the characteristic impedance Z of the line is higher than the cathode impedance r_0 of the tube, a series resistor is needed (Fig. 34), its value being the difference between Z and r_0 from eq. (51).

In calculating the gain of a cathode follower feeding a line as in Fig. 33, the resulting impedance on the tube cathode is the cathode resistor r_k and the line impedance Z in parallel. This resultant impedance Z_k is used in eq. (44) to obtain the gain of the stage.

In the second case, where the line characteristic impedance Z is greater than r_0, as in Fig. 34, the gain to the line is

$$\text{Gain to line} = \left(\frac{Z}{r_s + Z}\right)\left(\frac{g_m(r_s + Z)}{1 + (r_s + Z)[g_m + (1/r_p)]}\right) \tag{55}$$

When matching a line with a characteristic impedance Z higher than the tube cathode impedance r_0 as in Fig. 34, there must be a d-c circuit through the line capable of carrying the tube plate current; otherwise the cathode follower will not operate. If r_k is too high, however, the operation may be improved by terminating the line of Fig. 33 for direct current as well as for alternating current.

When an amplifier operates with an unbypassed cathode resistor (a type of cathode follower), the effective plate resistance r_p' is increased.

$$r_p' = r_p(1 + g_m r_k) \tag{56}$$

When a cathode follower is operated with a resistor in the plate circuit equal to the resistor in the cathode circuit, it is termed a "phase splitter." That is, the voltage developed in the plate circuit will be equal to the voltage developed in the cathode circuit.

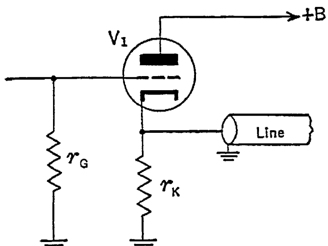

FIG. 33. Cathode-follower Circuit Used to Match a Transmission Line, When the Characteristic Impedance (Z) of the Line Is Lower Than the Cathode Impedance (r_0) of the Tube (V_1)

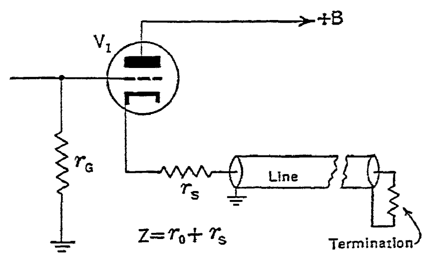

FIG. 34. Cathode-follower Circuit Used to Match a Transmission Line, When the Characteristic Impedance (Z) of the Line Is Higher than the Cathode Impedance (r_0) of the Tube (V_1)

However, the polarity of the voltage in the plate circuit will be the inverse of the voltage in the cathode circuit. This type of circuit may be used to obtain pushpull operation from a single amplifier. The gain to the plate will be given by eq. (31), and the gain to the cathode will be given by eq. (43).

7. GROUNDED-GRID AMPLIFIER

A grounded-grid amplifier is usually a triode which has its grid grounded and the input connected to the cathode. The output circuit is in the plate in the usual manner. Figure 35 shows such a circuit. A triode connected in this manner has some of the characteristics of a screen-grid tube, as the grid acts as a shield between the input and output circuits. It also has some of the characteristics of a cathode follower, as the cathode-input impedance is equivalent to that of a cathode follower with a plate load. Another feature of the cathode-input amplifier is that there is no voltage inversion between the input signal and the output signal as with conventional grid input.

The input impedance Z_1 is given by:

$$Z_1 = \frac{r_L + r_p}{1 + r_p[g_m + (1/r_k)] + (r_L/r_k)} \tag{52}$$

The input impedance Z_1 of a cathode-input amplifier may be adjusted to match a line the same as a cathode follower. Solving eq. (52) for r_k gives

$$r_k = \frac{1 + (r_L/r_p)}{1/2\,[1 + (r_L/r_p)] - [g_m + (1/r_p)]} \tag{57}$$

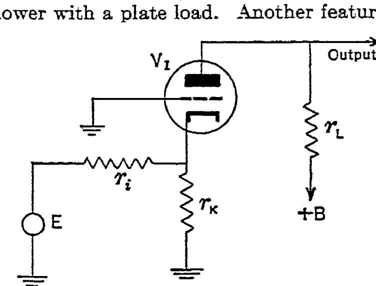

FIG. 35. Circuit of the Grounded-grid Amplifier

The effective impedance Z_k in the cathode circuit must be determined before it is possible to obtain the gain to the plate and the effective plate resistance r_p'. Referring to Fig. 35, r_i represents the internal impedance of the signal input source, and r_k is the cathode resistor.

$$Z_k = \frac{r_i r_k}{r_i + r_k} \tag{58}$$

Where a transmission line is being matched, r_i would be replaced by Z, the characteristic impedance of the line.

The gain of the cathode-input amplifier is given by eq. (31) using Z_k as obtained from eq. (57).

$$\text{Gain } A = \frac{g_m r_L}{1 + (r_L/r_p) + Z_k[(1/r_p) + g_m]} \tag{31}$$

It can be seen from eq. (31) that to obtain high gain with a cathode-input amplifier the cathode impedance Z_k should be kept low and r_L should be made as high as possible. Making r_L high also increases the input impedance as shown by eq. (52).

The effective plate impedance r_p' of a cathode-input amplifier is given by eq. (56), substituting Z_k as obtained from eq. (58)

$$r_p' = r_p(1 + g_m Z_k) \tag{56a}$$

which gives an increase in plate resistance over that of the tube operated in the conventional manner.

8. IN-PHASE AMPLIFIERS

The name in-phase amplifier applies to an amplifier that has the same polarity of signal in the output as that applied to the input. In sine-wave operation this is of little importance, but for pulse amplifiers, or television amplifiers, the polarity of the signal is important. These types of signals are not symmetrical about an a-c axis and must be treated accordingly.

There are four general types of in-phase amplifiers:

1. Cathode follower.
2. Cathode-input amplifier.
3. Combined cathode follower, cathode-input amplifier (cathode-coupled amplifier).
4. Suppressor input, screen output amplifier.

The cathode follower and cathode-input-type amplifiers have been covered in the preceding sections and will not be discussed further.

The third type of in-phase amplifier is a combination of cathode follower and cathode-input amplifier, termed cathode-coupled amplifier. This type of amplifier is best made by using a dual triode with a common cathode, such as a 6J6 or a 6SN7 tube. The circuit is shown in Fig. 36. In an amplifier of this type the polarity of the signal is unchanged at any point through the stage.

The value of r_k should be such that the negative bias developed by the combined plate currents of V_1 and V_2 is proper for class A operation of the tubes V_1 and V_2. In operation the cathode-coupled amplifier exhibits characteristics in some respects similar to those of a screen-grid tube. It can be used with tuned input and tuned output circuits without danger of oscillation, such as would occur if a triode in conventional circuits were used.

FIG. 36. The In-phase Amplifier of the Cathode-coupled Type

The gain of (V_1) the cathode follower can be calculated by using eq. (31), the value of Z_1 obtained from eq. (52) being substituted for Z_k. These two equations can be combined to give the gain to the cathode of V_1; assuming that both tubes are the same, then

$$\text{Gain to cathode of } V_1 = \frac{g_m(r_L + r_p)}{2(1 + r_p g_m) + (r_L + r_p)/r_k + r_L[g_m + (1/r_p)]} \tag{59}$$

The cathode follower is working into the cathode of the second tube which exhibits a low cathode-input impedance, as does any cathode-input amplifier. This cathode impedance must be considered in the gain equation. This is done by using Z_1 of the cathode-input tube as the cathode load for the cathode follower. This is a lower value than that of the cathode resistor.

In obtaining the gain of the cathode-input section V_2, the cathode-output impedance Z_1 for the cathode follower V_1 must be used for the cathode load of the cathode-input amplifier V_2. The value of Z_1 from eq. (53) must be substituted for Z_k in eq. (31). Combining these two equations, the gain of the cathode input section is given by:

$$\text{Gain from cathode to plate of } V_2 = \frac{g_m r_L[1 + (r_p/r_k) + r_p g_m]}{2(1 + r_p g_m) + (r_L + r_p)/r_k + r_L[g_m + (1/r_p)]} \tag{60}$$

The overall gain of the cathode-coupled amplifier is given by the product of the gain to the cathode of V_1 times the gain from the cathode to the plate of V_2. This can be written in a single equation as

Overall gain of cathode-coupled stage

$$= \frac{g_m^2 r_L(r_L + r_p)[1 + (r_p/r_k) + r_p g_m]}{\{2(1 + r_p g_m) + [(r_L + r_p)/r_k] + r_L[(1/r_p) + g_m]\}^2} \tag{61}$$

SUPPRESSOR INPUT, SCREEN OUTPUT AMPLIFIER. The circuit for this amplifier is given in Fig. 37. The circuit requirements are as follows: the tube should be of a type that normally operates with the screen at a lower voltage than the plate, and also it must have a suppressor grid structure that has an effective mutual conductance to the plate. The 6AS6 is a satisfactory tube for this type of operation, as the suppressor-grid-to-plate has a mutual conductance of about 1000 micromhos, and the suppressor grid-to-screen-grid has a mutual conductance g_{ms} of about 850 micromhos. The screen impedance Z_s is of the order of 10,000 ohms.

By the use of a 6AS6 for an in-phase amplifier, the values shown in Fig. 37 give satisfactory results. Care must be taken when operating a tube in this manner not to exceed the screen dissipation.

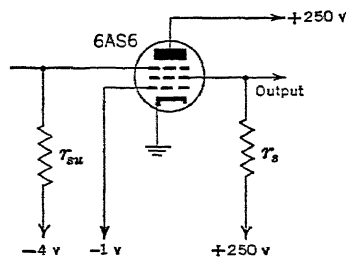

FIG. 37. The In-phase Amplifier of the Suppressor Input Screen Output Type

The gain A to the screen is given by eq. (3) using r_s in place of Z and the screen impedance Z_s in place of r_p; the equation then becomes

$$\text{Gain } A = \frac{g_{ms} r_s Z_s}{r_s + Z_s} \tag{62}$$

where g_{ms} is the mutual conductance of the suppressor to the screen.

9. NEGATIVE-FEEDBACK AMPLIFIERS

In the negative-feedback amplifier a voltage obtained from the amplifier output is fed back to the input in such a way as to oppose the applied signal.

There are two general types of negative feedback. The first is negative voltage feedback which occurs when a fraction β of the output proportional to the voltage across the output load is fed back to the input. The second is negative current feedback, which occurs when the voltage fed back is proportional to the current through the output load. The major difference in the results produced by voltage and current feedback are that negative voltage feedback results in a reduction of the effective internal resistance of the amplifier, whereas negative current feedback produces an effective increase in the internal resistance of the amplifier.

Owing to the effect of reactance in the circuit, the voltage which is fed back may not be wholly out of phase with the input voltage. This phase shift is likely to occur at extremely low or extremely high frequencies. In a single stage it cannot exceed 90°, which results in no feedback and a corresponding increase in gain. When more than one stage is included in the feedback amplifier, the phase shift may exceed 90°, which results in regeneration and perhaps oscillation. The method used to combat this phase shift and resulting oscillation is to make one stage with a narrower band width than the others. This should result in a loss of gain through the narrow stage to a value at which oscillation cannot occur, by the time the phase shift has exceeded 90°.

The effects of negative voltage feedback are (1) reduction in gain, (2) reduction in distortion, (3) reduction in noise, (4) improvement in the fidelity with frequency, (5) greater consistency of characteristics with changes in applied voltages, and (6) reduction of the effective internal resistance of the final amplifier stage.

The gain or amplification in the presence of voltage feedback is given by the relation

$$\text{Gain with feedback } A' = \frac{A}{1 - A\beta} \tag{63}$$

However, for negative feedback β is negative and the relations become

$$\text{Gain with negative feedback } A' = \frac{A}{1 + A\beta} \tag{64}$$

which is a reduction in gain from A, the amplification without feedback.

When the value of A is large in comparison to 1, the gain becomes practically independent of the amplifier characteristics, becoming approximately $A' = 1/\beta$.

Negative voltage feedback reduces the non-linear harmonic distortion produced in the amplifier for a given output voltage according to the relation

$$(D') \text{ Distortion with negative feedback} = \frac{D}{1 + A\beta} \qquad (65)$$

where D is the distortion with no feedback. This assumes that no distortion is produced when reamplifying the distortion voltages fed back, which is quite accurate if the distortion with no feedback is not large.

Feedback will reduce the distortion up to a certain point, but feedback cannot increase the power-output capabilities of a given amplifier. The distortion will be low over a portion of the output range but then will increase faster than for an amplifier with no feedback (Fig. 38).

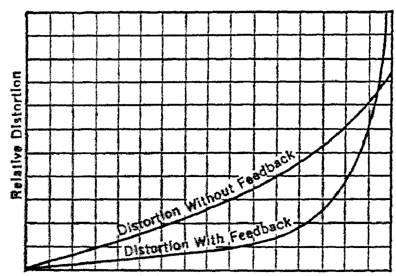

FIG. 38. The Effect of Negative Voltage Feedback on Distortion

Negative voltage feedback will improve the signal-to-noise ratio, if the source of noise is in the amplifier and not fed in as part of the input signal. For this case, assuming equal output voltages,

$$\frac{\text{Signal to noise with feedback}}{\text{Signal to noise without feedback}} = \frac{A_1}{A_2(1 + A\beta)} \qquad (66)$$

where A_1 is the amplification from the point of introduction of the noise to the output with negative feedback, and A_2 the amplification from the point of noise introduction to the output without feedback.

With negative feedback, as the response starts to drop with either high or low frequency, the feedback also decreases, opposing the change and resulting in a flatter frequency response. Thus

$$\frac{\text{Gain at } f_1(A_1)}{\text{Gain at } f_2(A_2)} = \frac{A_1(1 + A_2\beta)}{A_2(1 + A_1\beta)} \qquad (67)$$

Negative voltage feedback causes an apparent reduction in the plate resistance of the final amplifier tube in a feedback amplifier. The actual plate resistance r_p does not change, so any impedance matching (as with an output transformer) should be done on the basis of no feedback. Then, with feedback, the response and damping effect as on a loudspeaker resonance is the same as though the plate resistance r_p were lowered to r_p'. The effective plate resistance r_p' is the same whether the feedback is over a single stage or several stages, provided the gain reduction is the same.

The effective plate resistance r_p' is given by

$$r_p' = \frac{1}{g_m\beta + (1/r_p)} = \frac{r_p}{1 + \beta\mu} \qquad (68)$$

Figure 39 shows some typical circuits with negative voltage feedback applied to a single stage of amplification.

Current feedback has some characteristics that make it less desirable than voltage feedback for use with the final amplifier stage. The effects of negative current feedback are: (1) reduction of gain, (2) increase of the effective internal plate resistance r_p' of the final amplifier stage, (3) increase of input resistance, and (4) reduction of input capacitance.

The gain of such an amplifier, A', taking feedback into consideration, is given by

$$A' = \frac{A}{1 - A\alpha} \tag{69}$$

but, since α has a negative sign for negative feedback, eq. (69) in reality should be

$$A' = \frac{A}{1 + A\alpha} \tag{70}$$

where α is the ratio of the feedback resistor r_n to the load resistance r_L, and A is the amplifier gain without feedback.

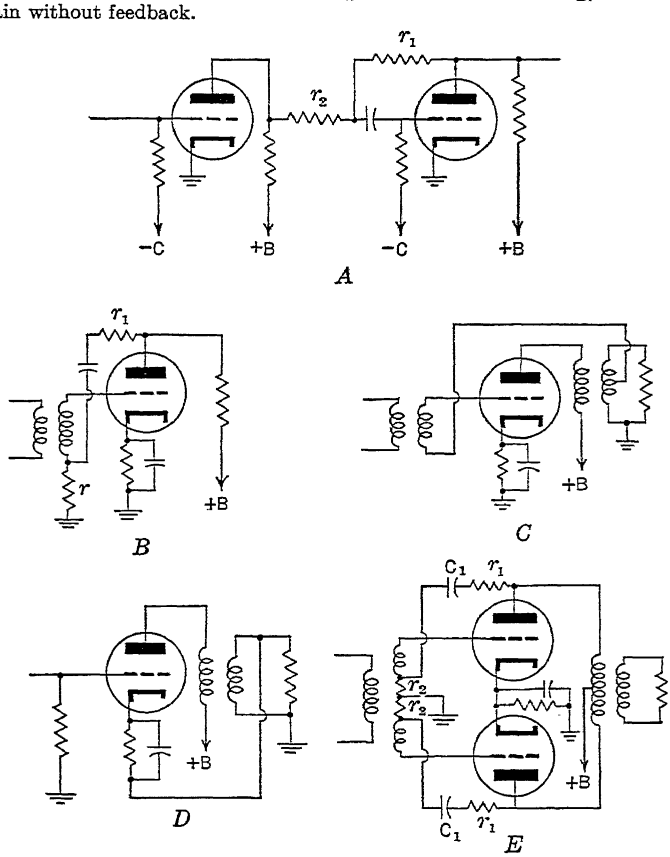

FIG 39. Typical Negative Voltage Feedback Circuits Applied to a Single Stage of Amplification

The effective plate resistance r_p' is given by the expression

$$r_p' = r_p(1 + g_m r_n) \tag{71}$$

where g_m is the mutual conductance of the amplifier output stage.

The increase of input resistance is similar to that obtained with a cathode follower. Equation (48) will give the effective input resistance; r_k should be replaced with r_n.

The input capacitance is given by eq. (46) by replacing r_k with r_n. Equations (46) and (47) apply to current feedback over a single stage.

Figure 40 shows some typical circuits with negative current feedback.

THE ONE-SHOT AMPLIFIER. The one-shot amplifier is a form of multivibrator with one of the tubes biased beyond cutoff. The circuit is shown in Fig. 41. Under steady-state conditions tube V_1 is cut off and tube V_2 draws plate current. The circuit remains in this condition until a positive trigger voltage of sufficient amplitude to cause V_1 to draw plate current is impressed upon the grid of V_1. This starts a regenerative action through V_2 and the grid of V_1 is driven positive (as indicated in Fig. 42). This causes grid current to flow, thus charging the coupling capacitances C_1 and C_2, resulting in a large negative potential on the grid of V_1. As soon as the current in the plate circuit of V_1 stops increasing, the voltage on the grid of V_2 starts to rise; this is also regenerative, and V_2 resumes its steady-state plate current, but V_1 is left with its grid highly negative. This negative voltage discharges through r_1 exponentially back to the applied bias voltage E_2, Fig. 42.

Owing to the regenerative action the output of this type of amplifier is a sharp pulse of short duration. The plate of V_1 gives a negative pulse, and the output from V_2 is a positive pulse.

The voltages acting on the grid of V_1 are shown in Fig. 42. The trigger pulses should be limited in amplitude so that, at the desired time after firing, the amplifier is again ready to fire. With the trigger pulse limited to amplitude P it cannot fire the one-shot amplifier earlier than the prescribed time. Assuming that C_1 and C_2 are small enough to permit them to change to the peak positive voltage applied, then the operating conditions can be calculated.

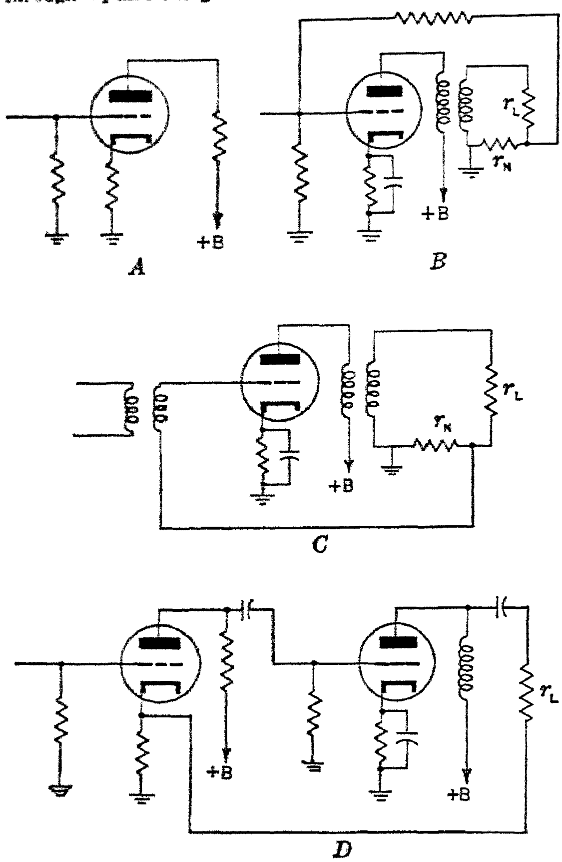

FIG. 40. Typical Negative Current Feedback Circuits

The Ir drop through the plate load resistor r_L of V_2 must be appreciably greater than the cutoff voltage required on V_1.

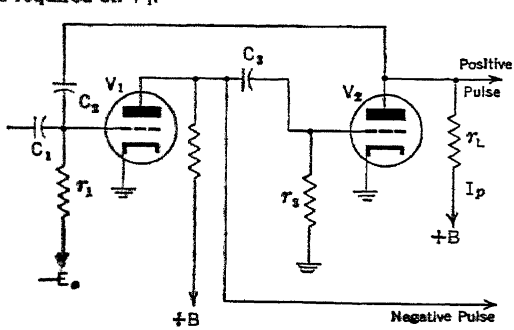

FIG. 41. Circuit Diagram of a One-shot Amplifier

Referring to Fig. 42 for voltages and symbols, assume the trigger pulse amplitude P to be equal to the cutoff bias E_1 of V_1, and the applied bias to be equal to $E_1 + P/2$.

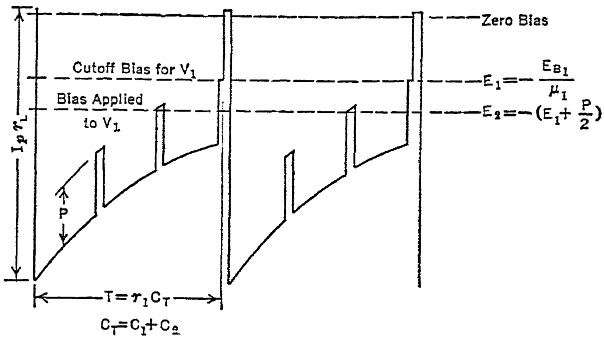

FIG 42. The Voltage on the Grid of Tube (V_1) of Fig. 41 during Operation

The time T that must elapse between firing of the amplifier and the second firing by a pulse of amplitude P is $T = r_1(C_1 + C_2)$. The applied bias $-E_c$ to V_1 of Fig. 41 is given by:

$$E_c = -\left(\frac{E_{B1}}{\mu_1} + \frac{P}{2}\right) \tag{72}$$

and E_{B1} is given by:

$$E_{B1} = \mu_1(r_L I_p - 1.85P) \tag{73}$$

where μ_1 is the amplification constant of V_1, and $r_L I_p$, the voltage drop across the plate load r_L of V_2, is assumed to be the maximum negative voltage on the grid of V_1 immediately after firing.

10. PULSE AMPLIFIER

With the advent of radar and television, pulse amplifiers became necessary. The pulse amplifier is an adaptation of the wide-band amplifier. The bandwidth necessary is dependent upon the pulse, the high-frequency response is governed by the rate of rise and decay of the pulse, and the low-frequency response is determined by the duration of the pulse. (See Section 9.)

The equivalent frequency f_2 of the pulse is considered to be equal to that of a sine wave that rises from zero voltage to peak voltage in the same time as that of the pulse. This results in a frequency f_2 that must be passed by the pulse amplifier, given by

$$f_2 = \frac{1}{4T} \tag{74}$$

where T is the rise time or decay time of the pulse, whichever is shorter (see Fig. 43).

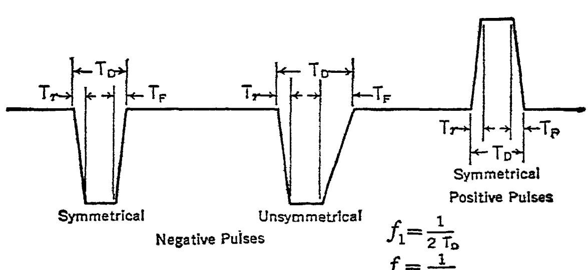

FIG. 43. Negative and Positive Pulses, Showing the Pulse Rise Time (T_r), the Pulse Decay Time (T_F), and the Pulse Duration (T_D)

Determine the frequency f_2 represented by the rise time, then refer to the section on wide-band amplifiers and determine the design of an amplifier having the required high-

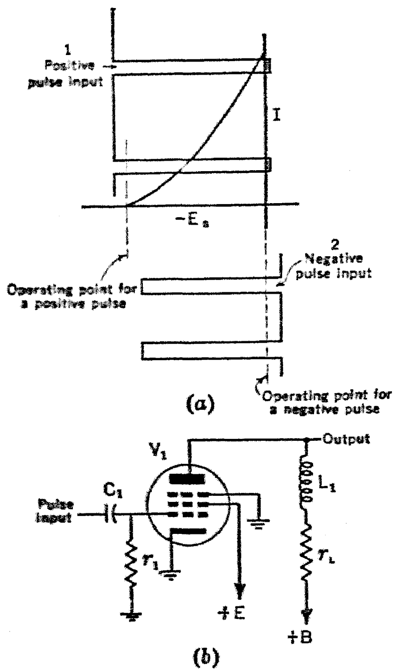

FIG. 44. Grid Bias, Plate Current Curve, Showing the Operating Point for a Positive Pulse, the Operating Point for a Negative Pulse, and a Circuit That Will Automatically Set the Bias at the Proper Voltage for Correct Operation Regardless of the Pulse Polarity or Amplitude

frequency response. The low-frequency response at $5f_1$ needed is obtained from the pulse duration T_D.

$$f_1 = \frac{1}{2T_D} \tag{75}$$

Again refer to the section on wide-band amplifiers to determine the constants needed to produce the required response.

The consideration for the initial bias point for the vacuum-tube grid is somewhat different in pulse amplifiers from what it is in conventional amplifiers. For a positive pulse a high bias is needed. This bias can be, and usually is, supplied by grid current (Fig. 44, A_1).

For a negative pulse a low bias is needed and the tube draws a heavy current except in the presence of the pulse which drives the tube grid toward cutoff. This is shown in Fig. 44, A_2.

The circuit shown in Fig. 44, B, is adequate for either a positive or a negative pulse amplifier. The time constant of the grid circuit r_1C_1 should be several times the pulse repetition rate to maintain bias between pulses.

With positive pulses the grid is biased by means of grid-leak bias to a value represented by the a-c axis of the positive pulse. This is self-adjusting and requires no controls. When one is operating with negative pulses, the bias will be essentially zero, depending upon the pulse a-c axis, and will operate equally as well as for a positive pulse. A circuit of this type is self-adjusting and assumes an operating point so as to provide efficient operation regardless of pulse amplitude or polarity.

INTERMEDIATE-FREQUENCY (I-F) AMPLIFIERS

By Charles J. Hirsch

Because it is difficult to amplify and separate signals at high radio frequencies, some receivers (known as superheterodynes) *convert the signal frequency to a fixed intermediate frequency*. The signal then is amplified and selected at the new frequency by means of an *i-f amplifier*. Such receivers differ from tuned-radio-frequency (t-r-f) receivers, which amplify by means of circuits tuned to the high carrier frequency.

The intermediate frequency is usually lower than the radio frequency and higher than the frequency of utilization (audio or video frequency).

The intermediate-frequency amplifier has the function of amplifying the signals within a specified i-f band and of rejecting all others. It is the most important factor in the determination of sensitivity, selectivity, and fidelity of superheterodyne receivers. Since these characteristics of the complete receiver are, in the main part, the characteristics of the i-f amplifier, it is easy to make them constant over the tuning range.

11. FACTORS AFFECTING THE CHOICE OF INTERMEDIATE FREQUENCY

The choice of intermediate frequency requires a careful study of the following factors: (1) overall gain, (2) selectivity, (3) image rejection, (4) tuning range, (5) tweets (whistles caused by harmonics of the i-f which are generated by the second detector and reimpressed on the r-f circuits to beat with the signal frequency), (6) i-f rejection, (7) strong stations separated by the intermediate frequencies, (8) cost, i.e., number of tuned circuits and their components.

Low intermediate frequencies have the advantages of (*a*) high stage gain because a higher impedance can be presented to the output of the amplifier tube; (*b*) narrow band width, i.e., better selectivity because a given frequency separation is a greater fraction of a low intermediate frequency than of a high intermediate frequency (see Universal selectivity curve, Section 6); and (*c*) greater freedom from tweets (when the i-f amplifier is preceded by a high degree of r-f selectivity) because only higher and therefore weaker (but more numerous) harmonics of the i-f occur at the signal frequency and beat with the signal to produce tweets.

High intermediate frequencies have the advantages of (*a*) *higher image rejection* by (1) increasing the separation (twice intermediate frequency) between the desired signal frequency and the image frequency, and (2) reducing or even eliminating that part of the tuning range within which signals can produce images; (*b*) reduction in the number of "tweets" because fewer harmonics of the intermediate frequency lie within the tuning range; (*c*) greater freedom from "birdies" (whistles produced by combinations of r-f signals) because combinations of r-f signals, separated in frequencies by the intermediate or subharmonics of the intermediate frequency, will not be impressed on the converter to produce intermediate frequency, or beat with the local oscillator to produce intermediate frequency; (*d*) greater freedom of interaction (pulling) between the local oscillator and the antenna circuit because of greater frequency separation.

High image rejection and freedom from "birdies" require costly r-f selectivity. Therefore, a high intermediate frequency is economical because it reduces the requirements for r-f selectivity.

The i-f amplifier frequency must not be too close to the tuning band as the receiver will then become unstable.

Table 1 presents a comparison of the receiver characteristics associated with two intermediate frequencies for the broadcast band; Table 2 gives some idea of the intermediate frequencies commonly associated with specific radio frequencies.

Table 1. Comparison of Two Radio Receivers Having (*a*) an Intermediate Frequency of 175 kc, (*b*) an Intermediate Frequency of 455 kc

Tuning Range 550–1720 kc	i-f 175 kc	i-f 455 kc
1. Frequency separation between desired station and image	2 × 175 = 350 kc	2 × 455 = 910 kc
2. Frequency range in which stations within the tuning range can cause images		
From	550 + 2 × 175 = 900 kc	550 + 2 × 455 = 1460 kc
To	1720 kc	1720 kc
(Note: The ability of stations outside the tuning range to produce images must not be overlooked.)		
3. Frequency range of stations which may be interfered with by images produced by stations in the tuning range. (See above.)		
From	550 kc	550 kc
To	1720 − 2 × 175 = 1370 kc	1720 − 2 × 455 = 810 kc

12. NARROW- AND MEDIUM-BANDWIDTH I-F AMPLIFIERS

I-f amplifiers can be classified into (*a*) narrow (10 kc) and medium (< 200 kc) bandwidth, and (*b*) wide-bandwidth (> 200 kc) amplifiers.

Narrow- and medium-bandwidth i-f amplifiers, which are used in most receivers receiving audio frequency a-m or f-m intelligence, usually consist of individual stages using pairs of coupled-tuned circuits. A rectangularly shaped selectivity curve (one having a flat top and steep sides) usually is desirable.

I-F AMPLIFIERS FOR A-M BROADCAST RECEIVERS. These usually consist of cascaded, critically coupled, double-tuned stages at a frequency between 455 and 465 kc.

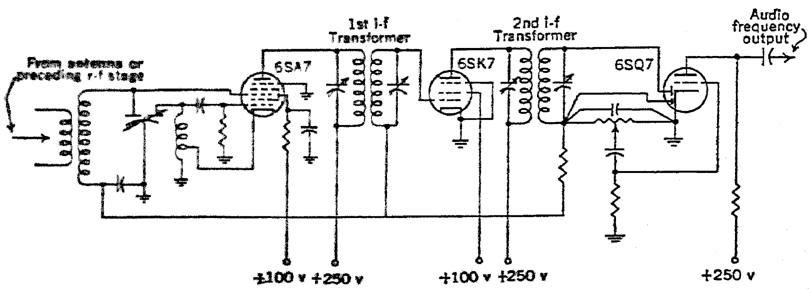

FIG. 1. Typical I-f Amplifier for Inexpensive 550–1720 kc Receiver

The design is affected by the need for (1) gain, (2) selectivity, (3) fidelity, (4) stability, and (5) economy.

Gain and Selectivity. The i-f amplifier is the major source of gain and selectivity in a radio receiver. The i-f gain (from radio frequency on the converter grid to the second detector) depends on the performance required. It will lie between a minimum of 1400 for single-band (usually 550–1750 kc) sets having a high gain r-f stage and large r-f pick-up up to a maximum of 50,000 for short-wave sets with small r-f pick-up and using low-noise converter tubes. For single-band sets it is seldom necessary to use more than one i-f stage to get the required gain and sensitivity. In general in such cases (two i-f transformers, see Fig. 1) the stage gain must be high. This requires high-impedance transformers which in turn implies high L/C ratio and high Q circuits to gain the required selectivity (see eqs.

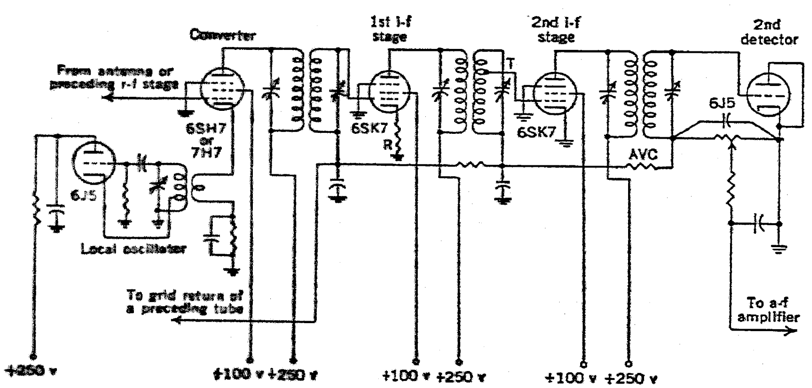

FIG. 2. Two-stage I-f Amplifier Using Six Tuned Circuits

(1)–(18) of this article). **The Q is made high** by using (*a*) litz wire, (*b*) iron-core coils, (*c*) sectionally wound (pie wound) coils, and (*d*) large shield cans.

When higher selectivity and gain are required, and in general for multiband sets, two i-f stages are often used (five to six tuned circuits, see Fig. 2). The gain and selectivity of such sets are given by eqs. (16)–(18) below. Values for typical sets are shown in Table 3.

Table 3. Average Stage Gains and Second Detector Sensitivities for Different Types of Broadcast Receivers Produced between 1934 and 1946

Type of Set \ Gain	Conversion at 600 kc μ	1st i-f μ	2nd i-f μ	Overall μ	2nd Detector Sensitivity Will Produce i-f Volts 30% Mod.	a-f Watts in Voice Coil
Ac-dc (no r-f stage)	30		94	2,800	0.3	0.05
Ac-dc (r-f gain of 6)	23		61	1,400	0.3	0.05
Battery (no r-f stage)	43		88	2,800	0.5	0.05
(no r-f stage)	32	35	44	50,000	0.5	0.05
(r-f gain of 10)	39		56	2,200	0.5	0.05
Ac (no r-f stage)	40		100	4,000	0.6–0.9	0.50
(no r-f stage)	26	10	56	14,300	0.6–0.9	0.50
(r-f gain of 12)	14	37	41	21,000	0.6–0.9	0.50
Auto (no r-f)	44		120	5,300	0.7–1.1	0.50
(r-f gain of 40)	39		90	3,500	0.7–1.1	0.50

If two i-f stages are used, the overall gain can be held down to reasonable values, stability can be improved, and the cost can be reduced by using (*a*) solid wire coils instead of litz as the five or six tuned circuits will supply adequate selectivity even with the lower Q of the solid wire coils (*b*) lower L/C ratio, (*c*) output voltage obtained from a tap on the secondary (but not in the stage feeding the diode, as a condenser across the diode load is necessary to present a low reactance to i-f harmonics generated by the diode), (*d*) unbypassed cathode resistor, (*e*) increased bias (however, this decreases the effect of avc on this tube).

Gain and Selectivity of Last Stage. The gain of the stage feeding the avc diode must be high enough so that its own grid will not overload owing to inadequate gain control of the preceding stage. In other words, it must, without overloading, supply enough power to the diode so that the diode may supply adequate control voltage to the preceding stages for all signal amplitudes to be expected. For remote cutoff tubes 30 to 40 volts of avc may well be needed, which represents from 60 to 85 per cent of the peak carrier voltage impressed on the diode.

The ratio of a-c to d-c diode load impedance should be as near unity as possible to prevent amplitude distortion on high percentage modulation signals.

Variable Selectivity. (See reference 4.) Extreme selectivity usually causes extreme cutting of the side bands with loss of fidelity. To overcome this, some receivers use variable selectivity. This usually is obtained by coupled circuits which are critically coupled (or undercoupled) when selectivity is required, but which are overcoupled when selectivity can be sacrificed. As the coupling increases, the selectivity of each coupled pair assumes the well-known two-peak form. The frequency separation between peaks $(f_1 - f_2)$ increases with the coupling. $\dfrac{f_1 - f_2}{f} = K$ approximately for overcoupled high-Q circuits.

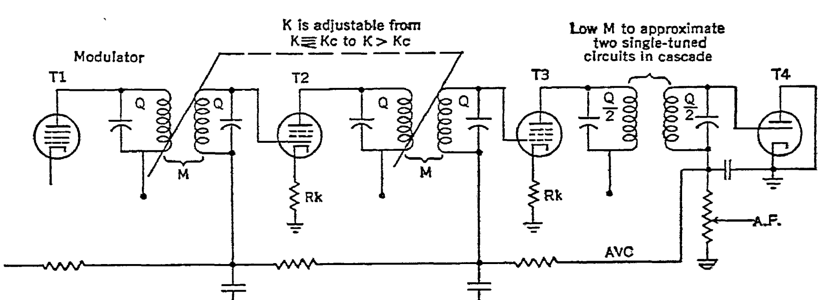

FIG. 3. I-f Amplifier Having Variable Selectivity

The valley between the peaks is filled in by the selectivity of a single-tuned circuit. A flat-topped selectivity curve can be approximated for all coefficients of coupling if the Q of each circuit of the coupled pair is equal to twice the Q of the single-tuned circuit. In practice, the i-f amplifier takes the form of Fig. 3, which consists of three double-tuned circuits. The coupling of the first two pairs is adjustable and capable of being overcoupled.

The coupling of the last pair is low so as to approximate the selectivity of two single-tuned circuits in cascade (one to fill in the valley of each overcoupled pair). The Q of the adjustable pairs is equal to twice the Q of the very loosely coupled pairs. The cathode resistors of about 100 ohms are unbypassed to minimize the detuning caused by variation of the bias by the avc. (See reference 3.)

Broad i-f amplifiers are sometimes used to reduce the need for frequency stability in the local oscillator in pushbutton sets or short-wave sets.

Tuning Stability. The amplifier should be tuned with enough capacitance (> 25 $\mu\mu$f) so that it will not be appreciably detuned by (*a*) replacement of tubes, (*b*) displacement of parts by vibration, (*c*) change in input capacitance of vacuum tubes caused by variation of gain. (This can be balanced by a small unbypassed cathode resistor (reference 3) of about 100 ohms; see Fig. 2.)

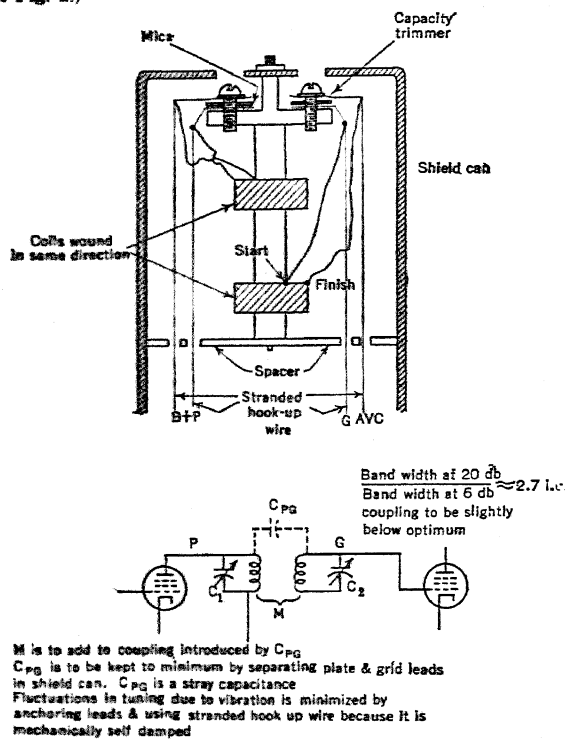

FIG. 4. Typical 0.455 Mc I-f Transformer

Where the amplifier will meet wide variations in temperature and humidity, the use of stable fixed condensers and tuning by means of adjustable iron-core coils is desirable.

The inductive coupling between windings can either aid or oppose the coupling due to the capacitance between the plate and grid terminals of the i-f transformer.

If very small transformers are desired, opposing inductive and capacitive coupling permits closer spacing of the windings. For coaxial coils, wound in the same direction, opposing coupling permits the coils to be partly self-shielded electrostatically by using the outside terminals as the low i-f potential terminals.

However, variation in the above capacitance, due to differences in production wiring or changing distance between wires due to vibration, causes much larger variations in the gain and bandwidth of an i-f stage with opposing couplings than with aiding coupling because the difference of two nearly equal quantities varies much more than their sum as either quantity is changed.

For the above reasons, whenever size and economy permit, aiding coupling is preferable to opposing coupling. However, the combined coupling should be sufficiently below optimum to prevent overcoupling due to production variations and vibration.

With either coupling, production will be much more uniform if the capacitive coupling is made as small as possible (see Fig. 4).

Feedback of I-f Harmonics. The second detector output must be well filtered and kept as far as possible from the r-f components so as to prevent harmonics of the intermediate frequency from being impressed on the r-f circuits where they can beat with the signal and cause "tweets."

I-F AMPLIFIERS FOR FM RECEIVERS. The same considerations hold for frequency modulation as for amplitude modulation except that:

1. Bandwidth must accommodate maximum signal frequency swing so as not to cause amplitude distortion.

2. Gain must be adequate to operate limiter on weakest signal.

3. Top should be reasonably flat so as not to overtax limiters and to reduce distortion in balanced detectors.

3*a*. Bandwidth at least 150 kc at −6 db. Adjacent channel attenuation ±400 kc at least 50 db.

4. Selectivity curve should be symmetrical.

5. Intermediate frequency for the 88–108 band is usually 10.7 Mc.

6. Amplifier consists usually of sets of double-tuned circuits.

7. A-m and f-m circuits usually are combined in one common shield can (but care must be taken to prevent interaction so that leads will not change couplings by adding capacity between windings).

8. To prevent detuning with avc, those tubes which have avc may be supplied with an unbypassed cathode resistor of about 100 ohms.

9. Tuning usually is accomplished by means of iron slug to increase the stability.

A typical design is given in Table 4 and Fig. 5.

Table 4. Typical Dual I-f Amplifier Stage for Am-Fm Set

	AM	FM
Frequency	0.455 Mc	10.7 Mc
$L_1 = L_2$ adjusted by iron core from	862 μh	4.2 μh
to	1395 μh	8.4 μh
Q	68–77	88
$\frac{K}{K_c}$	0.70 approx.	0.80
Gain	43 db	28 db
W_6	13.5 kc	215 kc
W_{20}	36 kc	540 kc
$\frac{W_{20}}{W_6}$	2.66	2.50

Note: The ratio of the bandwidths of two signals 20 db and 6 db stronger than the signal at resonance is a measure of the coupling. This is indicated as W_{20}/W_6 and is equal to 2.37 when $L_1C_1 = L_2C_2$, $Q_1 = Q_2$, and the circuits are critically coupled. When $Q_1 \neq Q_2$ as in a transformer feeding a diode, experience indicates that this ratio should be 2.7–3.0. When the transformer is used in the plate of a modulator tube, the ratio should be 2.5–2.6.

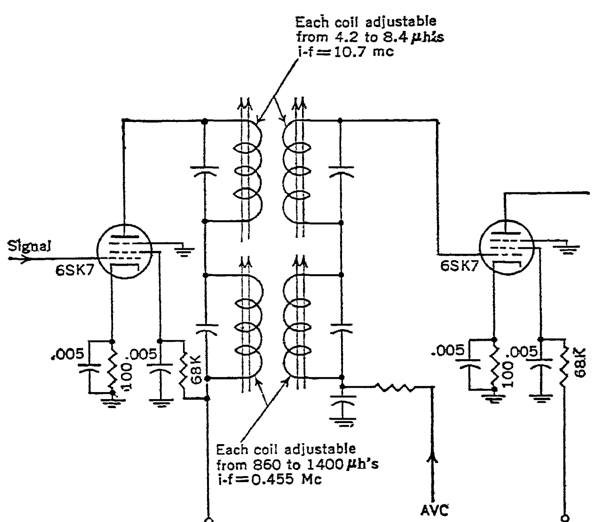

FIG. 5. Typical 0.455 and 10.7 Mc I-f Stage for Combined A-m and F-m Receiver

USEFUL RELATIONS FOR HIGH-Q CIRCUITS.

Selectivity can be expressed in two ways:

(a) With constant input as

$$S = \frac{\text{Output voltage at any frequency } f \text{ (or bandwidth } f_w \simeq 2[f - f_0])}{\text{Output voltage at the resonant frequency } f_0} \tag{1}$$

= a number less than unity

(b) With constant output as

$$A = \frac{1}{S} = \frac{\text{Input voltage at any frequency } f \text{ (or bandwidth } f_w \simeq 2[f - f_0])}{\text{Input voltage at the resonant frequency } f_0} \tag{2}$$

= a number larger than unity

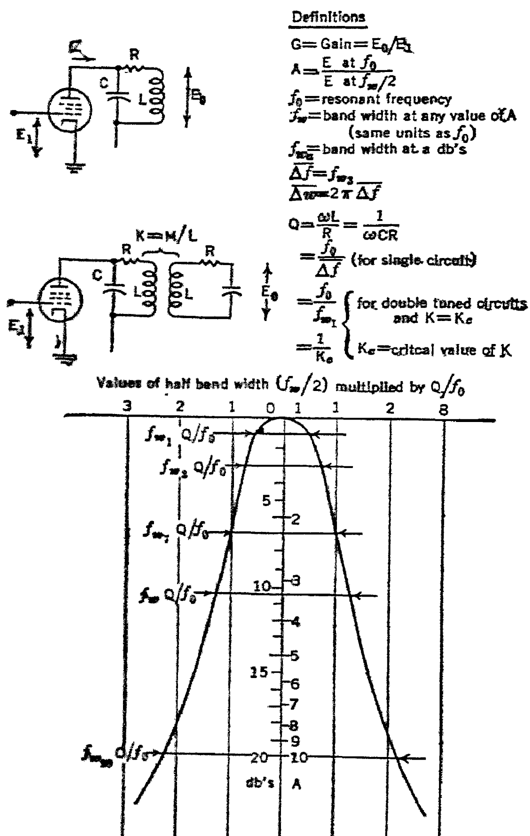

FIG. 6. Definition of Symbols in Text. Curve shows selectivity, A, of single double-tuned stage for $K = K_c$; and $Q_1 = Q_2$.

A. ***Single-tuned Stage*** (see Fig. 6 for definition).

1. $$Q = \frac{\text{Resonant frequency}}{\text{Bandwidth to signal 3 db greater than resonance}} = \frac{f_0}{\Delta f} \tag{3}$$

$\overline{\Delta f}$ is bandwidth for signal 3 db greater than the signal applied at the resonant frequency.

$$\overline{\Delta\omega} = 2\pi\,\overline{\Delta f} \tag{4}$$

2. *Selectivity* $= S = \dfrac{\text{Signal at } f \text{ (or } f - f_0)}{\text{Signal at } f_0} = \dfrac{1}{A}$ (5)

$$= \frac{1}{\sqrt{1 + 4Q^2\left[\dfrac{f - f_0}{f}\right]^2}}$$ (See Section 6, article 1, for universal selectivity curve) (5a)

3. *Gain per Stage*

$$G = g_m Q X \tag{6}$$

4. *Stage Gain Multiplied by Bandwidth at 3 db*
   (a) One stage

$$G\,\Delta\omega = g_m/C \tag{7}$$

   (b) n stages

$$G\,\overline{\Delta\omega} = \frac{0.835}{\sqrt{n}}\frac{g_m}{C} \text{ (approx.)} \tag{8}$$

B. *Double-tuned Stage* (Fig. 6).

The following formulas hold when $L_1C_1 = L_2C_2$; $Q_1 = Q_2$; K = coefficient of coupling; K_c = critical coupling coefficient.

1. When $K \leqq K_c$, then, for each stage,

(a) $$\frac{\text{Resonant frequency}}{\text{Bandwidth to signal 1 db greater than resonance}} = \frac{f_0}{f\omega_1} \geqq Q \tag{9}$$

(b) $$\frac{\text{Bandwidth to signal 20 db above resonance}}{\text{Bandwidth to signal 6 db above resonance}} = \frac{W_{20}}{W_6} \geqq 2.37 \tag{10}$$

2. *Selectivity*, S

(a) $K \leqq K_c$

$$S = \frac{\text{Signal at } f \text{ (or } f - f_0)}{\text{Signal at } f_0} = \frac{1}{A}$$

$$= \frac{1 + (K^2/K_c^2)}{\sqrt{\left[1 + (K^2/K_c^2) - 4Q^2\left(\dfrac{f - f_0}{f_0}\right)^2\right]^2 + 16Q^2\left(\dfrac{f - f_0}{f_0}\right)^2}} \tag{11}$$

(See Section 6, article 5.)

(b) $K = K_c$

$$S = \frac{1}{\sqrt{1 + 4Q^4\left(\dfrac{f - f_0}{f_0}\right)^4}} = \frac{1}{A} \tag{12}$$

3. *Gain per Stage*, G

(a) $K \leqq K_c$

$$G = g_m Q X \frac{K/K_c}{1 + (K^2/K_c^2)} \tag{13}$$

(b) $K = K_c$

$$G = \tfrac{1}{2} g_m Q X \tag{14}$$

4. *Stage Gain Multiplied by Overall Bandwidth*
   (a) One stage

$G\,\overline{\Delta\omega} = 0.707\,\dfrac{g_m}{C}$ where C is the actual tuning C and is $\tfrac{1}{2}$ of total C (approx.) (15)

   (b) n stages

$$G\,\overline{\Delta\omega} = \frac{1}{1.1\sqrt[4]{n}}\left(0.707\,\frac{g_m}{C}\right) = \frac{0.643}{\sqrt[4]{n}}\frac{g_m}{C} \tag{16}$$

13. WIDE-BAND I-F AMPLIFIERS

The amplification of video signals such as are used in television and pulse communications requires band widths wider than 200 kc. Hence techniques have been developed to design much wider band amplifiers of high overall gain. One special problem arising is that much of their use is for visually displayed information where the phase distortion introduced by a rectangular-topped selectivity curve cannot be tolerated. For this reason, the edges of the selectivity curve must be somewhat rounded.

ALTERNATIVE DESIGNS. Wide-band amplifiers may be designed using (1) synchronously tuned single-tuned circuits, (2) double-tuned circuits (loaded either on one or both sides, (3) stagger-tuned amplifiers, or (4) inverse-feedback amplifiers. Stagger-tuned amplifiers consist of n single-tuned circuits of poor skirt selectivity which are tuned to different frequencies so that the peak of one circuit tends to fill in a deficiency of the others. For instance a stagger-tuned pair consists of two single-tuned stages, one of which is peaked at a frequency higher than, the other lower than, the center frequency of the amplifier. In inverse-feedback amplifiers a fraction of the output of a single-tuned synchronous amplifier is fed back in degenerative phase to the input. More voltage, therefore, is fed back at resonance than off-resonance. Consequently, the overall gain is reduced more at resonance than off, and the nose of the selectivity curve is rounded.

FIGURE OF MERIT. The figure of merit of a wide-band amplifier is defined as

$$\text{Stage gain times overall bandwidth} = G\,\Delta\omega$$

where the band width $\Delta\omega$ means the band width for gains 3 db below the peak. The 3-db bandwidth is chosen because it makes the mathematics easier, it approximates the noise bandwidth of the receiver, and so facilitates signal-noise comparisons. Furthermore, with the usual coupling circuits, the rise time of pulses is quite simply connected with it. Defining rise time as the time required for the response to the step function to increase from 10 to 90 per cent of its final value, then

$$\text{Rise time} = \frac{0.7}{\Delta f}$$

Thus a 10-Mc (3 db down) i-f amplifier would have a minimum pulse rise time of 0.07 μs. (For a complete criterion of a pulse amplifier, percentage of pulse overshoot must also be considered.)

For a single-stage single-tuned circuit the gain of an amplifier is (Z is the plate load impedance)

$$G = g_m Z = g_m \frac{\omega^2 L^2}{r} = g_m Q\omega L = \frac{g_m}{\omega c}\frac{\omega}{\Delta\omega} = \frac{g_m}{C\Delta\omega}$$

so that

$$G\,\Delta\omega = g_m/C \tag{17}$$

which is also eq. (7). The factor C represents the total capacitance in the plate circuit, including tube output and input capacitances and the capacitance of circuit components to ground.

Since double-tuned circuits divide the total tube and circuit capacitance between two tuned circuits they use less capacitance per tuned circuit and have a higher figure of merit. For equal Q's this is $\sqrt{2}\,g_m/C$, and for one side loaded it is $2g_m/C$.

SYNCHRONOUS SINGLE-TUNED CIRCUITS.* The simplicity and stability of an amplifier made up of single-tuned circuits all tuned to resonance commend it to the designer, and most 2- to 3-Mc-wide amplifiers are of this type. For really wide-band high-gain amplifiers the decrease in bandwidth arising from multiplication of the successive selectivity curves makes this type unsuitable. Table 5 shows the overall bandwidth of n-stage amplifiers in terms of the stage bandwidth. It shows that a nine-stage synchronous single-tuned amplifier with an overall bandwidth of 4 Mc requires a single-stage bandwidth of 14.3 Mc with its correspondingly low gain. It can be shown that the maximum overall bandwidth of synchronous single-tuned circuits occurs for a mean stage gain of

$$G = \sqrt{\epsilon} = 4.34 \text{ db}$$

Table 5. Overall Bandwidth of Sychronously Tuned Amplifiers

Stages	% of Stage Bandwidth
2	64
3	51
4	44
5	39
6	35
7	32
8	30
9	28

DOUBLE-TUNED CIRCUITS. Double-tuned circuits have a theoretical advantage in the figure of merit. However, the large number of adjustments (three per stage) and the criticalness of some of them (interlocking effects) make design and maintenance most difficult. For this reason double-tuned circuits have been used very little.

STAGGER-TUNED SINGLE-TUNED CIRCUITS. Wallman defines an exact staggered pair (or triple) of bandwidth Δf and geometrically centered at f_0 as consisting of (a) two single-tuned circuits of dissipation factor $d = 1/Q$ and frequencies αf_0 and f_0/α, and

* The following three paragraphs were abstracted from a paper by H. Wallman, "Stagger-tuned i-f Amplifiers," *Rad. Lab. Report* 524 NDRC Div. 14.

(for one triple) (*b*) one single-tuned circuit of dissipation factor $\delta = \Delta f/f$ centered at f_0. d and α are plotted as functions of $\delta = \Delta f/f$ in Figs. 7 and 8. (*Note*: The values of d and α for a pair are not the same as their value for a triple.)

The stage gain times overall bandwidth of (*a*) a single-tuned stage, (*b*) an exact staggered pair, and (*c*) an exact staggered triple is

$$G\,\overline{\Delta\omega} = g_m/C$$

However, the same 3-db bandwidth $\Delta\omega$ is obtained in the first case (*a*) for one tuned circuit; in the second case (*b*) for two tuned circuits, and (*c*) for three tuned circuits.

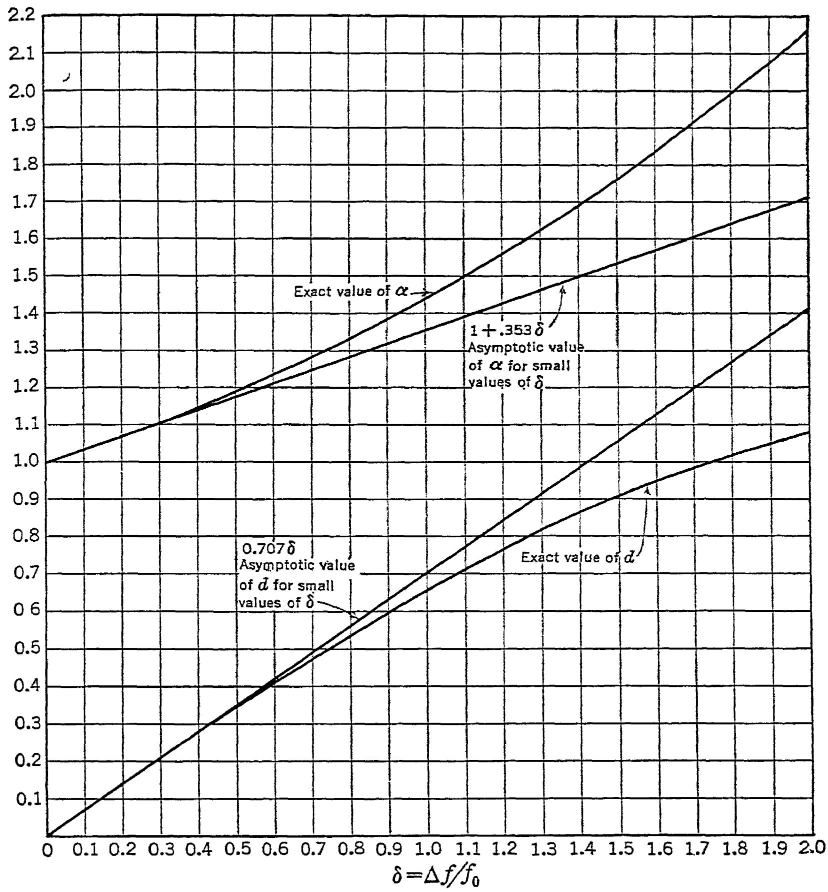

FIG. 7. Design Curves for an Exact Flat Staggered Pair

The algebra in the analysis of these circuits is quite involved, but Wallman has reduced the design to charts. Given the tube type and the general layout, the g_m is known and an estimate of C is made. This determines the product of *single*-stage gain and *overall* bandwidth, i.e., $G\,\overline{\Delta\omega} = g_m/C$ of the pair or triple.

The overall bandwidth of the amplifier can be obtained from the following approximate relations

1. $$\text{Bandwidth of } n \text{ pairs} = \frac{\text{Bandwidth of one pair (i.e., } \overline{\Delta\omega})}{1.1\sqrt[4]{n}}$$

2. $$\text{Bandwidth of } n \text{ triples} = \frac{\text{Bandwidth of one triple (i.e., } \overline{\Delta\omega})}{1.06\sqrt[6]{n}}$$

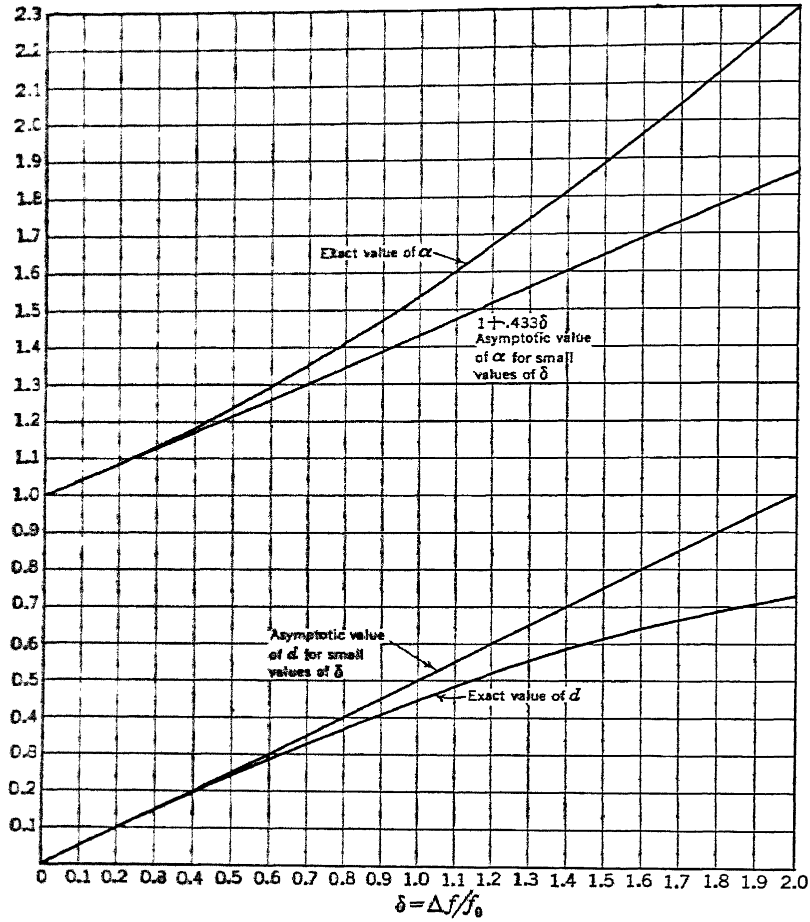

FIG. 8. Design Curves for an Exact Staggered Triple

Conversely, the overall bandwidth and overall gain being known, the number of stages as well as the required unit performance can be determined.

Example. A nine-stage amplifier having a gain of 108 db centered on 30 Mc is wanted. 6AC7's having a g_m of 0.0085 ampere/volt and a total capacitance of 25.5 $\mu\mu f$ are to be used.

Nine stages divide conveniently into three triples.

The stage gain is 108/9 = 12 db, that is, a voltage gain of 4 times.

$$G\,\overline{\Delta\omega} = \frac{g_m}{C} = \frac{0.0085}{25.5} \times 10^{12} = 332 \times 10^6$$

$$\overline{\Delta f} = \frac{332 \times 10^6}{4 \times 2\pi} = 13.3 \text{ Mc}$$

Each triple has a bandwidth of 13.3 Mc. The three triples that make up the amplifier have an overall bandwidth of

$$\text{Overall bandwidth} = \frac{13.3}{1.06\sqrt[6]{3}} = 10.55 \text{ Mc}$$

Constants making up each triple are found from Fig. 8 as follows:

$$\delta = \frac{\Delta f}{f_0} = \frac{13.3}{30} = 0.443$$

$$d = \frac{1}{Q} = 0.215 \quad \text{and} \quad \alpha = 1.21; \quad Q = 4.65$$

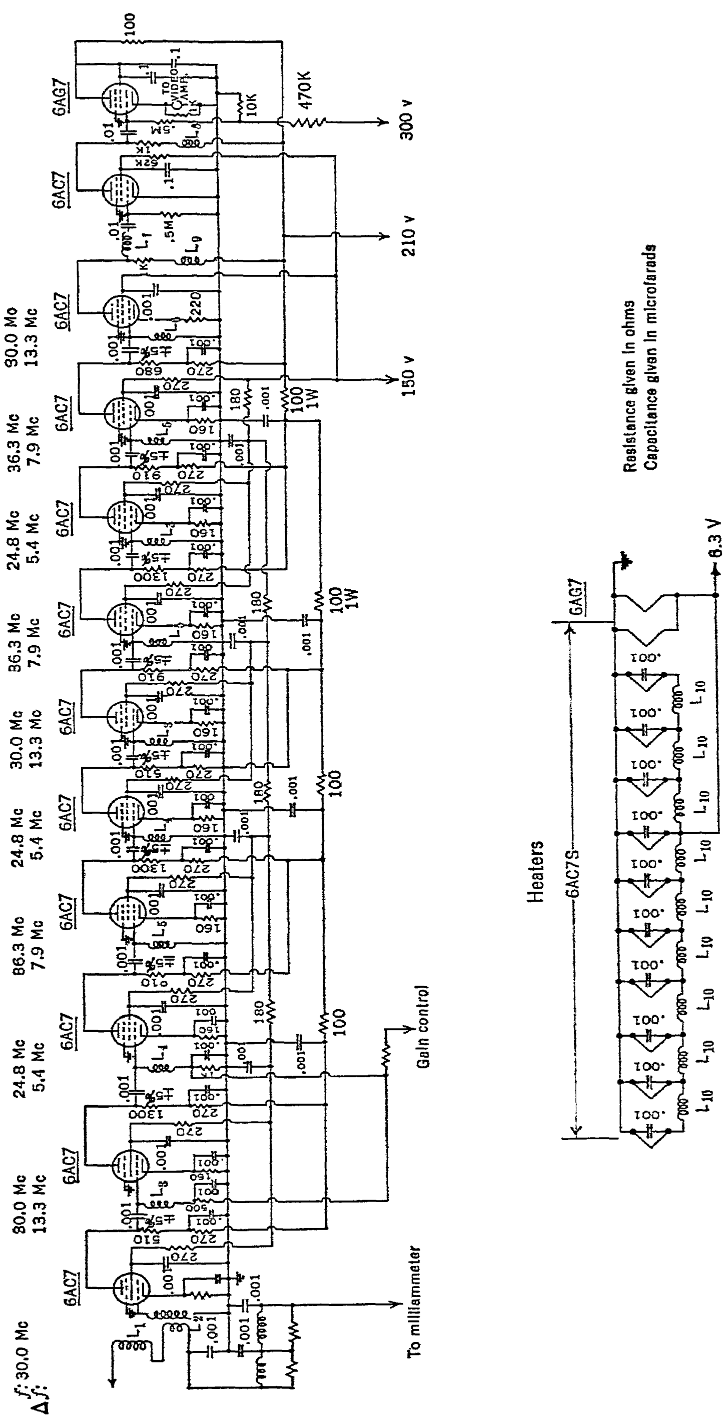

FIG. 9. Wide-band Amplifier Consisting of Three Staggered Triples, Having an Overall Gain of 108 db and an Overall Bandwidth of 10.5 Mc

The amplifier, therefore, is made up of three triples, each of which consists of:

1. One circuit tuned to $30 \times 1.21 = 36.3$ Mc and having a Q of 4.65.
2. One circuit tuned to $30/1.21 = 24.8$ Mc and having a Q of 4.65.
3. One circuit tuned to 30 Mc and having a Q of $1/0.443 = 2.26$.

Since $Q = \omega CR$ (R in this case is the equivalent resistance across the tuned circuit), then

$$R = \frac{Q}{\omega C} = \frac{4.65}{2\pi \times 36.3 \times 10^6 \times 25.5 \times 10^{-12}} = 790\omega \text{ for the 36.3-Mc circuit}$$

$$R = \frac{4.65}{2\pi \times 24.8 \times 10^6 \times 25.5 \times 10^{-12}} = 1150\omega \text{ for the 24.8-Mc circuit}$$

$$R = \frac{2.26}{2\pi \times 30 \times 10^6 \times 25.5 \times 10^{-12}} = 470\omega \text{ for the 30-Mc circuit}$$

The amplifier is shown in Fig. 9. Actually the physical values of the shunting resistors are higher than calculated because of the effect of tube loading and of the finite Q of the coils which effectively shunt the physical resistor to the calculated value. The final value of these resistors must be determined experimentally.

The bandwidth of each stage of the triple is determined from the relation

$$G\,\overline{\Delta\omega} = \frac{g_m}{C}$$

$$g_m R\,\overline{\Delta\omega} = \frac{g_m}{C}$$

$$\overline{\Delta\omega} = \frac{1}{RC}$$

$$\overline{\Delta f} = \frac{1}{2\pi RC}$$

so that the results for each triple can be tabulated as follows:

f_0, Mc	Q	$\overline{\Delta f}$, Mc	Shunt Resistance, ohms
(1) 36.3	4.65	7.9	790
(2) 24.8	4.65	5.4	1150
(3) 30.0	2.26	13.3	470

Wallman gives tables which extend the design to quadruples, and so forth, called n-upples.

TYPICAL INVERSE FEEDBACK I-F AMPLIFIER CIRCUITS. Typical feedback circuits are shown in Figs. 10a, 10b, and 10c. These are drawn without regard to d-c potentials. Thus the grids must be protected from the plate voltages by blocking condensers or, preferably, transformers having unity coupling.

The feedback chain of Fig. 10a is of little use, despite its high gain times bandwidth factor, because its gain cannot be controlled. Figures 10b and 10c show respectively a

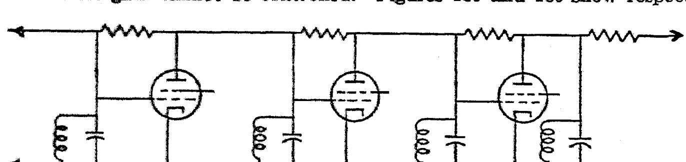

FIG. 10a. Ideal Inverse Feedback Chain

typical feedback pair and feedback triple. In each case the voltage which controls the gain is applied to the first tube.

A complete i-f amplifier using 6AK5's and inverse feedback is shown in Fig. 11.

This amplifier consists of two triples made up respectively of tubes V-301, V-302, V-303, and V-304, V-305, V-306. Gain control is applied to V-301 and V-304. This amplifier is centered on 60 Mc and has an overall gain of approximately 90 db and a bandwidth at 3 db of approximately 10 Mc.

The design of feedback amplifiers is not as readily computed as that of stagger-tuned amplifiers and therefore is based to a greater extent on test and experience.

For an excellent study of feedback amplifiers see reference 9, 10, 11, 13, and 14.

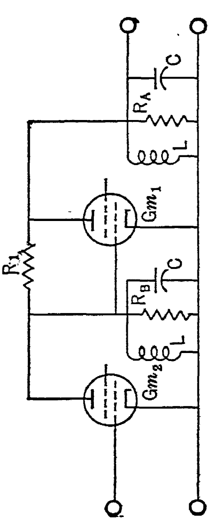

Fig. 10b. Inverse Feedback Pair. The gain is controlled by biasing the first tube because it is not involved in the feedback loop.

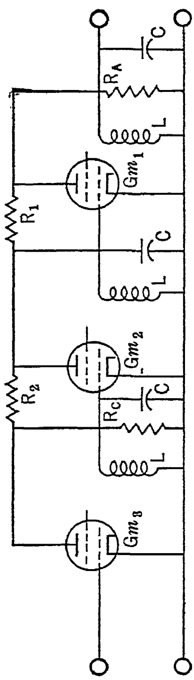

Fig. 10c. Inverse Feedback Triple. The gain is controlled by biasing the first tube because it is not involved in the feedback loop.

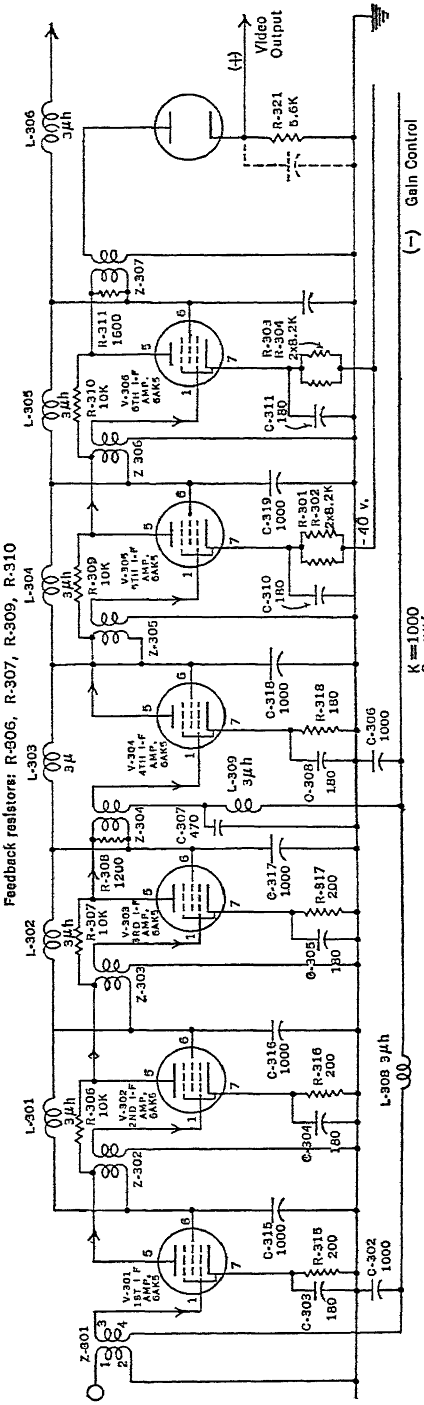

Fig. 11. 60-Mc Inverse Feedback I-f Amplifier Consisting of Two Triples

STAGGER-TUNED AMPLIFIERS VS. INVERSE FEEDBACK AMPLIFIERS. The choice between a stagger-tuned and an inverse-feedback amplifier depends largely on the circumstances surrounding its use. There is no fixed answer as to which is best for all conditions. The differences are outlined below.

Figure of Merit. Both these types of amplifiers have been shown to have a much higher figure of merit than the synchronous single-tuned circuit type. Theoretically the inverse-feedback amplifier can have a higher one than the stagger-tuned, but it is difficult to achieve this in practice, so that they may be assumed equal.

Gain Control. Gain adjustment may be desired (1) to change the output, (2) to change the gain with time (gain time control, gtc in radar applications), (3) to reduce interference, (4) for automatic gain stabilization (ags), (5) for automatic gain control (avc).

A stagger-tuned amplifier's bandwidth being practically independent of the tube's g_m, gain control can be applied to any tube.

An inverse-feedback amplifier can use for gain control only those tubes which are not in the feedback chain. Otherwise, the bandwidth will change with gain.

Gain Variation with g_m. The gain varies more slowly with g_m in a feedback amplifier (approximately as $g_m^{1/2}$) than in others (linearly with g_m). This means that the gain of amplifiers not equipped with automatic gain stabilization (ags) will be less susceptible to voltage change, tube ageing, and tube replacement if of the feedback type.

Effect of Replacement Tubes on Bandwidth. In a feedback amplifier, the resonant frequency, and therefore the overall bandwidth, is less affected by replacement tubes of differing capacitance. However, the bandwidth is more affected by tubes of differing g_m.

Resonant Frequency. An inverse-feedback amplifier has all its circuits tuned to the center frequency of the pass band.

Independence of Tuning. In a stagger-tuned amplifier the tuning of one stage is independent of the tuning of the other stage.

MODULATORS

By J. E. Young

Modulation is the process whereby the amplitude, or other characteristic, of a wave is varied as a function of the instantaneous value of another wave. The first wave, which is usually a single-frequency wave, is called the "carrier wave"; the second is called the "modulating wave."

The carrier frequency is the frequency of the carrier wave.

Sidebands are the frequency bands on each side of the carrier frequency within which fall the frequencies of the waves produced by the process of modulation. In amplitude modulation, the width of a transmitted sideband is usually no greater than the bandwidth of the modulating wave. The bandwidth of a frequency-modulated signal is determined by both the modulating frequency and the frequency swing employed.

Percentage modulation (amplitude modulation) is the ratio of the difference between the maximum current (I_m) when a signal is impressed and the maximum unmodulated current (I_s) to this maximum unmodulated current, expressed in percentage, or $M = 100(I_m - I_s)/I_s$. For less than 100 per cent modulation this may optionally be expressed as the ratio of half the difference between the maximum and minimum amplitudes of a modulated wave to the average amplitude, expressed in percentage.

Percentage modulation (frequency modulation) is the ratio of the frequency swing when a signal is impressed, to an arbitrary frequency swing which is defined as 100 per cent modulation, expressed in percentage. The frequency swing defined as 100 per cent modulation is different for various services. For f-m broadcasting, for example, 75 kc is used.

14. TYPES OF MODULATION

A single-frequency current wave can be expressed as

$$i = A \sin (\omega t + \theta) \tag{1}$$

where A is the amplitude, $\omega/2\pi$ the frequency (when constant), and θ the relative phase. If any of the three independent magnitudes, A, ω, or θ, is slowly varied (slow in comparison to $\omega/2\pi$) the wave is said to be modulated. The three cases are called amplitude, frequency, and phase modulation, respectively.

If ω and θ are held constant but A is varied sinusoidally, so that $A = A_0(1 + m \sin \omega_1 t)$, eq. (1) becomes

$$i = A_0(1 + m \sin \omega_1 t) \sin (\omega t + \theta) \tag{2}$$

which, when expanded trigonometrically, gives

$$i = A_0 \sin (\omega t + \theta) + \frac{mA_0}{2} \{\sin [(\omega + \omega_1)t + \theta] + \sin [(\omega - \omega_1)t + \theta]\} \tag{3}$$

The quantities in the bracket of the second term on the right represent sum and difference frequencies of the two original frequencies. They are the sidebands. Comparison of these two equations shows that a wave of a single frequency and periodically varying amplitude is mathematically equivalent to a wave of constant amplitude and frequency and a pair of sidebands.

Roder has shown (*Proc. I.R.E.*, Vol. 19, 2145 [1931]) that, if A and θ are constant but $\omega = \omega_0(1 + k_f \cos \mu t)$, the current is (let $\omega_0 t = \omega t + \theta$)

$$\begin{aligned} i = A_0 \sin \omega_0 t &+ J_1(m_f)[\sin (\omega_0 + \mu)t - \sin (\omega_0 - \mu)t] \\ &- J_2(m_f)[\sin (\omega_0 + 2\mu)t - \sin (\omega_0 - 2\mu)t] \\ &+ J_3(m_f)[\sin (\omega_0 + 3\mu)t - \sin (\omega_0 - 3\mu)t \end{aligned} \tag{4}$$

where $m_f = k_f\omega/\mu$ so that m_f is the ratio between the maximum frequency shift and the audio frequency; also $J_n(m)$ means the Bessel function (see Section 1, article 14) of the first kind and nth order for the argument m. In this expression there are theoretically an infinite number of sidebands, although the amplitude of all those of higher order than the first is usually negligible.

If A and ω are constant but $\theta = \theta_0(1 + K_p \sin \mu t)$, Roder gives the current as identical in form with eq. (4) except that $m = K_p\theta_0$. Here, again, there are theoretically an infinite number of sidebands, but only those of the first order are of importance or of appreciable amplitude.

Except for some very early and ineffective attempts to use frequency or phase modulation, amplitude modulation was used exclusively for communication and broadcasting up to 1936. Exploration into the higher radio frequencies and the adaptation of these frequencies to wide use for numerous services has brought frequency- and phase-modulation techniques into great importance, since the wider frequency bands required, if they are to be used effectively, become available as the usable frequency spectrum is extended into the hundreds and thousands of megacycles.

AMPLITUDE MODULATION. Since the e^2 term of the power series of development for current in a non-linear circuit gives rise to the term $\sin \omega_1 t \sin \omega t$, characteristic of modulation, it follows that modulation occurs *whenever any of the circuit parameters vary with instantaneous voltage* (or current). In particular, if it is assumed that a single high-frequency voltage $e_p' = E_s' \cos (\omega_s t + \theta_s)$ is introduced in the plate circuit of a vacuum tube and a varying audio voltage $e_g = \sum_k E_{gk} \cos (\omega_k t + \theta_k)$ is impressed on the grid, then, from Section 5, article 21, eq. (17), the terms having frequencies near that of $\omega_s/2\pi$ are

$$i_{ps} = \frac{E_s \cos(\omega_s t + \theta_s')}{z_s'} - \frac{r_p}{2}\frac{\partial r_p}{\partial e_p}\sum_k \frac{\mu E_s E_k}{z_s' z_k'}\left[\frac{\cos(\omega_s t + \omega_k + \beta_{4k})}{z'_{(s+k)}} + \frac{\cos(\omega_s t - \omega_k t + \beta_{5k})}{z'_{(s-k)}}\right] \quad (5)$$

where the phase angles are developed as illustrated there in eq. (22). This may optionally be written (assume the phase angles of $z_{(s+k)}$ and $z_{(s-k)}$ negligible as is usual in practical circuits).

$$i_p = \frac{E_s \cos(\omega_s t + \theta_s')}{z_s'}\left[1 - r_p \frac{\partial r_p}{\partial e_p}\sum \frac{\mu E_k \cos(\omega_k t + \theta_k')}{z_k' z_s'}\right] \quad (6)$$

Then the percentage modulation is

$$M = -\frac{100 r_p}{z_s'}\frac{\partial r_p}{\partial e_p}\left[\sum_k \frac{\mu E_k \cos(\omega_k t + \theta_k)}{z_k'}\right]_{\max} \quad (7)$$

The expression in the bracket is simply the maximum value of the audiofrequency plate current. These currents are shown in Fig. 1.

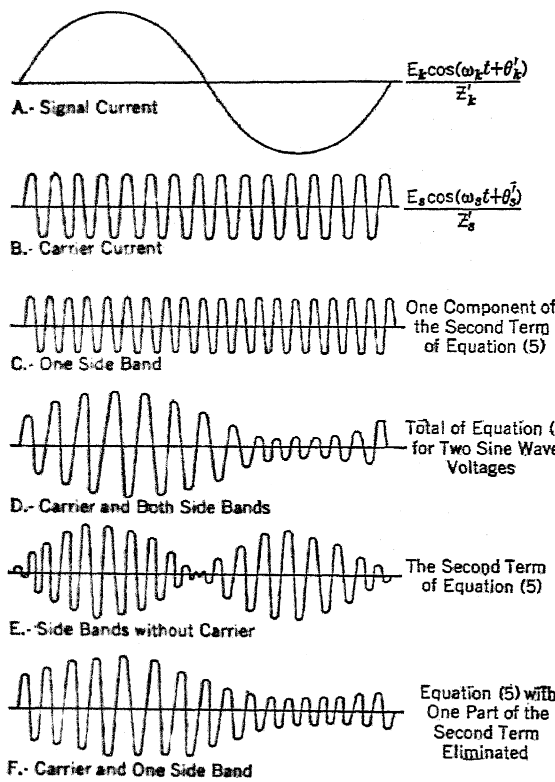

FIG. 1. Combination of Sine Wave Carrier and Signal Currents

METHODS OF PRODUCING AMPLITUDE MODULATION. Systems of modulation may be divided into two classes:

1. Systems in which the impedance of a r-f oscillator, amplifier, or combination of amplifiers is varied by the modulating wave.

2. Systems employing a constant-impedance r-f oscillator, or amplifier, having a variable impedance in series with it in which the variation of the magnitude of the series

impedance is controlled by the modulating wave, thereby controlling the input to the r-f unit.

The first method of modulation may be accomplished by varying the grid bias of the r-f oscillator or amplifier if a triode is used or, alternatively, varying the suppressor or screen-grid potential if multielectrode tubes are used.

The second method depends for its operation on the introduction of the modulating emf in series with the plate power supply of the modulated oscillator or amplifier. Since appreciable amounts of power are required to accomplish modulation in this manner, auxiliary tubes are employed as modulators.

15. GRID MODULATION

The term *grid modulation* is commonly used to describe modulation systems of the first class mentioned above. Modulation is effected by varying the d-c grid bias voltage or suppressor grid voltage at an a-f rate, by connecting the modulating source, such as the output transformer of an audio-amplifier stage, between the bias source and the r-f stage. Since the grid input resistance is high, the audio amplifier need be capable of only a few watts output. The power required is still further reduced in some designs by the use of a tube in the r-f circuit which is capable of large plate currents without exceeding zero grid bias. In this case the a-f amplifier looks into a circuit of substantially infinite impedance. The operating bias for the r-f stage is determined as follows: The r-f tube is first biased to cutoff, with no r-f grid voltage. The r-f grid voltage is then increased until the knee of the saturation curve is reached. Then, with a constant r-f grid voltage, the d-c grid voltage is increased until the plate current is substantially zero. If e_1 is the d-c grid voltage for maximum output, and e_2 is the d-c grid voltage for zero output, the operating grid voltage should be $(e_2 + e_1)/2$. The peak a-c voltage required from the audio stage to produce complete modulation is $(e_2 - e_1)/2$. Because of the relatively low efficiency obtained, grid modulation methods are generally applied only where the amount of modulated power required is very small. Higher powers are sometimes obtained by following the grid modulated stage by r-f amplifiers. The outstanding advantages of grid modulation are its simplicity and cheapness, which make it attractive for small, light-weight applications, such as portable or airborne.

POWER AND EFFICIENCY OF GRID-BIAS-MODULATED AMPLIFIERS. The following discussion may be applied in determining peak power requirements, efficiency, driving power, etc., of class B r-f amplifiers as well as bias-modulated amplifiers, since the tubes operate under the same conditions in each case. The peak power output capability of the tube must be four times the carrier power if complete modulation is to be obtained. This follows from the fact that the output current and voltage must be doubled on peaks of 100 per cent modulation. The efficiency is proportional to the percentage of modulation, and it is of the order of 20 to 33 per cent for normal carrier or unmodulated conditions. The ratio of driving power of the r-f exciter to carrier power of the modulated stage should not exceed 1 : 10, since the exciter must maintain a constant r-f voltage on the grid of the modulated tube. The following formulas show the current, voltage, power relations, and effect of the variation of the percentage of modulation.

Let W_P = peak instantaneous power output; W_C = carrier output power; W_A = average power output, 100 per cent modulation (used in determining heating effect); i_{pc} = peak plate current averaged over an r-f cycle, 100 per cent modulation; i_{pm} = average plate current, unmodulated; f_p = maximum instantaneous plate efficiency averaged over an r-f cycle, 100 per cent modulation; f_c = average plate efficiency, carrier unmodulated; F = modulation factor = $M/100$; W_{LP} = plate loss averaged over an audio cycle, 100 per cent modulation; and W_{LC} = average plate loss, carrier unmodulated.

Assume that d-c plate voltage remains constant, and that modulation is effected by variation of plate current and efficiency. Then:

$$F = \sqrt{\frac{W_P}{W_C}} - 1 \tag{8}$$

$$W_A = 1.5W_C \tag{9}$$

$$i_{pm} = 2i_{pc} \tag{10}$$

$$f_p = f_c(1 + F) \tag{11}$$

$$W_{LP} = W_{LC} \tag{12}$$

16. PLATE MODULATION

The earliest system of plate modulation, devised by Heising, was known as the constant-current system. See Fig. 2. It derived its name from the fact that variation of the power input to the r-f stage is obtained by using another tube or tubes as an absorber. The current drawn from the supply source remains constant and shifts between the absorber and useful load as the absorber or modulator impedance is changed by the a-f voltage impressed in its grid. Because of the curvature in the extremes of the vacuum-tube characteristics when used as a modulator, the percentage of modulation, where the r-f stage and modulator are both supplied with the same plate potentials, is limited. To obtain complete modulation, the d-c voltage impressed on the radio stage is often reduced by a series resistor. The a-f voltage developed by the modulator is transferred, unattenuated, by a suitable by-pass capacitor connected around the resistor. It is usually possible to obtain complete modulation by reducing the r-f amplifier voltage to 60 or 70 per cent of the modulator voltage.

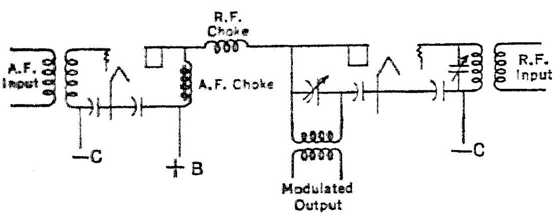

Fig. 2. Heising Amplitude Modulation

The high efficiency of plate-modulated class C amplifiers has led to their extensive use in high-power telephone transmitters. Modulator efficiency has been greatly improved by matching the modulator to the class C amplifier load by means of a coupling transformer and by using pairs of modulator tubes in class B circuits. Radio-frequency amplifiers following the modulated stage may be dispensed with entirely in this system, and power outputs obtained which are limited only by the capabilities of the vacuum tubes used in the modulator and modulated amplifier, with high overall efficiency. For the calculation of such circuits the reader is referred to p. 7-16. Transformer-coupled modulator circuits may be calculated by treating the modulator as a transformer-coupled a-f amplifier terminated on the secondary side of the coupling transformer by a load resistance equal to the modulated amplifier d-c plate voltage divided by its plate current. It should be noted that, where transformer-coupled modulators are used, the current delivered by the power source is no longer constant. In fact, in the case of the pushpull modulator, the current required by the modulator is very largely second harmonic. Special attention must be paid to the filter design, since harmonic voltage developed across the power supply terminals

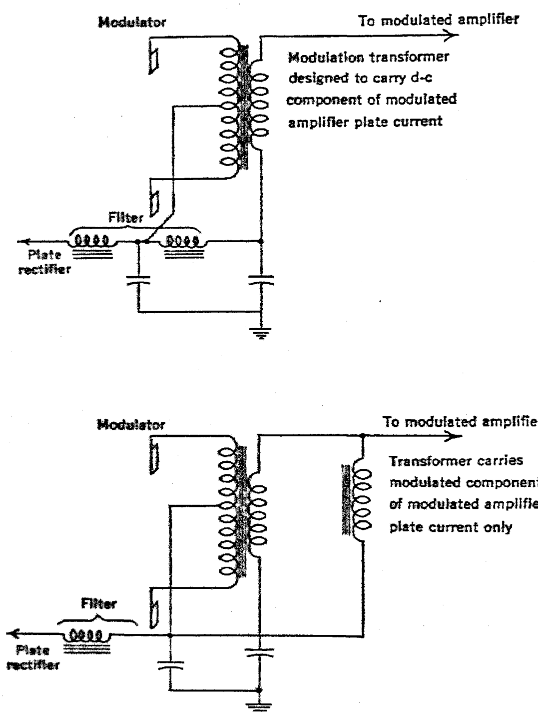

Fig. 3. Modulator-amplifier Coupling Circuits

by the modulator current demand will be applied to the modulated amplifier and appear as distortion in the modulated envelope. Recommended coupling circuits are shown in Fig. 3.

The modulated amplifier is operated class C; however, if distortion is to be minimized, special considerations are involved. It will be noted that the applied plate supply voltage to the class C stage has the wave shape of the modulating wave. It follows that, for 100 per cent modulation, the voltage rises to twice the carrier level, and the plate current must likewise rise to twice its quiescent level. Adequate grid excitation must be provided to insure this increase in plate current. This is usually achieved by driving the modulated amplifier somewhat harder than is required to produce rated carrier power at maximum efficiency. In addition, grid leak bias is used, and since the grid current decreases as the plate voltage increases (and the plate robs the grid of some of its electrons) the grid bias falls, the amount of grid driving power falls, and, owing to the combination of decreased bias and driver regulation, the a-c grid driving voltage increases, thus producing a condition favorable to a linear relation between modulating plate voltage and r-f output voltage.

The rise in driving voltage required to minimize distortion is, to some extent, a function of the design of the tube. Some types of tubes require less increase in drive, as the plate voltage rises, than is obtained by the combination of grid leak bias and driver regulation. Lowest distortion will be obtained in these cases if a combination of fixed and grid leak bias is used. The desired combination may easily be obtained by by-passing part of the grid leak with a capacitor large enough to retain most of its charge over the lowest a-f cycle.

Another method of obtaining the necessary variation in drive is to modulate the driver stage. It is usually not necessary, for optimum results, to use a depth of modulation greater than 30 or 40 per cent for this stage, when the modulated amplifier is modulated 100 per cent.

Tetrodes and pentodes may be used as modulated amplifiers. If low distortion is required, it is necessary to modulate the screen-grid voltage.

As in driver modulation, it is usually not necessary to modulate the screen voltage completely. The modulating voltage may be obtained from the plate circuit of the tube through a blocking capacitor and dropping resistor or, more conveniently, by a tertiary winding on the modulation transformer.

Let F = modulation factor; E_M = maximum plate voltage averaged over an r-f cycle; E_C = d-c plate voltage; W_{LP} = watts output, complete modulation; W_{LC} = watts output, normal carrier; W_M = modulator output power; and W_{CI} = modulated amplifier input power.

The following formulas show the current voltage relations in a plate-modulated amplifier:

$$E_M = E_C(1 + F) \tag{13}$$

$$W_{LP} = 1.5W_{LC} \tag{14}$$

$$F = \sqrt{\frac{2W_M}{W_{CI}}} \tag{15}$$

The last equation assumes that the modulated amplifier matches the output impedance of the modulator either directly or through a transformer, since, owing to limitation of the plate swing of the modulator, incorrect matching may limit the modulation factor, even though the modulator is potentially capable of producing complete modulation.

17. COMPARISON OF MODULATION SYSTEMS

Any comparison of modulation systems develops into a comparison of means of getting a specified amount of modulated power into a load, or antenna, under specified conditions of operation, weight, portability, fidelity, etc. For light-weight, portable transmitters, grid modulation has some advantage, although it is not capable without feedback of high fidelity. For most other applications plate modulation is used either directly, in the last r-f amplifier, or in a stage followed by one or more r-f amplifiers. In the last case, such amplifiers are usually of the high-efficiency Doherty type. For transmitters operating in the standard broadcast band where a transmission is almost always over a single path, both the "high-level" system of modulation in the last r-f amplifier, and the "low-level" system using Doherty amplifiers, are satisfactory. However, where multipath transmission exists, and incidental phase modulation may cause objectionable distortion, high-level modulation is generally preferred.

FREQUENCY MODULATION. Equation (4), in Article 14 was shown to represent the modulated r-f current for either the frequency-modulated wave or the phase-modulated wave. It will be noted, however, that the frequency swing, in frequency modulation, depends on the amplitude of the modulating signal but is independent of its frequency, whereas, in phase modulation, the resulting frequency swing is proportional to both the amplitude and the frequency of the modulating signal. It is possible, therefore, to convert from frequency modulation to phase modulation or vice versa by simply operating on the frequency-amplitude characteristic of the modulating signal. Frequency modulation is more generally used than phase modulation in broadcasting and communication systems. However, because of the ready conversion from one system to the other, the basic modulator employed in the transmitter is sometimes a phase-modulated device, which by alteration of the modulating-signal frequency characteristic is converted to produce frequency modulation. The relation between phase shift, frequency swing, and modulating signal frequency is given by:

$$\theta = \frac{K_f \omega}{\mu}$$

where θ = phase shift in radians.
$K_f\omega$ = frequency swing in cycles per second.
μ = modulating-signal frequency in cycles per second.

Methods of producing frequency and phase modulation are discussed more fully in Section 8.

DETECTORS

By Vernon D. Landon

Demodulation, or detection, is the process whereby a wave resulting from modulation is so operated upon that a wave is obtained having substantially the characteristics of the original modulating wave.

Square-law detection is that form of detection which depends on the fact that e^2 of the power series for a non-linear circuit excited by a modulated wave contains the difference frequency between the carrier and one of its sidebands, which is the original modulating frequency.

Linear detection is that form of detection in which the output voltage under consideration is substantially proportional to the instantaneous peak carrier voltage throughout the useful range of the detecting device.

18. SQUARE-LAW DETECTION

Any device having a non-linear current-voltage characteristic will serve as a detector. Such devices include certain crystals and thermionic vacuum tubes. (See Figs. 1, 2, and 3.) The applied modulated voltage is of the form given in eq. (5), p. 7-72, which, when squared, gives audio-frequency terms of the form

$$\begin{aligned} i_{pa} = -\frac{r_p}{2}\frac{\partial r_p}{\partial e_p}\Bigg[& \frac{E_sE_n \cos(\omega_n t + \phi_1)}{Z'_s Z'_{(s+n)} Z'_n} + \frac{E_sE_n \cos(\omega_n t + \phi_2)}{Z'_s Z'_{(s-n)} Z'_n} \\ & + \frac{E_sE_m \cos(\omega_m t + \phi_3)}{Z'_s Z'_{(s+m)} Z'_m} + \frac{E_sE_m \cos(\omega_m t + \phi_4)}{Z'_s Z'_{(s-m)} Z'_m} \\ & - \frac{E_nE_m \cos(\omega_n t - \omega_m t + \phi_5)}{Z'_{(s+n)} Z'_{(s+m)} Z'_{(n-m)}} - \frac{E_nE_m \cos(\omega_n t - \omega_m t + \phi_6)}{Z'_{(s-n)} Z'_{(s-m)} Z'_{(n-m)}} \\ & - \frac{E_nE_m \cos(\omega_n t + \omega_m t + \phi_7)}{Z'_{(s-n)} Z'_{(s+m)} Z'_{(n+m)}} - \frac{E_nE_m \cos(\omega_n t + \omega_m t + \phi_8)}{Z'_{(s+n)} Z'_{(s-m)} Z'_{(n+m)}} \\ & - \frac{E_n^2 \cos(2\omega_n t + \phi_9)}{Z'_{(s+n)} Z'_{(s-n)} Z'_{(2n)}} - \frac{E_m^2 \cos(2\omega_m t + \phi_{10})}{Z'_{(s+m)} Z'_{(s-m)} Z'_{(2m)}} \Bigg] \end{aligned} \qquad (1)$$

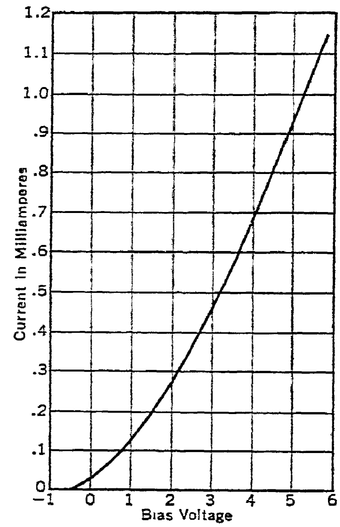

Fig. 2. Static Characteristic of Diode

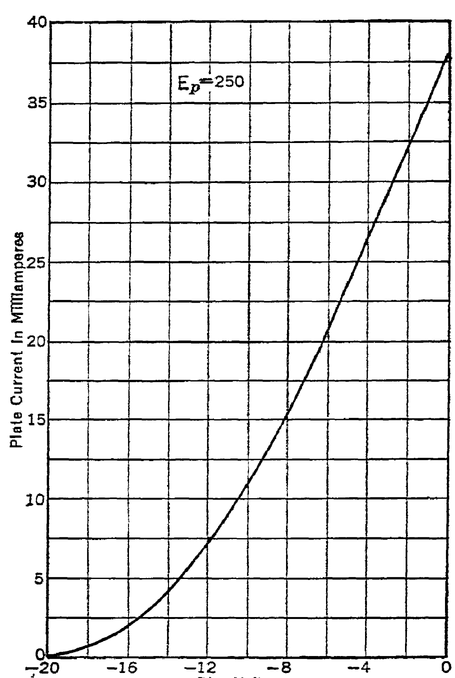

Fig. 3. Static Characteristic of Triode

There are two terms present of each original signal frequency, resulting from the beating of two sidebands against the carrier. From this it is seen that there will not be detection unless the carrier is present, but that the *carrier and one sideband* are sufficient. If regard is paid to differences of phase, terms of the same frequency may be added; the terms present and their phase angles are given in Table 1.

Table 1. Square-law Detection

Simplified Expression for the Audio-frequency Current resulting from Square-law Detection of a Carrier and Both Side Bands. Similar Terms Appear for each Pair of Audio Components.

$\dfrac{2\,E_s\,E_n(r''' + r'''_p)\cos(\omega_n t + \beta'_1)}{z'''_s\,z'^2_s\,z'_n}$	$\theta_n - \tan^{-1}\dfrac{x'''_n}{r''' + r'''_p} - \tan^{-1}\dfrac{x_n}{r + r_p}$
$\dfrac{2\,E_s\,E_m(r''' + r'''_p)\cos(\omega_m t + \beta'_2)}{z'''_s\,z'^2_s\,z'_m}$	$\theta_m - \tan^{-1}\dfrac{x'''_m}{r''' + r'''_p} - \tan^{-1}\dfrac{x_m}{r + r_p}$
$-\dfrac{2\,E_n\,E_m\cos(\omega_n t - \omega_m t + \beta'_2)}{z'^2_s\,z'_{n-m}}$	$\theta_n - \theta_m - \tan^{-1}\dfrac{x'''_n}{r''' + r'''_p} + \tan^{-1}\dfrac{x'''_m}{r''' + r'''_p} - \tan^{-1}\dfrac{x_{n-m}}{r + r_p}$
$-\dfrac{2\,E_n\,E_m\cos(\omega_n t + \omega_m t + \beta'_4)}{z'^2_s\,z'_{n+m}}$	$\theta_n + \theta_m - \tan^{-1}\dfrac{x'''_n}{r''' + r'''_p} - \tan^{-1}\dfrac{x'''_m}{r''' + r'''_p} - \tan^{-1}\dfrac{x_{n+m}}{r + r_p}$
$-\dfrac{E_n^2\cos(2\,\omega_n t + \beta'_5)}{z'^2_s\,z'_{2n}}$	$2\theta_n - 2\tan^{-1}\dfrac{x'''_n}{r''' + r'''_p} - \tan^{-1}\dfrac{x_{2n}}{r + r_p}$
$-\dfrac{E_m^2\cos(2\,\omega_m t + \beta'_6)}{z'^2_s\,z'_{2m}}$	$2\theta_m - 2\tan^{-1}\dfrac{x'''_m}{r''' + r'''_p} - \tan^{-1}\dfrac{x_{2m}}{r + r_p}$

* Each term must be multiplied by $-\dfrac{r_p}{2!}\dfrac{\partial r_p}{\partial e_p}$.

With only one audio component present the per cent modulation is $200E_n/E_s = M$. Hence the per cent second harmonic present, in terms of the fundamental, is $M/4$. For large per cent modulation this system is therefore not satisfactory. When more than one signal frequency is present as modulation on the carrier wave, extraneous frequencies are produced corresponding to the sum and difference frequencies of all the signal components taken in pairs.

The square-law detector is now largely used only for detection of carriers having small percentage modulation and for the reception of single sideband signals. It is the only form which will work with these latter. In detecting single sideband and carrier, second harmonics of the audio components are not produced, but frequencies corresponding to the sums and differences between the frequencies of the components of the original signal are present.

SQUARE-LAW DETECTOR CIRCUITS. Any non-linear circuit excited by a voltage small enough so that the static characteristic over the region used is closely a parabola is satisfactory as a square-law detector. When the vacuum tube is used, detection may

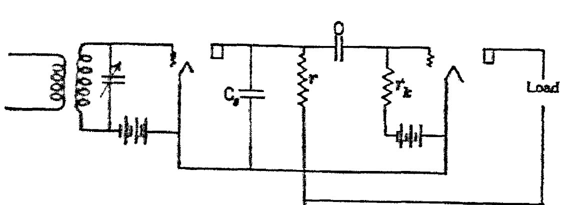

Fig. 4. Plate Current Detector, Resistance Coupled to Succeeding Amplifier Tube

occur either in the grid or plate circuits. Figure 4 shows a circuit which is biased practically to plate-current cutoff so that detection takes place owing to the curved mutual characteristic.

The voltage at any frequency k impressed on the amplifier tube is

$$E_{LK} = \frac{A_K \mu^2 r_p z_K}{z'^2_s z'_K} \frac{\partial r_p}{\partial e_p} \tag{2}$$

For high detected voltage the external plate impedance at the carrier frequency (z_s) should be small, but that at the signal frequencies (z_k) should be large. The high audio impedance is shunted by C_s to achieve this result.

Figure 5 shows a circuit in which detection occurs in the grid. The grid and cathode elements act as a diode detector. The a-f currents, resulting from demodulation, produce an a-f voltage across the grid leak and so between grid and cathode. This voltage controls the electron stream so the tube also acts as an amplifier. A high audio impedance and low radio impedance are necessary so that the grid leak is shunted by a small condenser.

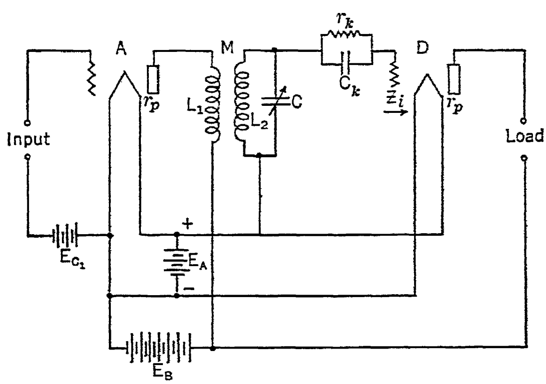

FIG. 5. Grid Current Detector (D), Transformer Coupled to Preceding Tube (A)

This type of detector broadens the tuning of the preceding tuned circuit (owing to the low impedance of the grid when positive), and overloads badly on strong signals, owing to the r-f and d-c components of the plate current. It is very sensitive, however.

19. LINEAR DETECTION

When very large signals are applied across non-linear circuits the power series convergence based on the static characteristics is so slow that the method is not useful. The equation for the modulated wave can optionally be written in the form (see eq. 6, p. 7-72):

$$e = E_s \left[1 - 2 \sum \frac{E_K}{E_s} \cos(\omega_K t + \theta_K) \right] \cos(\omega_s t + \theta_s) \tag{3}$$

which represents a voltage, of fixed frequency, whose amplitude is slowly varying about a mean value E_s. The sum (Σ) within the brackets will represent a voltage of the same wave shape as the original modulating voltage, provided the modulation and transmission have been distortionless. The instantaneous peak voltage of the carrier current is

$$E_m = E_s \left[1 - 2 \sum_K \frac{E_K}{E_s} \cos(\omega_K t + \theta'_K) \right] \tag{4}$$

Rectification diagrams of the detecting device are obtained by plotting the total *direct current* in the detector circuit against various *steady* values of rms (or peak) carrier voltage. (See Fig. 6.) Then when E_m is varied (in accordance with the signal voltage) this current varies; this detected current is equivalent to a steady direct current, whose value is determined by the value of direct current which flows when $E_m = E_s$, on which is superposed a varying current which will follow the variations in E_m (and so in the signal voltage) more or less closely, depending on the linearity of the rectification diagram. Since the periodicity (ω_s) of the carrier voltage is not of importance except in fixing the circuit impedances, the rectification diagrams can be obtained by using any convenient frequency, such as 60 cycles, rather than an actual carrier frequency, provided the circuit impedances are made equal in the two cases.

It will be noticed from the rectification diagrams shown in Figs. 7–12 that the increment in direct current due to a varying grid voltage varies approximately as the square of the maximum value of this voltage when E_m is small (as required by the power series expansion), but that, as E_m increases, the d-c response varies *linearly* with E_m. When it does so the distortion introduced in detection will be small.

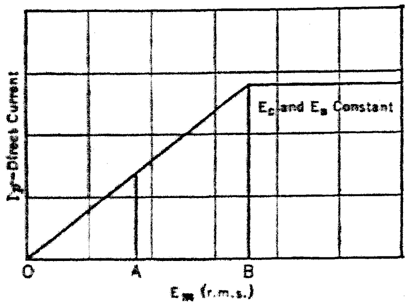

FIG. 6. Ideal Detector Characteristic (Rectification Diagram)

As an illustration, consider the plate-current detector shown in Fig. 4. Currents of radio frequency are by-passed by C_s; hence the only current which flows through r when E_m is steady is a direct current. If the value of this current were varied in accordance with the signal voltage, the varying voltage impressed on the grid of the succeeding amplifier tube would be simply the signal voltage. If the variation of direct current against E_m were given by the curve of Fig. 6 and the average value of E_m were equal to OA, then the variation of current would be exactly proportional to the signal voltage, *even for 100 per cent modulation*, provided $E_m < OB$. This means that there would be *no distortion* introduced by the detector.

Although no device available at present has exactly the characteristic of Fig. 6, certain crystals approximate it, and the vacuum tube can be made to approach it by a proper

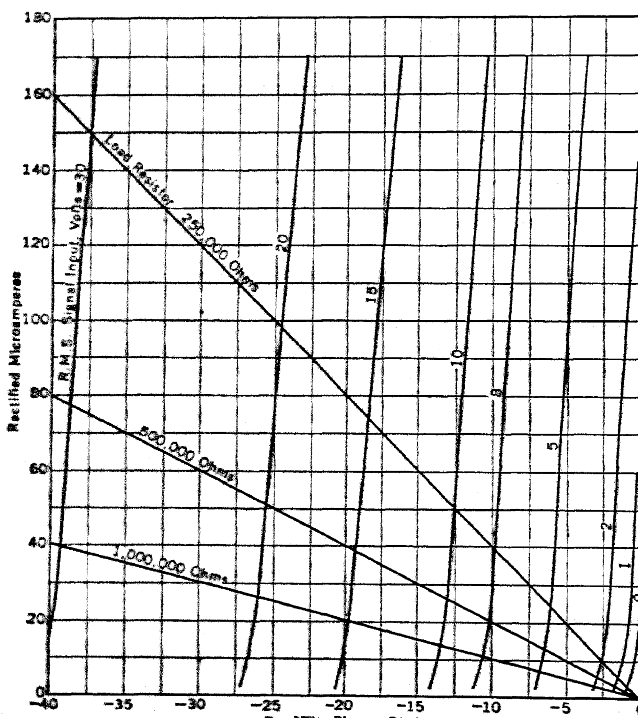

FIG. 7. Rectification Diagram for Diode Detector

choice of operating conditions and load. Figure 7 shows a set of curves for a diode from which rectification diagrams for any load resistance can be obtained; the diagram for 500,000-ohm load is shown in Fig. 8, which could also have been obtained experimentally. A diode gives the nearest approach to linear detection of any known detector.

When the characteristic is not a straight line, a Taylor's series expansion can be used in terms of e_{pa} and the change (e_m) in E_m:

$$i_{pa} = e_{pa}\frac{\partial i_p}{\partial e_p} + e_m\frac{\partial i_p}{\partial e_m} + \frac{1}{2}\left\{e_{pa}^2\frac{\partial^2 i_p}{\partial e_p^2} + 2e_{pa}e_m\frac{\partial^2 i_p}{\partial e_p \partial e_m} + e_m^2\frac{\partial^2 i_p}{\partial e_m^2}\right\} + \quad (5)$$

where i_{pa} is the current due to the variations e_{pa} and e_m, i_p is the plate-current ordinate of the rectification diagram, and e_{pa} is the plate potential due to i_{pa} and e_m. The reciprocal of $\partial i_p/\partial e_p$ is the analog of the plate resistance used in Section 5, and has been named the *detection plate resistance*. The derivative $\partial i_p/\partial e_m$ is the slope of the rectification curve—it is analogous to the mutual conductance of a triode and is called the *detection mutual conductance* or the *transrectification factor*.

All the calculations given for class A amplifiers now may be utilized in the detector circuit, including calculations of distortion, detection efficiency, etc.

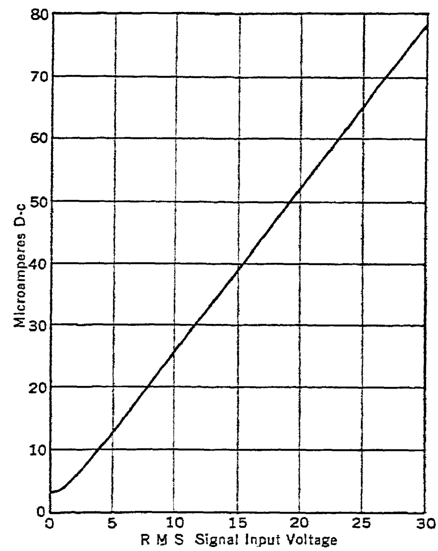

FIG. 8. Load Rectification Diagram for Diode Using 500,000-ohm Load

LINEAR DETECTORS. As stated above, the diode gives the nearest approach to linear detection known today. It has the objection of putting a fairly small resistance in parallel with a tuned circuit and so considerably broadening the tuning. When a diode is used the applied r-f voltage should be made as high as the tube can stand and a load resistance selected to give minimum distortion.

The triode is not as distortionless as the diode but sometimes fits in better with the circuit requirements. Rectification diagrams of a triode alone and with load are given in Figs. 9 and 10. In general, the plate voltage should be as high as possible, limited only by the supply available or the limits of the tube itself (flashover or heating).

When the plate voltage has been determined, rectification diagrams of the tube alone at various grid biases are obtained. If it is desirable, as is usual, to use the tube with carrier voltages which are 100 per cent modulated, the plate current should not reduce to zero for any finite value of E_m, or part of the modulation will produce no effect. In other words, the tube should not be biased below cutoff. The best results will be obtained if the tube is biased at, or slightly above, cutoff (on the static characteristic); this condition will be indicated on the rectification diagram by a small plate current for $E_m = 0$. For the tube of Fig. 9 the grid voltage is thus determined as either -1.5 or -3.0 volts.

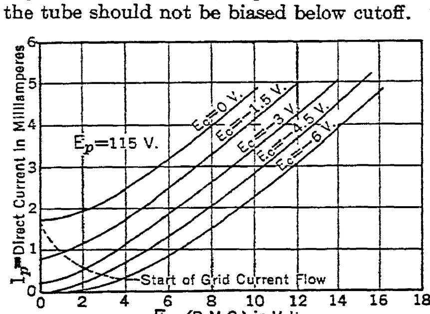

FIG. 9. Rectification Diagrams of Triode (Alone). All data were taken with 60-cycle impressed voltage.

To determine the proper load resistance, rectification diagrams of the tube with different loads (see Fig. 10) are obtained. If E_m is varied over a straight portion of one of these curves, distortion-free detection will result; if the variation is over a curved portion the distortion may be calculated as for an amplifier. (See p. 7-07.) For the tube used here a load impedance of 30,000 ohms would cause the tube to introduce a very low percentage of distortion for a carrier having an average rms value of 6.25 volts, and 100 per cent modulated. The difference between curves C and E illustrates the gain in efficiency, but increased distortion, obtained by by-passing the load resistance.

When the triode is used as a detector with large signal voltages of high percentage of modulation, operation with minimum distortion is always accompanied by a positive grid swing and so a flow of grid current. This causes a low input impedance and so decreases the selectivity of the tuned circuit just preceding the detector.

The use of a tetrode (see Fig. 11) makes it possible to obtain rectification diagrams which reach saturation for negative values of control grid voltage, so giving straighter operating curves without lowering the input impedance of the tube. The same method of analysis is followed, the only additional factor being the proper voltage to use for the screen grid. The method employed in selecting the screen-grid voltage depends to a large extent upon the type of plate load. In general, a higher screen-grid voltage gives a better rectification diagram (straighter and steeper). However, when there is a large d-c resistance in the plate circuit, the plate voltage falls considerably for large signal voltages, so that, if the screen-grid voltage is comparable with the plate voltage, electrons will land on the screen grid rather than on the plate.

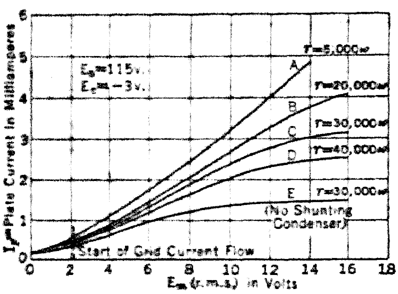

FIG. 10. Load Rectification Diagrams of Triode. For all curves but E the load was shunted by a 2 μf condenser. All data were taken with 60-cycle impressed voltage.

When reactance coupling is used the screen-grid voltage should be the maximum consistent with the plate voltage. For this type of coupling the d-c resistance of the detector plate load is small enough so that large carrier voltages will not cause sufficient drop for the plate voltage to become comparable to the screen-grid voltage. Therefore, there is no necessity of keeping the screen voltage low to prevent saturation (on the rectification diagram), and the gain in mutual conductance with high screen voltage raises the sensitivity and maximum output as well as decreases the curvature of the rectification characteristic.

When resistance coupling is used the selection of the optimum screen-grid voltage is somewhat more difficult. The problem is to select a value of screen-grid voltage that will give reasonable detector output at the normal values of input and yet not cause overloading for the larger values of input voltage. Two rectification diagrams for different values of screen-grid voltage and a high resistance load are shown in Fig. 12. The curve for

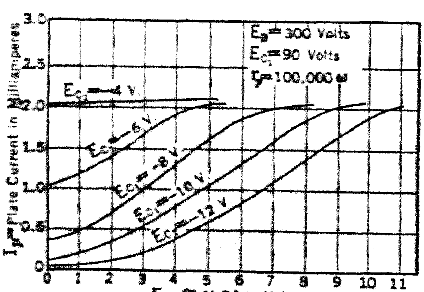

FIG. 11. Load Rectification of a Tetrode. All measurements were made at 60 cycles.

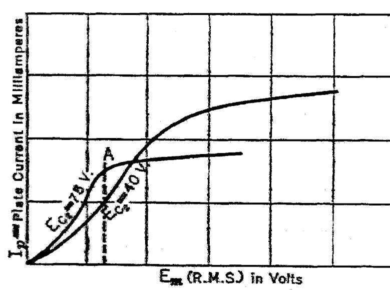

FIG. 12. Load Rectification Diagrams of a Tetrode, Showing the Effect of Screen Grid Voltage on Saturation. (Resistance load.)

E_{c_2} = 75 volts is better than that for E_{c_2} = 40 volts for inputs up to a point A, but the tube overloads for voltages greater than A. It is thus necessary to know the maximum signal voltage which will be impressed on the detector, and the screen-grid voltage which will just not overload at that voltage should be chosen.

OSCILLATORS

By Carl C. Chambers

An oscillator is a non-rotating device for producing alternating current, the output frequency of which is determined by the characteristics of the device. Oscillators can be conveniently divided into three classifications: (1) vacuum-tube oscillators, (2) electromechanically controlled oscillators, and (3) spark-gap oscillators.

20. VACUUM-TUBE OSCILLATORS

The most generally used oscillator in the field of communication engineering is the vacuum-tube oscillator. Since a vacuum tube can act as an amplifier of power, it can act as an oscillator. The power needed in the grid circuit can be supplied by the plate circuit. A vacuum-tube oscillator circuit acts as a power converter, changing d-c power into a-c power, having a frequency determined by the parameters of the circuit. The efficiency of vacuum-tube oscillators can be above 90 per cent, although for many purposes they operate at low efficiency. Vacuum tubes are constructed to dissipate as high as 125,000 watts, the power output of oscillators using such tubes being much greater.

SIMPLE OSCILLATOR CIRCUITS. In ordinary vacuum-tube oscillators, power is fed into the grid circuit from the plate circuit by means of either electrostatic or electromagnetic coupling between these circuits. When sufficient voltage of proper phase is introduced into the grid circuit, the a-c component of the plate current will persist, or, in other words, the circuit will oscillate.

Many oscillator circuits have been devised, several of which are shown in Fig. 1. In each of these circuits, the oscillatory circuit is the mesh containing L and C. In the Hartley circuit, the inductance L is tapped (not necessarily at the center); in the Colpitts circuit, the capacitance C is the series capacitance of C_1 and C_2. The tuned-plate tuned-grid oscillator has two separate oscillatory circuits, one in the plate circuit and one in the grid circuit, both tuned to approximately the same frequency. In each of these oscillators the load is coupled to the oscillatory circuit. This coupling is usually but not always inductive coupling.

The voltage introduced into the grid circuit due to the plate current, in (*a*) and (*b*), is the drop across part of the oscillatory circuit. In (*c*), (*e*), and (*f*), it is the voltage across one winding of the transformer, one winding of which is the inductance, L, of the oscillatory circuit. And in (*d*) it is the voltage drop across the grid oscillatory circuit due to the current through it and the grid to plate capacitance. The peak value of this feedback voltage in each case must be great enough to cause oscillation to persist. For stable operation, it should be roughly two and one-half to three and one-half times the d-c grid voltage necessary to bias the tube to plate current cutoff at the operating d-c plate potential.

The capacitances, C_B, are by-pass condensers, and the inductances, L_B, are choke coils arranged to prevent the alternating current from passing through the d-c supply source, E_B, or through the biasing resistor or grid leak, r_B. The grid voltage in most oscillators goes positive for part of the cycle. Thus the grid bias voltage is conveniently obtained by means of a grid leak and condenser. This method of biasing the oscillator tube tends to self-adjust the grid bias to permit operation over a wide range of values of the feedback voltage, since with greater excitation the grid tends to go more positive and consequently the grid bias becomes greater, resulting in essentially the same plate-current flow. Some oscillators have a comparatively small external grid bias (or self-bias by means of a cathode resistor) in addition to the grid leak. This externally supplied bias is a safety device to prevent too much plate current from flowing if the oscillations should cease for any reason.

NON-LINEAR THEORY OF OSCILLATIONS. The complete solution of even the simplest oscillator circuits is extremely complex. However, van der Pol, by means of very radical assumptions, has obtained the solution of several oscillator circuits. One of these solutions is for the circuit shown in Fig. 1*f*. The following assumptions are made concerning the circuit: (1) that the grid bias voltage is obtained by means of an external electromotive force; (2) that no current flows in the grid circuit; (3) that the capacitances C_B are so large that their a-c impedance is zero; and (4) that μ, the amplification factor, is constant. These approximations make the solution useful only from a qualitative standpoint.

The necessary condition for oscillation to persist is found to be that α, the damping constant of the circuit taken as a whole, is negative. To a rough approximation the amplitude of the oscillation is proportional to the square root of the ratio of α to the coefficient of the cube term in the power series expansion of the characteristic of the vacuum tube.

The wave form of the oscillation is dependent upon ϵ, the product of α and LC. The solutions of the circuit for several values of ϵ as calculated on the differential analyzer at

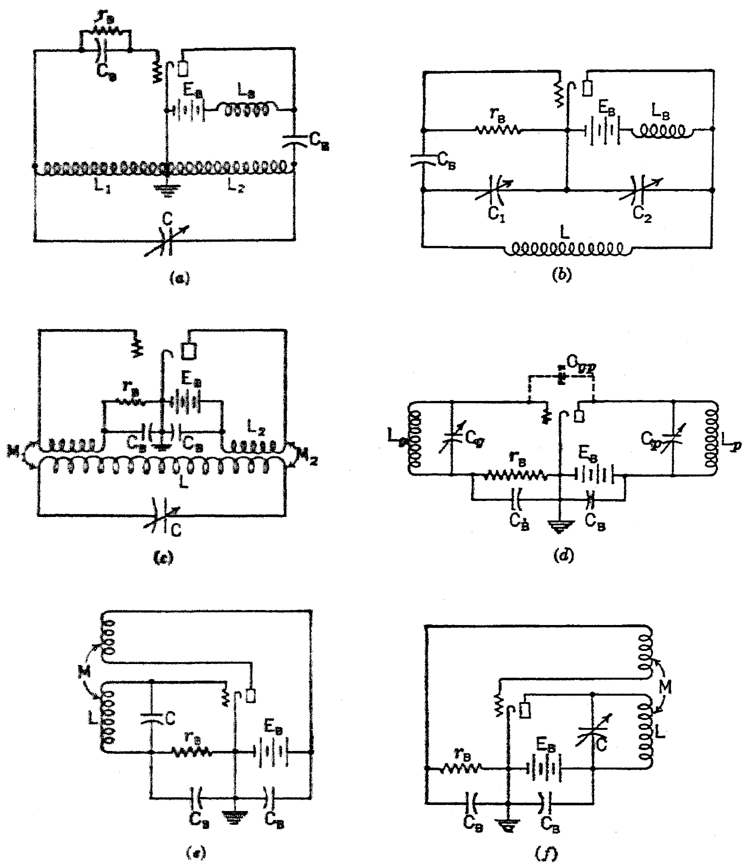

FIG. 1. Conventional Oscillator Circuits

the Moore School of Electrical Engineering are shown in Fig. 2. For small values of ϵ, the oscillations are essentially sinusoidal, the frequency being given by $\dfrac{1}{2\pi\sqrt{LC}}$. For large values of ϵ, the oscillations depart radically from sine waves. This form of oscillation has been called *relaxation oscillation*. It occurs in the multivibrator, the human heart, the hydraulic ram, etc. Van der Pol gives the period for $\epsilon \gg 1$ as roughly equal to 2ϵ.

CONDITIONS FOR SELF-OSCILLATION. For small amplitudes of oscillation, the non-linear resistances of the plate and grid circuits can be approximated by linear resistances. The condition for these small oscillations to build up is that the damping constant is negative. This is the condition for unstable systems in transient circuit theory. However, as the oscillations increase in amplitude, the linear circuit theory fails.

Llewellyn has shown that, under steady-state operation for any frequency component of the current, a non-linear resistance can be replaced by an equivalent impedance which can usually be roughly approximated by a pure resistance. When the circuit oscillates normally, the fundamental frequency of oscillation has a constant amplitude so that the plate to filament circuit in the tube can be replaced by such an effective resistance. In order for steady-state currents of a given frequency to flow in a circuit containing no emf of that frequency, the determinant of the coefficients of the currents in the mesh equations must be zero. An oscillator must satisfy such a condition. The approximate resulting conditions are noted for most of the circuits in Fig. 1. The value of the effective plate resistance, r_p, for any amplitude is given approximately by the inverse slope of the secant joining the limiting points of operation on the plate characteristic of the tube. By the reverse calculation the magnitude of oscillation for any given circuit can be predicted.

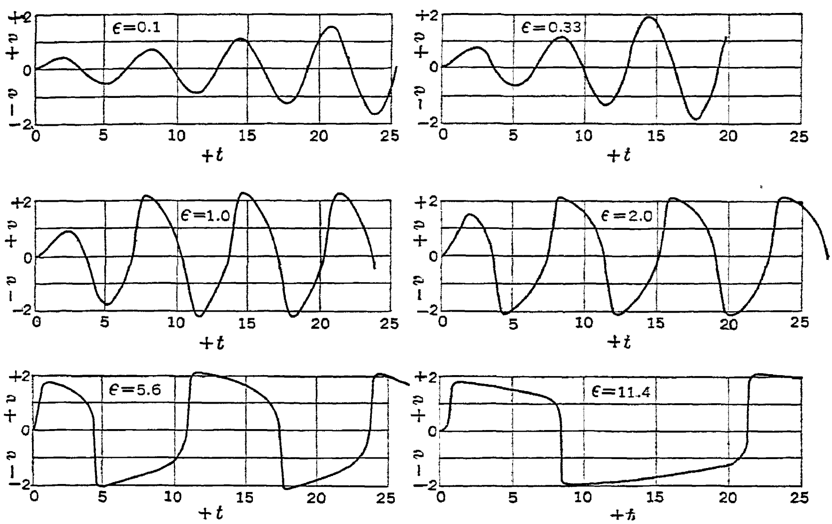

FIG. 2. Solutions of van der Pol's Equation for the Non-linear Theory of Oscillations:

$$\left(\frac{d^2v}{dt^2} - \epsilon(1 - v^2)\frac{dv}{dt} + v = 0\right)$$

CURRENT AND VOLTAGE RELATIONS IN SIMPLE OSCILLATOR CIRCUITS. As stated at the beginning of this chapter, the vacuum-tube oscillator is simply an amplifier arranged so that the power needed in the grid circuit is supplied by the plate circuit. Ordinarily, the amplifier so arranged belongs to that group known as class C amplifiers.

The current and voltage relations of a typical oscillator are shown in Fig. 3 for one complete cycle. The plate current flows during the portion of the cycle when the instantaneous plate voltage is least so that, since the energy dissipated at the plate of the vacuum tube is the integral of the instantaneous plate voltage times the instantaneous plate current, the tube plate loss is least when the current flows for as small a portion of the cycle as possible. When plate current flows, the grid voltage is positive with respect to the grid bias necessary for plate-current cutoff. Thus the duration of plate current decreases and consequently the plate efficiency increases with simultaneous increases in the grid bias and the a-c grid voltage. However, increasing the grid voltages in this way increases the losses in the grid circuit. The a-c grid voltage usually has a peak value of two and one-half to three and one-half times the grid bias necessary for plate current cutoff at the d-c plate voltage.

Since plate current flows only during minimum instantaneous plate voltage, the minimum plate voltage is of major importance. The impedance of the oscillatory circuit at resonance is adjusted so that, for the normal power output, the peak a-c voltage across it is slightly smaller than the applied d-c plate voltage. Therefore, the plate voltage causing current to flow is small compared with the d-c plate voltage, since it is essentially the d-c plate voltage minus the peak a-c voltage across the oscillatory circuit. Thus the a-c and d-c voltages remain practically equal as the d-c voltage is varied. It is this equality between the d-c and a-c voltages that makes the plate modulation of oscillators and class C amplifiers so nearly linear.

In ordinary triodes, the maximum plate current flows for a positive value of the grid voltage somewhat less than the minimum instantaneous plate voltage. In most oscillators at full load, the relation between the plate voltage and the grid voltage is such that the maximum instantaneous grid voltage and the minimum instantaneous plate voltage are respectively slightly greater and less than voltages satisfying the condition of maximum plate current.

When the bias is obtained by means of a grid leak and condenser, the a-c voltage introduced into the grid circuit has only a negligible effect on the maximum positive grid voltage, this being controlled by the magnitude of the resistance of the grid leak. The value of the grid leak is best determined by trial and error until the peak positive grid voltage is about 0.8 of the minimum instantaneous plate voltage. In small oscillators

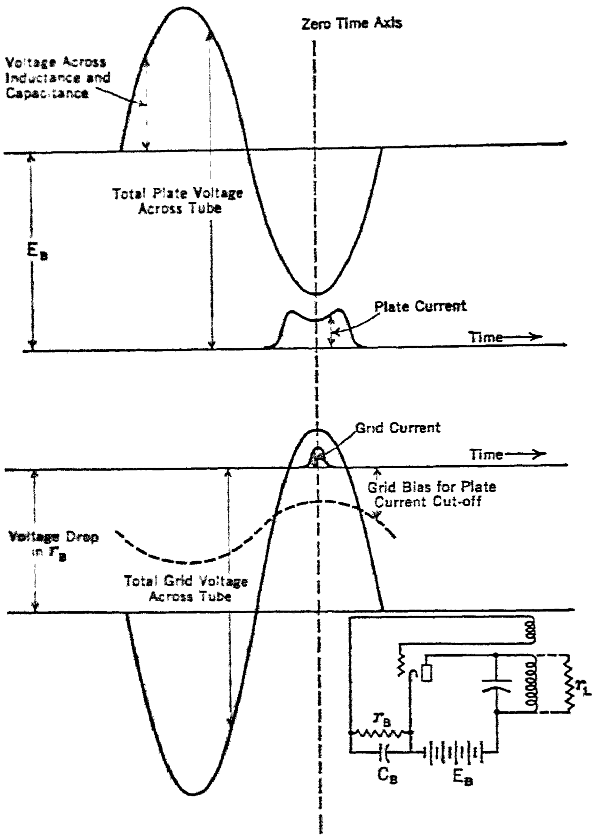

Fig. 3. Current and Voltage Relations of a Representative Oscillator

where efficiency is not vital the value of the grid leak can vary over wide limits; a value anywhere from a few thousand ohms to a megohm may be determined by trial and error until the oscillator operates satisfactorily.

Sometimes when the time constant of the grid leak and condenser is high and when the ratio of the a-c plate voltage to the a-c grid voltage is low, "blocking" will take place. Blocking is a relaxation oscillation and is due to the grid being at a higher potential than the plate so that the secondary emission from the grid causes the grid leak and condenser to develop a high bias which stops the oscillation until the charge leaks off the condenser, at which time oscillations again start and the cycle repeats itself. It can be corrected by increasing the ratio of the a-c plate voltage to the a-c grid voltage.

OSCILLATORY CIRCUIT DESIGN. The heart of any sinusoidal oscillator is the oscillatory circuit consisting of an inductance and a capacitance connected in series. Energy is supplied to this circuit from a d-c source by means of a vacuum tube, and energy is taken away from it by coupling the load to it in one of various ways. The circuit performs a function similar to that of the flywheel on a reciprocating steam engine.

The oscillatory circuit must store the energy used by the load long enough so that it can supply the load continuously even though it receives energy only during a small portion of the cycle. It has been found empirically that in order to do this job effectively, i.e., to give a good wave form, the ratio of the peak energy stored per cycle must be at least twice the energy fed into the load per cycle. From ordinary circuit theory it is known that a load resistance paralleling a tuned circuit, or coupled to a tuned circuit, can be replaced approximately by a resistance in series with the tuned mesh. When this is done the ratio of the peak stored energy to the energy dissipated per cycle is

$$\frac{V^2Cf}{I^2r} = \frac{VI}{2\pi I^2r} = \frac{fL}{r} \tag{1}$$

where V is the rms voltage across the capacitance, C, and across the inductance, L; I is the rms current through the inductance and capacitance; $r(= L/r_LC$, where r_L is the shunting resistance load) is the effective series resistance of the circuit, assumed to be small compared with 2π times the frequency, f, times L. Thus if the ratio is to be greater than 2, $2\pi fL/r(= Q)$ must be greater than 4π. This Q refers to the inductor together with the equivalent resistance due to the load.

On the other hand, if the ratio $L/r(= r_LC = r_L/4\pi^2f^2L)$ is made too large the resonant resistance of the circuit will be too high to obtain a satisfactory power output. It is therefore necessary to compromise between power output and wave form. It is in general good practice to make the ratio of the stored power to the power output about 2, i.e., to make $Q = 4\pi$. L and C are then given in terms of the power, the frequency, and the voltage (essentially the d-c plate voltage) as

$$L = \frac{V^2}{8\pi^2Pf} \tag{2}$$

$$C = \frac{2P}{V^2f} \tag{3}$$

These formulas are not meant to be critical. If good wave form is more important, use a value of P in these formulas greater than the actual power; if power output is more important use a value of P less than the actual power. This principle is frequently stated by saying that the wave form is improved by decreasing the L to C ratio of a tuned circuit. These circuit considerations apply equally well to the tuned circuit of a class C amplifier.

CONSTANT-FREQUENCY OSCILLATORS. Using the equivalent impedance discussed under Conditions for Self-oscillation, above, (*a*) and (*b*) of Fig. 1 are special cases of the equivalent circuit shown in Fig. 4. The ordinary mesh equations for this circuit are

$$I_p(z_p + z_1 + z_5) - I_1(z_1 + z_m) + I_g(z_m + \mu z_g) = 0 \tag{4a}$$

$$-I_p(z_1 + z_m) + I_1(z_1 + z_2 + z_3 + 2z_m) - I_g(z_2 + z_m) = 0 \tag{4b}$$

$$I_pz_m - I_1(z_2 + z_m) + I_g(z_g + z_2 + z_4) = 0 \tag{4c}$$

Most of these impedances are functions of the frequency. And, since the condition that any of these currents can be other than zero is that the determinant of the coefficients of the I's is zero, the frequency of oscillation is the frequency which will make that determinant zero. Thus the frequency depends not only upon the parameters of the oscillatory circuit but also on the other parameters of the circuit. In order that the frequency shall remain constant, all these parameters must in general remain constant.

To keep the inductances, capacitances, and resistances external to the tube constant is a problem in the design and temperature control of those parts. On the other hand, regardless of the design, the effective impedance of the tube itself changes with use and supply voltages. Several methods have been devised to maintain essentially constant supply voltages, and seasoned tubes tend to reduce the changes in the tubes themselves. However, by adjusting the other circuit parameters the dependence of the frequency on the tube impedances can be minimized.

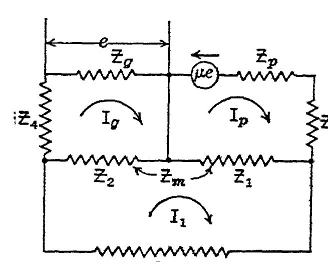

FIG. 4. The Equivalent Circuit of Most of the Circuits of Fig. 1

The most common method is simply to increase the sharpness of the oscillatory circuit, that is, decrease the decrement of the circuit. This is carried to the extreme by the use of mechanical resonators such as the quartz crystal and the magnetostriction rod.

Llewellyn has discovered that, by proper adjustment of the impedances Z_4 and Z_5, it is possible in the limiting case of no harmonic currents in the tube to eliminate the dependence of the frequency of oscillation on the tube impedances. Although this limiting case is never reached, the use of these impedances tends to stabilize the frequency. In addition it is sometimes possible to change the frequency by a simple change in the parameters of the oscillatory circuit without disrupting this independence of the frequency on the tube impedances. A circuit derived from the Colpitts circuit for this purpose is shown in Fig. 5, where $L_4 = L_3C_1/C_2$. Thus the frequency can be adjusted by changing C_1 and C_2 proportionally without changing the calculated value of L_4.

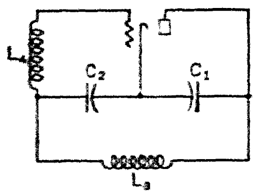

FIG. 5. A Constant Frequency Circuit Derived from a Colpitts Oscillator

THE HARMONIC CONTENT OF OSCILLATORS. From the non-linear theory of oscillators (see article 20) it is known that an oscillator is stable only if it is non-linear. Thus an oscillator always produces harmonics in its output. The percentage of the harmonics becomes small when ϵ becomes small, that is, when the feedback from the plate circuit to the grid circuit is small. A circuit applicable at low frequencies in which the feedback can be controlled is shown in Fig. 6. The variable resistance r controls the amount of feedback. This circuit not only has a controlled harmonic content, but it also is very stable with frequency. It is excellent for a laboratory oscillator where r can always be adjusted to compensate for changes in the tube characteristic.

In large oscillators and class C amplifiers a series tuned circuit is sometimes connected in series with the plate circuit to offer a high impedance to the harmonics. Such a tuned circuit, in addition to decreasing the harmonic content to a marked extent, increases the efficiency.

SEPARATELY EXCITED OSCILLATORS. Separately excited oscillators are a special group of class C amplifiers. The voltage and current relations of the true oscillator are essentially those of a properly operated class C amplifier. If, however, the frequency of the exciting voltage differs from that at which the tube would oscillate, the plate-current wave form is not symmetrical about the zero ordinate shown in Fig. 3. Increasing the dissymmetry of this wave by varying the capacitance of the oscillatory circuit increases the average or d-c current. Thus the frequency of the oscillatory circuit is adjusted in this type of class C amplifiers until the d-c current is a minimum.

Most of the theory and empirical relations given for oscillators can be applied to class C amplifiers.

SYNCHRONIZATION OF OSCILLATORS. When two oscillators oscillating at neighboring frequencies are loosely coupled together, they mutually distort the voltage drop across their oscillatory circuits. This distortion in turn distorts the current and voltage relations discussed above. This distortion causes a magnified distortion of the plate current since even a small per cent change in the oscillatory circuit voltage has a great effect on the minimum plate voltage. This change in plate current causes an additional change in the voltage by affecting the oscillatory circuit drop directly and indirectly through the change in grid excitation. Thus the voltage due to the one oscillator causes a magnified change in the other oscillator. This distortion tends to shift the phase of the plate voltage with respect to the grid voltage. When this phase shift exceeds the limit allowable for stable oscillation, the oscillator jumps into oscillation at the frequency of the other oscillator.

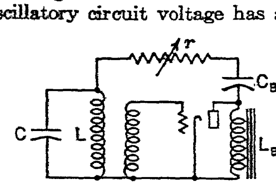

FIG. 6. An Oscillator for Low Harmonic Distortion

The vulnerability of an oscillator to synchronization increases with the L to C ratio of the oscillatory circuit. Thus, when two oscillators are to oscillate independently even though there is a coupling between them, the L to C ratio should be made as small as is consistent with stable oscillation.

In order for one oscillator to oscillate at the frequency of a master oscillator without changing the frequency of the master oscillator, it is necessary that the coupling between the oscillators be unidirectional. That is, the reaction of the secondary oscillator on the master oscillator must be negligible. Such coupling can be obtained by means of the ordinary amplifier. Using several such amplifiers, each fed by the master oscillator, the frequency of several oscillators can be controlled by the frequency of the master oscillator.

An oscillator can be synchronized at a subharmonic of an introduced voltage. The tendency to synchronize with a subharmonic of the introduced voltage is not as great as at the fundamental, and oscillations so obtained are relatively unstable.

BEAT FREQUENCY OSCILLATORS. In order to satisfy the conditions for stable oscillation many of the circuit parameters must be changed when the frequency is changed over a relatively large range. For continuously variable frequency over a wide range, especially over the audio range, it is difficult to make the necessary changes in these parameters. For the same absolute change in frequency beginning at some high frequency, only one parameter, usually the capacitance, need be changed. If the outputs of two oscillators of relatively high frequency are introduced into a square-law detector, and if all the high frequencies are filtered out, only the difference frequency is left. Then as the frequency of one of these oscillators is varied from the frequency of the other to that frequency plus 10,000 cycles, the output of the detector varies in frequency from 0 to 10,000 cycles. Such an arrangement is called a beat frequency oscillator and when properly built is an excellent laboratory instrument.

Care must be taken to insure that the intercoupling between the oscillators is so small that there is no tendency for them to synchronize, since this will introduce distortion in the output of the detector due to the distortion in the oscillators themselves. This can be prevented by mechanical or electromagnetic segregation and balanced bridge circuit feed to the detector, or by amplifiers between the oscillators and the detector.

DYNATRON OSCILLATORS. If, in a vacuum tube, the grid voltage is made more positive than the plate voltage, some of the electrons which attain a high velocity between the cathode and the grid pass through the grid openings, their velocity carrying them on to the plate. These electrons may then knock electrons from the plate. This process is called secondary emission. In some cases secondary emission may exist to such an extent that an increase in plate voltage actually causes a decrease in plate current. Thus, when a tube is operated under these conditions, the a-c plate resistance is negative. A tube operating in this way is called a dynatron.

An oscillatory circuit connected across this negative resistance (Fig. 7) will oscillate provided the absolute value of the negative resistance is less than L/rC. Owing to the small range of plate voltage over which the resistance is negative, these oscillators have not been made to give very large power.

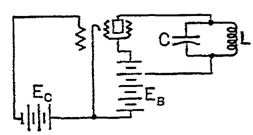

FIG. 7. The Circuit of a Dynatron Oscillator

OSCILLATORS AT HIGH FREQUENCIES. At high frequencies, of the order of 50 Mc, in the case of ordinary receiver tubes, where the time of transit of the electrons between the tube electrodes becomes an appreciable part of the period of the wave, the grid impedance can no longer be considered an open circuit or even a pure capacitor. Under these conditions, the displacement currents arising from the motion of the electrons in the space between the grid and the other electrodes causes a true dissipation of energy in the grid circuit within the tube and a direct conductive coupling to other electrodes. This causes a grid-circuit loading of the tank circuit, decreasing the oscillator efficiency. As the transit-time effect first becomes important, the resistance of the grid due to this decreases approximately as the square of the frequency. Consequently, as the frequency of oscillation is increased through this frequency range, the efficiency decreases rapidly to the point where oscillations can no longer be sustained, even though no external load is coupled to the tank circuit. Decreasing the dimensions and spacing of the electrodes increases the frequency at which transit-time effects become important but correspondingly decreases the power-dissipating capacity of the tube.

At high frequencies, another effect becomes important. The leads within the tubes and the socket are found to have an appreciable impedance. Such impedances must, of course, be considered part of the circuit when that circuit is designed. In many tube types the impedances associated with the leads are so prominent at high frequencies that the highest frequency at which these tubes will oscillate is limited by this consideration rather than by the transit-time effect discussed above.

Since the efficiency of ordinary oscillatory circuits decreases as the frequency for which these circuits are designed increases, it is common to replace coil and condenser type tank circuits by resonant concentric lines. Thus in the tuned-plate tuned-grid oscillator circuit of Fig. 1*d*, two concentric lines are used, one replacing the tuned-plate circuit and one replacing the tuned-grid circuit. The adjustment of the resonant frequency is accomplished by movable short-circuiting plugs in the lines. Various configurations of the concentric lines can be readily adapted to this circuit.

To accomplish the combination of improvements to overcome the adverse effects of transit time and lead impedance, and to adapt the tube for use with concentric line circuit elements, the so-called "lighthouse" tube was developed (see Section 4). Using such tubes, triode oscillators have been operated above 3000 Mc.

THE MULTIVIBRATOR. For large values of ϵ the non-linear theory of vacuum-tube oscillators discussed above indicates that voltages having a discontinuous wave form would be produced. At low frequencies such oscillations can be obtained from a circuit shown in Fig. 1e or f by reducing the capacitance C to zero. The only capacitance is then the distributed capacitance plus the tube capacitance. At low frequencies these have an effect small enough so that the value of ϵ is large. A similar effect can be obtained at higher frequencies by means of two resistance-capacitance coupled amplifiers connected as shown in Fig. 8, so that the output of the second is fed into the input of the first. Under these conditions the phase of the output voltage is such as to aid the grid of the input tube. The period of the oscillation is given roughly by $r_{g1}C_1 + r_{g2}C_2$. Using ordinary tubes these oscillators can be made to operate at frequencies up to 1,000,000 cycles.

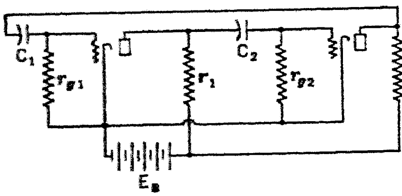

FIG. 8. The Usual Multivibrator Circuit

DISTORTIONLESS OSCILLATORS. As indicated under Non-linear Theory of Oscillators, p. 7-83, it is generally necessary for a stable oscillator to operate in such a way that an increase in grid-voltage amplitude would cause an increase in limiting-type distortion so that the voltage developed in the plate circuit produces too small a voltage in the grid circuit to maintain that voltage in the plate circuit. And similarly a decrease in grid-voltage amplitude would produce such a relatively increased voltage in the plate circuit that a larger voltage would be produced in the grid circuit, tending to return the grid-voltage amplitude to its original value. Under these conditions, the stable grid-voltage amplitude is such that the voltage developed in the plate circuit is just sufficient to maintain that stable grid voltage in the grid circuit. In other words, the voltage gain at the oscillating frequency must decrease as the amplitude increases and must increase as the amplitude decreases. The greater the magnitude of this dependence of gain upon amplitude, the greater the stability of the oscillator. In the ordinary oscillator, where this dependence of gain upon amplitude is accomplished through amplitude limiting, the greater the dependence, the greater the distortion. Consequently, it is generally true that an increase in stability of an oscillator is accompanied by an increase in distortion.

In any oscillator where the gain of the amplifier part of the circuit is controlled by the average amplitude, averaged over one or more cycles, rather than by the relatively instantaneous limiting action of the ordinary oscillator it is possible to operate the amplifier in that part of its characteristic where distortion is negligible. One such oscillator is the resistance-capacitance oscillator.

R-C OSCILLATOR. The resistance-capacitance tuned oscillator is shown in Fig. 9. The bridge circuit at the left of the circuit is a somewhat unbalanced Wien bridge at the oscillating frequency, $1/2\pi\sqrt{r_1r_2C_1C_2}$. The unbalance is such that, were r_b to be somewhat increased, the bridge would be balanced. Actually, r_a and r_b are so chosen that the unbalance voltage which is introduced in the grid circuit of the first amplifier tube is just sufficient when amplified to produce the required bridge suppy voltage between A and B to maintain that magnitude of unbalance voltage. If the gain of the amplifier were to increase from its normal value, increasing the voltage between A and B, the added heat developed in the lamp would cause r_b to increase, causing the bridge to become more nearly balanced and thus decreasing the input voltage to the amplifier to compensate for the increased gain. In the opposite fashion, a decrease in gain causes the bridge to be less nearly balanced. Thus such an oscillator is amplitude stable at the frequency which would balance the bridge. If $r_1C_1 = r_2C_2$, the maximum positive balance voltage appears at this frequency. Therefore, this oscillator operates stably at only one frequency. The gain control is averaged over several cycles owing to the thermal lag of the resistance change of the lamp. By means of ganged condensers for C_1 and C_2, the fre-

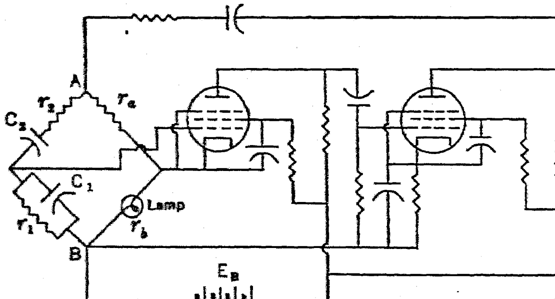

FIG. 9. Resistance-capacitance Tuned Oscillator

quency of such an oscillator can be conveniently varied. Oscillators of this type can be designed for frequencies well below the audible limit to several hundred kilocycles.

OSCILLATIONS OF GAS-FILLED TUBES. The gas-filled tube characteristic differs from the vacuum tube in one outstanding particular. The plate resistance varies from a very high value to a very low value almost discontinuously. Such a characteristic does not lend itself to the production of sinusoidal oscillations. However, it is highly advantageous for the production of almost discontinuous wave forms, the most important of which is the so-called sawtooth wave used for linear scanning in cathode-ray oscillographs.

The circuit of such an oscillator is shown in Fig. 10*a*. The condenser C is charged through the resistance r until the voltage across C is equal to the critical starting voltage of the plate circuit, the voltage at which the resistance suddenly decreases to a low value. The condenser is then discharged until the voltage across it equals the critical stopping voltage, the voltage at which the plate resistance returns to its high value again. This stopping voltage is always less than the starting voltage. The cycle then repeats itself as shown in Fig. 10*b*. These oscillators can be operated fairly satisfactorily up to 15,000 cycles, being limited by the ionization and deionization time of the gas. Above this value multivibrators must be used for linear sweep circuits.

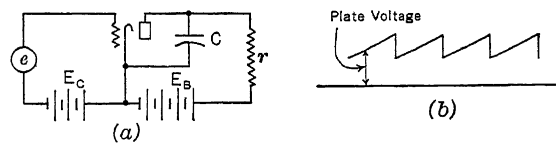

FIG 10. A Relaxation Oscillator, Using a Gaseous Tube, and Its Voltage Wave Form

These oscillators are easily synchronized with an external frequency by introducing a voltage at that frequency in the grid circuit as shown in the figure. As with vacuum-tube oscillators, these oscillators can be synchronized at a subharmonic of the synchronizing frequency.

BARKHAUSEN OSCILLATORS. In 1920 Barkhausen and Kurz discovered that, using certain tubes, oscillations a few centimeters in wavelength were produced when the grid supply voltage was highly positive and the plate was at or near the cathode potential Several theories of the operation of tubes under these conditions have been proposed but none agrees entirely with the experimental results. Practically all tubes which will oscillate under these conditions consist of cylindrical and coaxial cathodes, grids, and plates. Some investigators have succeeded in getting oscillations from other geometrical configurations, notably planes instead of cylinders.

Qualitatively, the explanation given is that electrons rapidly accelerated by means of the high grid potential pass through the grid as a result of their momentum and are turned back toward the grid, owing to its high potential, before they reach the plate. This causes each electron to set up a displacement current between the grid and the plate. A chaotic distribution of the phases of the oscillations of these electrons can be shown to be an unstable distribution. However, when these electrons oscillate in clouds the operation is stable so that the resultant current is not zero.

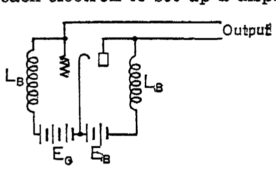

FIG. 11. The Barkhausen-Kurz Oscillator

The customary circuit for these oscillators is shown in Fig. 11. The power of the oscillations has been observed as high as 10 watts, the wavelengths go to 6 cm, and the efficiencies are from a fraction of 1 per cent to 7 per cent. The lowest efficiency and the lowest power usually occur at the shortest wavelengths.

OTHER SPECIAL OSCILLATORS. Other forms of oscillators use resonant cavities for the oscillating circuit element. These are treated in Section 4, article 8, on magnetrons, and article 22 of this section on cavity resonators.

21. ELECTROMECHANICAL OSCILLATORS

The frequency stability of mechanical vibrating systems is in general better than the frequency stability of electrical oscillatory circuits. For this reason mechanical vibrating systems are coupled to electrical circuits to give an electrical output of constant frequency.

TUNING-FORK OSCILLATORS. The circuit of a tuning-fork oscillator is shown in Fig. 12. This type of oscillator can be described as a refined buzzer. The resonant tuning fork corresponds to the oscillatory circuit, and the carbon button corresponds to the vacuum tube with the carbon as the plate circuit and the diaphragm as the grid. The feedback occurs through the transformer T. Although the electric circuit is tuned by means of the transformer inductances and the capacitance C, the harmonic content of the output is high. These oscillators are very convenient sources of audio-frequency voltage.

MAGNETOSTRICTION OSCILLATORS. When a body is placed in a magnetic field, stresses are produced within the body tending to distort it. Inversely, when a body is distorted, there is a change in the magnetic permeability. Magnetostriction is the name given to this effect. Many metals and alloys exhibit magnetostriction, but according to Ide it is most pronounced in alloys having 8–10 per cent chromium, 36–38 per cent nickel, and the remainder iron with about 1 per cent manganese to facilitate forging.

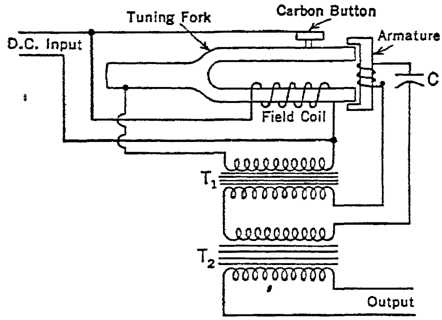

Fig. 12. The Tuning Fork Oscillator

When a rod of this material is magnetically polarized and placed in a coil carrying alternating current, it vibrates longitudinally at the frequency of the alternating current. If this frequency is the resonant frequency of the rod mechanically, the amplitude of the effect will be large even for very small currents in the coil. Thus it can be considered equivalent to a parallel tuned circuit coupled by means of the coil into the electric circuit. The resonant frequency is given by v/l, where v is the velocity of sound through the rod, about 4 km per sec, and l is the length. With the composition as above, and proper heat treatment and magnetization, the temperature coefficient is of the order of one part in a million per degree centigrade.

These devices are used as the oscillatory system of a vacuum-tube oscillator by means of a circuit such as that shown in Fig. 13. An additional coil carrying direct current may be necessary if the plate current is not sufficient to polarize the rod. Oscillations are more easily controlled when the relation between the direction of the coils is as shown, in contrast to that of the Hartley circuit (Fig. 1*a*). The positive feedback is obtained by means of the condenser C so that the electrical analogy is more nearly like the tuned-plate-tuned-grid oscillator shown in Fig. 1*d*. The rod is clamped in the middle (a node of its mechanical vibration), and the ends are free to vibrate.

The frequency stability of the magnetostriction oscillator compares favorably with that of the quartz crystal oscillators. The lower limit of frequency is determined by the practical limit of the length of the rod. The high-frequency limit is due to the magnetic skin effect of the rod. However, the harmonics of these high frequencies can be filtered out of the plate circuit so that frequencies of several million cycles can be obtained from these oscillators.

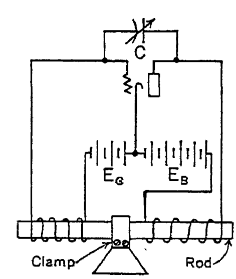

Fig. 13. The Magnetostriction Oscillator

PIEZOELECTRIC CRYSTAL OSCILLATORS. With respect to frequency, the most stable oscillators are oscillators controlled by piezoelectric crystals. Crystal oscillators are used in practically all transmitters as master oscillators. A crystal oscillator, used by the Bureau of Standards for the broadcast of standard frequency signals, gave a frequency stability of better than 1.5 parts in a million over a period of a year, and its stability was better than 2 parts in 100,000,000 over a period of several hours. By synchronizing oscillators to subharmonics of these standards, clocks can be driven which are considerably more accurate than pendulum clocks.

Crystal oscillators are applications of the piezoelectric effect, which is a means of coupling a mechanical motion to an electric circuit. When a strain is produced in a piezoelectric material, electric charges appear on its surface. Conversely, when an electric field is produced between surfaces of a piezoelectric material, a stress appears in the material. Thus if an alternating electromotive force is applied between two surfaces of the material, the material will vibrate, and if the material vibrates it will set up a displacement current between these surfaces.

This effect has been observed in many crystals, the most important of which are: quartz, tourmaline, and Rochelle salt (sodium potassium tartrate). Quartz and tourmaline have been used in oscillators, quartz crystals dominating the field. Tourmaline is more expensive than quartz but has the advantage that it can be ground to smaller sizes to produce oscillators having higher frequencies.

For use in conjunction with electric circuits, these crystals are cut in slabs, the geometry of which bears certain relations to the geometry of the crystal structure. These slabs are mounted in crystal holders, which consist essentially of two parallel conducting plates for the purpose of making an electrical connection with the surfaces of the crystal. An alternating emf set up between these plates causes a current to flow because of the piezoelectric properties of the crystal. When the frequency of this emf is equal to the mechanical resonant frequency of the crystal, the conductivity between the plates is maximum. This resonant frequency depends upon the dimensions of the slab and upon the relation between the geometry of the slab and the geometry of the crystal structure. The frequency of these resonators is therefore limited by the practical limitations of size of the slab. The frequency limits are from a few kilocycles to a few megacycles. (See Section 13, articles 32-34.)

For the analysis of electric circuits containing crystals it is convenient to replace the crystal by its equivalent electric circuit. This equivalent circuit is simply a series resonant circuit containing resistance, capacitance, and inductance paralleled by the capacitance of the holder. Because of the sharpness of tuning of this circuit, it is impossible actually to construct the electrical equivalent circuit.

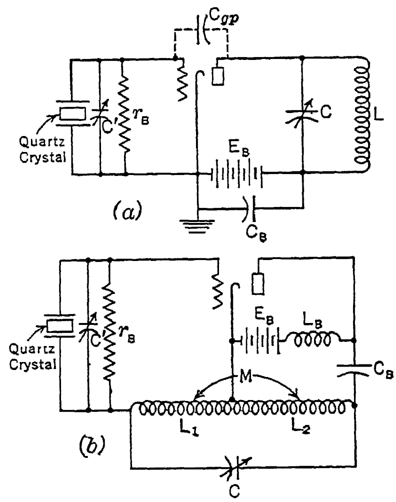

FIG. 14. Piezoelectric Crystal Oscillator Circuits

There are several oscillator circuits employing crystals, two of which are shown in Fig. 14. Circuit (*a*) makes use of the grid to plate interelectrode capacitance for feedback, as in the tuned-plate tuned-grid oscillator circuit (Fig. 1*d*); circuit (*b*) uses inductive feedback as in the Hartley oscillator (Fig. 1*a*). As in Fig. 1, the capacitances, C_B, are by-pass condensers, and the inductance, L_B, is a choke coil arranged to prevent the alternating current from passing through the d-c supply source, E_B. The tuned circuits containing L and C [in (*b*) $L = L_1 + L_2 + 2M$] are tuned to essentially the resonant frequency of the crystal.

The grid leaks r_B, as in ordinary vacuum-tube oscillators, furnish the operating bias for the tubes. The grid leak is in this case limited by an additional factor, namely, that the a-c current through the crystal, which is controlled by this resistance, must not exceed the safe operating value for the crystal. For low-frequency crystals this limit is 100 ma; for crystals in the megacycle range it reduces to 50 ma. Above this limit the crystal may vibrate violently enough to shatter itself. Since the d-c current through the grid leak is of the same order of magnitude as the a-c current through the crystal, an estimate of the value of this current can readily be obtained from the d-c grid current. In addition to this limitation the correct value for the grid leak is governed by the operating bias for the tube and varies from 10,000 ohms for high-μ tubes to 50,000 or more for low-μ tubes.

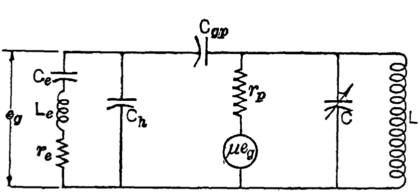

FIG. 15. The Equivalent Circuit Corresponding to Fig. 14*a*

The circuit shown in Fig. 14*a* is the most popular crystal-controlled oscillator circuit. Wheeler has analyzed the equivalent of this circuit (Fig. 15) by the method of van der Pol for the theory of non-linear oscillators. He obtained certain criteria for the frequency to be dependent primarily upon the resonant frequency of the crystal. First, the Q of the plate circuit tuning coil, i.e., the L to r ratio, should be as small as is consistent with stable oscillation. Second, the plate resistance of the tube should be as high as is consistent with stable oscillation. Third, C_h, which includes the capacitance C' and the grid to filament tube capacitance as well as the crystal holder capacitance, should approach but not exceed $\mu - 1$ times C_{gp}. Fourth, the plate tuning capacitance, C, should be adjusted to give maximum plate current.

The plate resistance can be made large by the choice of the tube and by decreasing the operating plate voltage. The capacitance C_h is usually made enough smaller than C_{gp}

$(\mu - 1)$ so that C' may be used as a fine adjustment of the frequency. The resonant frequency of the resonant circuit in the plate circuit must be above the resonant frequency of the crystal, while, if this resonant circuit has too high a frequency the plate load impedance is so low that oscillations cannot exist. As the capacitance, C, is varied from too low a value toward that value at which the resonant frequency of the plate circuit is the same as that of the crystal, the circuit at first fails to oscillate, then feeble oscillations start which increase steadily until just before the critical frequency the amplitude of oscillation rapidly drops to zero. The total variation in frequency of oscillation throughout this adjustment is 2 to 5 parts in 10,000. The optimum adjustment is for C to have a value just less than that for critical frequency.

Without some special means of temperature control, the resonant frequency of the crystal itself changes. The temperature coefficients of crystals vary, depending upon the relation between the geometry of the slab and the geometry of the crystal structure, from 1 part in 10,000 to 1 part in a million or less per degree centigrade. To minimize the variation in frequency due to the temperature, elaborate temperature-controlled ovens are used to maintain the temperature constant to better than 0.01 deg cent. For frequency control of an ordinary transmitter, ovens capable of maintaining temperatures to within 0.1 deg are sufficiently accurate.

A crystal oscillator may be designed to supply as much as 10 watts of output power at a plate efficiency of 30 to 60 per cent. The plate current and power output are limited by the current through the crystal. The usual d-c plate voltage is from 200 to 400 volts.

Because of the low power output and in order to prevent feedback into the crystal, a buffer amplifier must be used between these oscillators and the place where the power is to be applied, especially when the load is variable as in modulation.

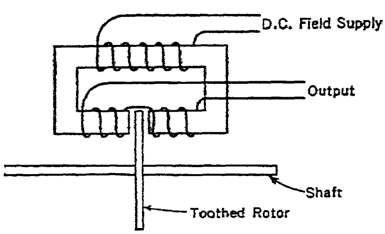

FIG. 16. Alexanderson Alternator

ALTERNATORS. Alternators are used primarily to produce a-c power at the low frequencies employed in power engineering. However, before the advent of high-power vacuum tubes, comparatively high frequencies for use in communication were obtained from specialized alternators. Two types of alternators were extensively employed for this purpose.

Alexanderson Alternators. The schematic diagram of an Alexanderson alternator is shown in Fig. 16. The toothed wheel is rotated between the poles of the magnet energized by a d-c field coil. This changes the magnetic flux density through the output coil periodically, setting up alternating currents in the load. The frequency of these alternators is limited to about 200 kc by the obvious mechanical limitations of construction and operation as well as by losses in the iron core and teeth.

Goldschmidt Alternators. The Goldschmidt alternators operated on a different principle. In a low-frequency single-phase alternator, the electromotive force developed in the armature contains not only the fundamental frequency but also the odd harmonics. Similarly, the field contains the even harmonics. Ordinarily, the reactances of the circuits are so arranged that the impedances to the fundamental and to the harmonics present are relatively high. The Goldschmidt alternators are designed so that the impedance at the frequencies of these harmonics is low. Then, by means of filters, one of the higher harmonics, usually the fourth harmonic, is selected for use. The frequency is limited here to about the same value by the same factors as in the Alexanderson alternator.

SPARK-GAP OSCILLATORS. Most of the early radio telegraph transmitters were damped-wave transmitters. These damped-wave oscillations were produced by means of spark-gap oscillators. The circuit of one of these oscillators is shown in Fig. 17. When the instantaneous voltage across the spark gap due to the audio-frequency generator exceeds the breakdown potential of the gap, a sudden rush of current shock-excites the oscillatory circuit consisting of the inductance L and the capacitance C, setting up an oscillatory current which is damped out by the resistance of the inductor, L, and by the load. The low resistance of the discharging arc is negligible until the voltage across it drops below some comparatively small value. This occurs twice during each cycle of the audio frequency. The most prominent frequency

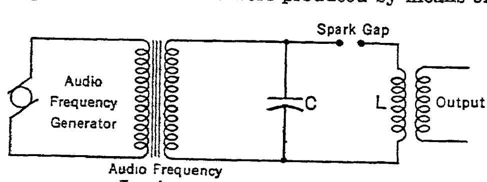

FIG. 17. Spark-gap Oscillator

in the output is the natural frequency of the resonant circuit, i.e., $\frac{1}{2\pi\sqrt{LC}}$. The output may be considered a carrier of this frequency modulated by an audio having a fundamental of twice the frequency of the generator voltage. There are so many harmonics of the audio that the bandwidth necessary for this type of transmission is very wide. For this reason, the ordinary use of spark transmitters is prohibited by law. However, many emergency stand-by transmitters on ships are of this type. The audio-frequency generator is frequently a buzzer using the transformer primary as the coil so that these transmitters may be operated by means of a battery.

Spark-gap transmitters are actively used at the present time for many industrial applications, chiefly to supply induction furnaces. The spark gaps are usually not air gaps, but a discharge in mercury vapor alone or with hydrogen. Such gaps can deliver high power at high efficiency, and they compare favorably with vacuum-tube oscillators for this purpose.

22. CAVITY RESONATORS

By I. G. Wilson and J. P. Kinzer

A cavity resonator is a section of dielectric completely surrounded by a metallic shell. In many ways, its performance is analogous to a resonant R, L, C low-frequency circuit. However L, C, and R can no longer serve as basic in the consideration of cavity resonators, because of the inability to define inductance and capacitance uniquely. (See reference 1.) In fact it is possible to find only two such quantities which describe the properties of a cavity resonator.

The first of these is the resonant frequencies (or wavelengths), defined as those values of f (or λ) which result in the boundary conditions being satisfied. With each resonance there is associated a particular standing-wave pattern of the electromagnetic fields. These have been called "eigenvalues" or "eigentones," but the term "normal modes" is now in general use.

The second is the quality factor, Q, defined by

$$Q = 2\pi \frac{\text{Energy stored}}{\text{Energy lost per cycle}} \tag{5}$$

In calculating λ, the assumption is made that the walls of the cavity have perfect conductivity. When Q is calculated, the assumption is made that λ is unchanged; that is, the fields that actually exist are those calculated on the basis of perfectly conducting walls. Since the Q's are generally high, the approximation is extremely good. (See reference 2.)

Since the energy is stored in the cavity volume, while the energy is lost in the walls, to obtain a high Q, the resonator should have a large ratio of volume to surface area. For this reason, cylinders, prisms, or spheres will in general have better Q's than cavities with re-entrant portions, or coaxial structures.

In computing the resonant frequencies and Q values of cavity resonators, solutions of the field equations involve, for the rectangular prism, circular functions; for the perfect cylinder, Bessel functions of the first kind; and, for two coaxial cylinders, Bessel functions of the first and second kinds. Only approximate solutions have been derived for cavities involving re-entrant sections.

MODES. By fundamental and general consideration, the modes in every cavity resonator, regardless of its shape, are infinite in number and more closely spaced as the frequency increases. The total number, N, of these having a resonant frequency less than f is given approximately by:

$$N = \frac{8\pi}{3c^3} Vf^3 \tag{6}$$

where V = volume of cavity in cubic meters.
c = velocity of electromagnetic waves in the dielectric in meters per second.
f = frequency in cycles per second.

PRINCIPLE OF SIMILITUDE. Another theorem generally applicable to all cavities is the principle of similitude, stated as follows (see reference 3): A reduction in all the linear dimensions of a cavity resonator by a factor $1/m$ (if accompanied by an increase in the conductivity of the walls by a factor m) will reduce the wavelengths of the modes by the factor $1/m$. For high-Q cavities, the condition given in parentheses need not be considered.

MODES IN RIGHT CYLINDERS. In right cylinders (ends perpendicular to axis) the modes fall naturally into two groups, the transverse electric (TE) and the transverse magnetic (TM). In the TE modes, the electric lines everywhere lie in planes perpendicular to the cylinder axis, and in the TM modes the magnetic lines so lie. Further identification of a specific mode is accomplished by the use of indices.

THE *MS* FACTOR. With a cylinder restricted to a loss-free dielectric and a non-magnetic surface, the value of Q (quality factor) for each mode depends on the conductivity of the metallic surface, the frequency, and the ratio of a cross-sectional dimension to the length. The quantity $Q\delta/\lambda$, however, depends only upon the mode and shape and is referred to as the mode-shape (MS) factor.

In this expression, δ refers to skin depth (see reference 4) in meters $= (1/2\pi)(\sqrt{10^7\rho/f})$, λ is wavelength in meters in the dielectric $= c/f$, and ρ the resistivity in ohm-meters. The skin depth is a factor which recognizes the dissipation of energy in the walls and ends of the cylinder. With increase of resistivity of these surfaces the currents penetrate deeper and the resulting Q is lower.

FUNDAMENTAL FORMULAS. Expressions for standing-wave patterns and $Q\delta/\lambda$ are given in Table 1, for right rectangular, circular, and full coaxial cylinders. The mode indices are l, m, n following the notation of Barrow and Mieher (reference 5). In the rectangular prism they denote the number of half-wavelengths along the coordinate axes. For the other two cylinders they have an analogous physical significance with l related to the angular coordinate, m to the radial, and n to the axial.

In an elliptical cylinder, a further index is needed to distinguish between modes which differ only in their orientation with respect to the major and minor axes; these paired modes are termed even and odd and have slightly different resonant frequencies (see reference 6). In the circular cylinder they have the same frequency, a condition which is referred to as a degeneracy (in this case, double); that is, in the circular cylinder, odd and even modes are distinguishable only by a difference in their orientation within the cylinder with reference to the origin of the angular coordinate. In Table 1, the field expressions are given for the even modes; those for the odd modes are obtained by changing $\cos l\theta$ to $\sin l\theta$ and $\sin l\theta$ to $\cos l\theta$ everywhere.

The value of N in the table for the circular cylinder is based on counting this degeneracy as a single mode; counting even and odd modes as distinct will nearly double the value of N, thus bringing it into agreement with the general eq. (6).

In Table 1, the mks system of units is implied. The notation is in general accordance with that used in prior developments of the subject. For engineering applications, it is advantageous to reduce the results to units in ordinary use and to change the notation wherever this leads to a more obvious association of ideas. For these reasons, in what follows attention is confined to the right circular cylinder, with changes in units and notation as specified later.

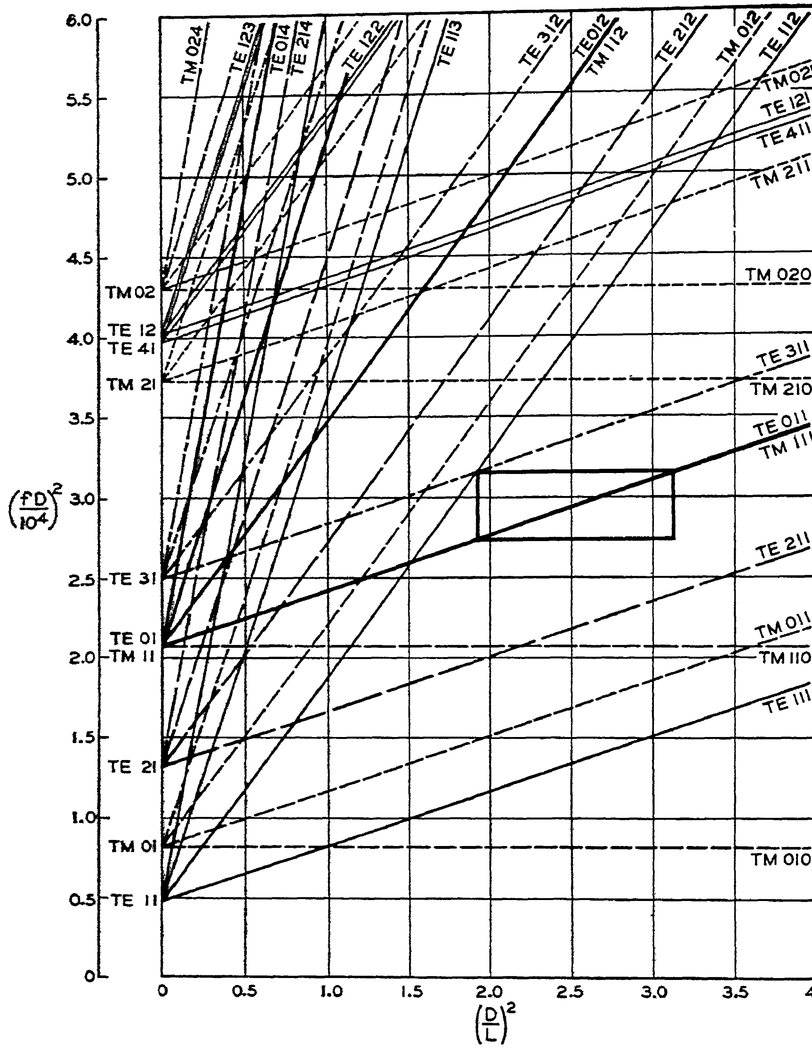

FIG. 18. Mode Chart for Circular Cylinder Cavity Resonator. D and L in inches; f in megacycles per second. The rectangle indicates the best operating region for the TE 011 mode.

THE MODE CHART. The formula relating the resonant frequency to the mode, shape, and dimensions may be written simply:

$$(fD)^2 = A + Bn^2\left(\frac{D}{L}\right)^2 \tag{7}$$

where f = frequency in megacycles per second.

D = diameter of cavity in inches.

L = length of cavity in inches.

A = a constant depending upon the mode. Values of A are given in Table 2 for the lowest 30 modes. Values of Bessel function roots are given in Table 3 for first 180 modes.

B = a constant depending upon the velocity of electromagnetic waves in the dielectric. For air at 25 deg cent and 60 per cent relative humidity, $B = 0.34799 \times 10^8$.

n = third index defining the mode, i.e., the number of half wavelengths along the cylinder axis.

Formula (7) represents a family of straight lines, when $(D/L)^2$ and $(fD)^2$ are used as coordinates, and leads directly to the easily constructed and highly useful mode chart of Fig. 18.

It will be noted from Table 2 that the *TE* 0*mn* and the *TM* 1*mn* modes have the same frequency of resonance. This is a highly important case of degeneracy. In the design of practical cavities it is necessary to take measures to eliminate this degeneracy, as the *TM* mode (usually referred to as the companion of its associated *TE* mode) introduces undesirable effects.

Table 2. Constants for Use in Computing the Resonant Frequencies of Circular Cylinders

$$(fD)^2 = \left(\frac{cr}{\pi}\right)^2 + \left(\frac{cn}{2}\right)^2 \left(\frac{D}{L}\right)^2$$

$$= A + Bn^2 \left(\frac{D}{L}\right)^2$$

$B = 0.34799 \times 10^8$

$c = 1.17981 \times 10^{10}$ in. per sec

DESIGN OF HIGH-Q CAVITY IN *TE* 01n MODE. In many applications, a resonator is used in its fundamental (gravest) mode. However, when high values of Q are desired, it may be necessary to use a high-order mode. In this case, it is desirable to keep the volume the minimum because other modes can cause undesired responses and other deleterious effects. As shown by eq. (6), the total number of resonances is a function of the volume. Analysis of the problem leads to the conclusion that operation in the *TE* 01n mode (unimportant exceptions occur for values of $Q\delta/\lambda$ less than 1.2) gives the smallest volume for an assigned Q and also leads to specific values of n and D/L which give this result. In fact, for maximum Q per volume in the *TE* 01n mode,

$$(fD)^2 \frac{D}{L} = 3.11 \times 10^8 \tag{8}$$

which permits easy plotting on a mode chart of the locus of the operating points for best Q per volume ratio.

The mode-shape (*MS*) factor for the *TE* 01n modes may be expressed as follows:

$$\frac{Q\sqrt{f}}{10^6} = 2.77 \frac{\left[1 + 0.168 \left(\frac{D}{L}\right)^2 n^2\right]^{3/2}}{1 + 0.168 \left(\frac{D}{L}\right)^3 n^2} \tag{9}$$

This has been derived from Table 1 by combining terms which are a function of frequency and by assuming the conductivity of copper ($\rho = 1.7241 \times 10^{-8}$ – the International Standard value for copper) for the cylinder walls.

The relative Q's for several metals are: silver 1.03, copper 1.00, gold 0.84, aluminum 0.78, and brass 0.48. Therefore, a brass cavity will have about one-half of the Q of a similar copper cavity. Silver-plating a copper cavity will increase Q about 3 per cent. Experience shows that only 80 to 90 per cent of the theoretical Q can be realized. This should be taken account of in the design.

With the frequency and desired Q known, the dimensions of the cavity can be determined.

CAVITY COUPLINGS. To be useful the cavity must be coupled to external circuits. The coupling to all modes can be analyzed, at least qualitatively, from the field expressions of Table 1. The problem is to get the correct coupling to the desired mode and as little coupling as possible to all others. This may be obtained either by a loop or a probe at the end of a coaxial line or by an orifice connecting the cavity with a wave guide. For optimum coupling the plane of a loop must be perpendicular to the H lines; the axis of a probe must be collinear with the E lines; and the H lines in a wave guide feeding through an orifice must be parallel to the H lines in the cavity.

Since the electric field is zero everywhere at the boundary surface of the cavity for the TE 01n mode, coupling to it must be magnetic; a probe cannot be used. The location for

* Nomenclature after Barrow and Mieher, Natural Oscillations of Electrical Cavity Resonators, *Proc. I.R.E.*, April 1940, p. 184.

M modes take zeros of $J_l(x)$; E modes take zeros of $J_l'(x)$. Number directly following E or M is l; number after hyphen is number of root.

Values less than 16.0 are abridged from six-place values and are believed to be correct; values more than 16.0 are abridged from five-place values and may be in error by one unit in fourth decimal place. Underlined $\underline{5}$ in fourth place indicates that higher value is to be used in rounding off to fewer decimals.

maximum coupling is on the side of the cavity, an odd number of quarter-guide wavelengths from the end, or on the end about halfway (48 per cent) out from the center to the edge. Correct orientation requires the axis of a loop to be parallel to the axis of the cylinder for side-wall feed and to be perpendicular to the cylinder axis for end feed. Wave-guide orientation is shown in Table 4.

The theory of coupling loops and orifices is not at present precise enough to yield more than approximate dimensions. On the basis of rather severely limiting assumptions, coupling formulas for a round hole connecting a rectangular wave guide and a TE 01n

NOTATION: λ = FREE SPACE WAVELENGTH OF CAVITY RESONANCE
λ_g = GUIDE WAVELENGTH
d = DIAMETER OF ORIFICE
$W_a = \frac{1}{Q_a}$ = CAVITY LOADING

NOTE: FOR FEED LIKE CASES 2 AND 3, BUT WITH WAVEGUIDE TERMINATED IN BOTH DIRECTIONS, DIVIDE W_a BY 2 cavity are given on Table 4. The assumptions are that the orifice is in a wall of negligible thickness, its diameter is small compared to the wavelength, it is not near any surface discontinuity, and the wave guide propagates only its principal (gravest) mode and is perfectly terminated. In some applications, the computed diameter is somewhat smaller than experiment shows to be correct.

Coupling by means of an electron beam can also be used, but, owing to transit time, a re-entrant-type cavity is usually used to keep down the distance the electrons must travel within the resonator.

POWER SUPPLY

By J. E. Young

23. RECEIVER POWER SUPPLY

The first receivers to employ vacuum tubes used batteries for filament and plate power supplies, but tubes were soon developed which had cathodes suitable for heating by alternating current. At the same time rectifier-filter combinations were developed to supply plate voltage, and it was no longer necessary to depend on batteries, where a-c power was available. During the ensuing years the size of batteries has been reduced, and their shape has been adapted to receiver applications. At the same time their life has been considerably increased. Batteries are now used extensively in receivers in areas where no power is available and for portable receivers which are often designed so that either battery or a-c power may be used. Sealed storage batteries have also been developed, and receivers using them arranged so that, if the receiver is plugged in an a-c line, the batteries are automatically recharged.

FILAMENT POWER. The filament power for a-c operated receivers is usually obtained from one or more windings of the receiver power transformer. The design of power transformers is covered on pp. 6-26 to 6-30. A common winding is customarily employed to excite all cathodes; however, it sometimes happens that both filamentary and indirectly heated cathode tubes are used in a receiver, and bias is applied to the filamentary tubes in such a way that the filament winding of the transformer is maintained at a potential considerably above ground. It is possible, in this case, that the difference in potential between the cathode and heater of the indirectly heated tubes will exceed the value specified by the tube designer. Where this condition exists, or where, because of the circuits in which the cathodes of the tubes are connected, it may likewise be possible to exceed the rated potential difference between the cathode and the heater for which the tube was designed, it is necessary to provide separate filament windings, grouping the tubes on these windings in such a manner that excessive voltage strain will not exist between cathode and heater of any tube.

PLATE POWER. The voltage supply for the plate circuits of the receiving tubes in a modern receiver is usually obtained from a vacuum-tube rectifier. A high a-c voltage is applied to the tube, and the rectified output is passed through a low-pass filter to attenuate the a-c components. In Fig. 1 a typical B supply circuit is shown. With a condenser

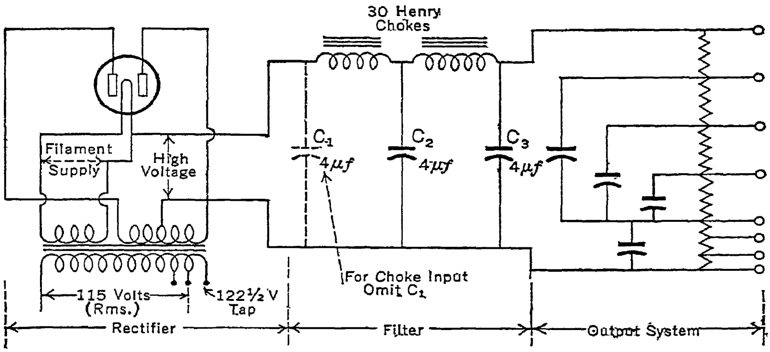

FIG. 1. Typical Receiver Power Supply

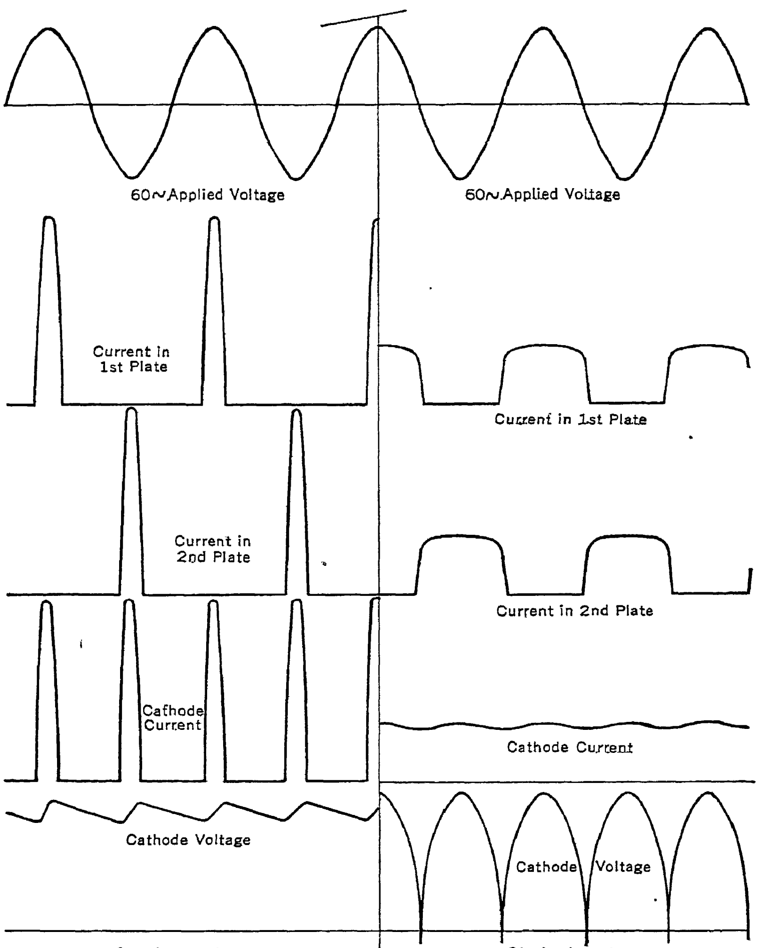

FIG. 2. Wave Form in Rectifier Circuits

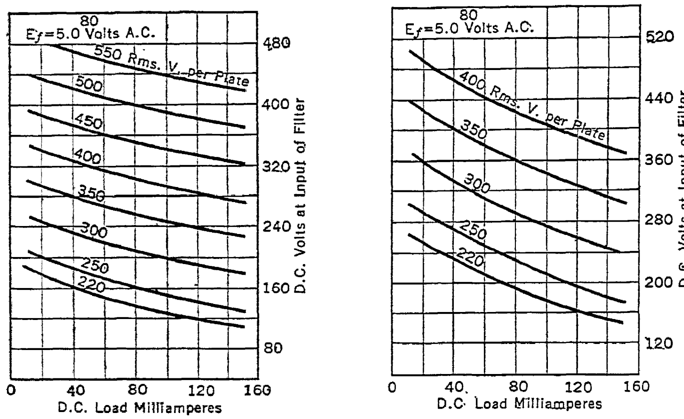
input to the B filter (C_1 connected) the ratio of d-c output voltage to a-c input voltage is higher than with a choke input (C_1 disconnected). The choke input has the advantage of lower peak currents with less danger of damage to the tube under overload conditions. The voltage regulation with variable load is also better with choke input.

In Fig. 2 the form of the currents and voltages is given for various portions of these two circuits.

Figures 3*A* and 3*B* illustrate the relations between output voltage and load current for a typical full-wave rectifier for a choke input filter circuit and for a condenser input filter circuit.



A. Choke Input to Filter. *B*. Condenser Input to Filter.

FIG. 3. Output Characteristics of Rectifier Tubes

MERCURY-VAPOR RECTIFIERS. The efficiency of rectification is improved by the presence of mercury vapor in the tube. The mercury vapor reduces the voltage drop in the tube and improves the voltage regulation. This type of tube may produce r-f interference unless special precautions are taken, such as shielding of the rectifier tube and the use of r-f chokes or resistors in the rectifier plate leads.

B SUPPLY FILTER. The capacitor input filter is the most economical type if the transformer impedance and rectifier tube type are such that excessive charging current will not be experienced. In general, electrolytic capacitors are compact and inexpensive enough so that filters are usually designed with a rather large ratio of capacitance to inductance. It frequently happens that tubes, or the elements of tubes used for different purposes in the receiver, require different voltages. In this event it is economical to obtain additional filtering by using the voltage drop resistors and shunt capacitors as a resistance-capacitor filter. Since the capacitive reactance will generally be small compared to the resistance, the attenuation of this type of filter is inversely proportional to the product of the resistance and capacitance. If this is so, sufficient filtering is provided in the main filter to produce the required ripple attenuation for the tubes which are supplied directly from this filter.

It is possible to obtain increased attenuation by substituting a shunt resonant circuit for the inductive element of the filter; however, this practice is rarely followed, since the attenuation of ripple frequencies higher than the resonant frequency of the circuit is reduced and it is costly, in production, to maintain the values of inductance and capacitance closely enough to insure resonance at the correct frequency. The speaker field is frequently used as one of the chokes of the filter, and occasionally a hum-bucking coil is provided on the voice coil of the loudspeaker.

24. TRANSMITTER POWER SUPPLY

A-C POWER. A-c power is used for filament and plate supplies for transmitters almost universally. Filaments are usually heated by alternating current directly; rectifier-filter systems are provided for plate and bias supplies. Where alternating current is not available, motor generators or, for very low power transmitters, batteries are used.

FILAMENT POWER. Small transmitting tubes, unless used in service requiring quick-heating types, usually have indirectly heated cathodes. Unipotential cathodes are also required to permit operation at very high radio frequencies. Considerations affecting the design of filament power supplies for such tubes are covered in Section 6, article 14. Large tubes are usually directly heated and have either a tungsten filament or, where practicable, a thoria-coated tungsten filament. The emission efficiency of the latter is higher and less filament power is, therefore, required to achieve a given space current.

Filament power is usually derived from a 115- or 230-volt bus connected to the transmitter supply through a regulator, rheostat, or other means of holding the filament voltage within required limits (generally ± 5 per cent), and necessary control switches and protective devices. Step-down transformers convert the bus voltage to a value suitable for application to the filaments of the tubes. It should be noted that the life of tungsten-filament tubes is greatly affected by small changes in voltage. It is advisable, therefore, to provide means of adjusting the filament voltage of each such tube independently. The filament voltage should be no higher than is required to provide the necessary emission current.

FILAMENT STARTING. The cold resistance of transmitting-tube filaments is generally less than a tenth of the hot resistance. Filament-heating currents are usually large enough to cause severe mechanical stresses in the filaments and their supports. It is necessary, therefore, to limit the filament starting current to a safe value. This is determined by the designer of the tube and is frequently specified as one and one-half times the normal running current. Starting-current limitation is secured either by applying the filament voltages in steps, controlled so that the current reaches a steady value before the next voltage increment is applied, or by using a current-limiting reactor in the filament transformer primary circuit. The necessary reactance may be designed into the filament transformer itself, or a separate reactor may be used. This method of limiting filament current is preferable since the voltage increase across the filament terminals is smooth and is directly controlled by the filament resistance.

HUM DUE TO FILAMENT CURRENT. The electron stream emitted by the filament is affected by the magnetic field set up around the filament by the heating current. This effect is a periodic change in the space impedance between the filament and each of the other elements of the tube, at twice the frequency of the filament exciting current. The magnitude of this effect is a function of the design of the tube. The transmitter designer may minimize it either by the use of a tube having a multistrand filament connected to a two- or three-phase heating source, or by heating the filaments of tubes connected in pushpull or parallel from different phases of a two- or three-phase power supply. Tubes connected in pushpull and delivering power to the load at different parts of the audio-frequency cycle should have their filaments heated by currents which are in phase. The reduction of ripple obtained by multiphase filament connection will generally be of the order of 10 db for a two-phase filament connection and 14 db to 18 db for three-phase. The improvement obtained by the use of more than three phases is small, and the increased sensitivity of the ear to the higher resulting ripple frequency may make the hum more objectionable.

PLATE POWER. Except for emergency or mobile equipment, a-c power supplies are generally used. The a-c potential is rectified and filtered to obtain direct current having the requisite freedom from ripple.

TYPES OF RECTIFIERS. Selenium or copper oxide rectifiers are frequently used to obtain the relatively low voltages required for bias or for the plate circuits of low power tubes. For high-voltage plate supplies, rectifier tubes are employed. These may be of several types. The most common are vacuum tubes having a hot cathode emitter and a cold plate. To neutralize the space-charge drop, a small quantity of mercury or one of the inert gases is introduced into the tube. Other types of rectifier tubes use a pool of mercury as the cathode. Electron emission is obtained, either by maintaining an electron discharge from a hot spot on the surface of the pool by means of an auxiliary electrode excited by a separate power source or by discharging a heavy current through a concentrated point on the surface of the mercury by means of an electrode which just touches the surface of the mercury. The first of these two types of tubes has been called the pool-type, mercury-arc rectifier; the second is known as the Ignitron. The pool-type tube is available for single- or multiphase operation, whereas the Ignitron is commonly a single rectifier unit and a number are connected in groups for multiphase operation. The steel-tank mercury-arc rectifier has been frequently used for high-power applications such as railway power supplies. It has also been used to a considerable extent in Europe as a source of high voltage for radio transmitters. Because of its relatively high cost and the necessity for the provision of considerable auxiliary equipment, it has not been widely used in radio transmitters in the United States.

25. RECTIFIER CIRCUITS

Figure 4 shows the common rectifier circuits for Kenotron and mercury-vapor tube type rectifiers with their voltage and current conditions. In calculating the d-c output voltage, from the "E average" given for the circuits shown, the voltage drop across the filter choke and the tube drop should be subtracted from E average to arrive at the d-c output voltage. The relations hold if a filter choke large enough to insure a constant load current is assumed. In practice, such a choke is usually required to obtain adequate ripple attenuation. Rectifier tubes and steel-tank rectifiers are rated on the basis of the maximum average plate current they can carry, the duration of the cycle over which the plate current flows, and the total voltage to which the tube is subjected during the period when it is not passing current. This voltage is known as the *peak inverse voltage*. In the hot-cathode, mercury-vapor tube, the safe peak plate current is also given, since, owing to the low internal tube drop, dangerously high currents may be passed through the tube, resulting in rapid deterioration of the filaments.

DOUBLE OUTPUT RECTIFIERS. In many transmitter applications it is desirable to provide two plate voltages, one for the low power stages and the other for the output amplifiers. If a single rectifier is to be used, the low voltages may be obtained by means of dropping resistors. However, if they are equal to or less than one-half the rectifier output voltage, one of the rectifier circuits which permits obtaining half-voltage is more economical. The single-phase bridge circuit or the three-phase full-wave circuit shown in Fig. 4, columns 2 and 5 respectively, may be so used. Half-voltage is obtained from a center tap on the secondary of the plate transformer in the single-phase full-wave circuit, or from the center of the wye-connected secondaries in the three-phase full-wave circuit. The additional transformer kilovolt-amperes required for the half-voltage loads can be computed by considering the equivalent rectifier circuits, which are the center-tapped circuit shown in column 1 for the single-phase rectifier or the three-phase half-wave circuit shown in column 3 for the three-phase rectifier. If the amplitude of the current to be supplied at half-voltage is an appreciable part of the total, a d-c component of current is produced in the secondaries of the high-voltage transformers, in the three-phase rectifier, which may seriously affect their operation. The effect of the d-c component may be eliminated by using a two-winding secondary for each phase of the wye, connected in broken star. It is generally desirable to use separate filters for the two voltage outputs in this type of rectifier; otherwise objectionable interaction may result, causing higher ripple voltage output than anticipated, or low-frequency feedback oscillation.

HIGH-VOLTAGE TRANSFORMERS. Transformers used in rectifier service are specially designed (see Section 6, article 14), since the insulation requirements and heating effects are quite different from those experienced in a-c circuit practice. Secondary winding insulation will depend on the type of rectifier circuit used. In the single-phase center-tapped secondary circuit shown in column 1, for instance, the center tap of the secondary winding is usually at substantially ground potential, whereas in the single-phase full-wave circuit shown in column 2 the midpoint of the secondary winding is at a potential equal to half the d-c voltage developed by the rectifier. Fault conditions will also seriously affect the insulation requirement of the transformer. In any of the circuits in which the center tap or midpoint of the wye of the transformer secondaries is connected to ground through the filter choke, a short-circuit fault will momentarily cause the full d-c voltage to be developed across the filter choke, raising the potential of the center point of the transformer secondaries to the full d-c voltage above ground.

Transformers for three-phase rectifier circuits may be constructed as a single three-phase unit, or three separate single-phase transformers may be used. The first cost of the unit transformer will generally be lower, but having three single-phase transformers permits temporary operation in an open delta circuit if one transformer fails. Transformers may be obtained for rectifiers rated up to several hundred kilowatts and up to 10,000 to 15,000 volts d-c output, in either the dry or oil-filled types. Oil-filled transformers for any power are available, filled with Transil oil or one of the non-inflammable oils sold under various trade names, such as Pyranol or Dykanol. The non-inflammable oils require special transformer designs, since they will attack some of the insulation materials ordinarily used. In installations subject to the rules of the insurance underwriters, it is usually necessary that transformers filled with inflammable insulating oil be mounted in separate fireproof vaults provided with oil sumps and drains. The size of the transformer for which such protection must be provided is determined by its oil content and varies in the different states. Local codes should be checked.

FILTER DESIGN. The design of the filter depends largely on the service for which the transmitter is to be used. Telegraph-transmitter filters are designed to the require-

FIG. 4. Rectifier Circuits

ment that the load current may vary at a rate corresponding to the telegraph characters, while the filters for telephone transmitters must, usually, be capable of supplying power at a very low audio frequency. It is usually necessary first to design the filter to secure the desired ratio between the load voltage and ripple voltage and then determine whether it fulfils other requirements.

Let F be the principal ripple frequency. Then F = supply frequency times number of rectifier phases. Let x_C = filter capacitive reactance; x_L = filter inductive reactance; C = filter capacitance in microfarads, and L = filter inductance in henrys.

Single stage:

$$\text{Per cent ripple} = \frac{mx_C}{x_L - x_C} \tag{1}$$

Double stage:

$$\text{Per cent ripple} = \frac{mx_C^2}{(x_L - x_C)^2} \tag{2}$$

where x_C and x_L are the capacitive and inductive reactances, respectively, of each of two similar stages; m = 70 for single-phase full-wave rectifier, 24 for a three-phase half-wave rectifier, and 5 for a three-phase full-wave rectifier.

Most Economical Filter Design. A single-stage filter is more economical than the double-stage type unless an unusually large reduction in ripple is desired, or the frequency is low, or low filter choke reactance is necessary, as for a telegraph transmitter.

Inductance-capacitance Ratio. The ratio between filter inductance and capacitance depends on a number of factors. If no other requirements are imposed on the filter than ripple reduction, the most economical ratio of L to C may readily be calculated. Ordinarily, however, the LC ratio is fixed by other considerations. If the rectifier tubes are worked near their current rating, the extra current flowing through the tube due to the impedance of the filter should be checked to determine whether the total tube current is excessive. This component of tube current may be calculated as follows:

$$I_p = \frac{\text{rms ripple voltage}}{x_L - x_C} \tag{3}$$

Filter for Telephone Transmitter. In most telephone transmitters the filter must supply an audio component of power, since the time lag through the filter and transformer reactances is too great to permit the audio component to be drawn directly from the transformer. The frequency and amplitude of the audio component depend on the type of modulation. The relations for the various systems are given below:

1. Class B Audio: Rectifier is required to supply an audio component having a peak value equal to the difference between the no-signal and maximum instantaneous signal plate currents of the class B stage at a rate corresponding to twice the lowest transmitted audio frequency.
2. Linear Amplifier and Grid-bias-modulated Amplifier: Rectifier is required to supply an audio component having a peak value equal to the unmodulated plate current multiplied by the modulation factor.
3. Constant-current: No audio component exists in the d-c power source.

It will be seen from the above considerations that the linear amplifier and the grid-bias-modulated amplifier impose the severest restrictions on filter design, while the constant-current system requires the filter to supply no audio-frequency power. The class B modulator requires some audio power, but the facts that the lowest audio frequency existing in the filter is twice the lowest modulating frequency and, further, that the class C modulated amplifier is usually supplied from the same source, drawing a steady current independent of the modulation frequency, make the filter design somewhat easier in this case.

Linear Amplifier. If we assume a linear amplifier, completely modulated, and it is desired to find a suitable filter combination, the following method may be used (if $r^2 > L/C$): Let F_0 = resonant frequency of L and C; F_d = frequency at which distortion begins; F = any audio frequency, to be investigated; K = ratio of load voltage at peak of audio cycle to unmodulated load voltage; K_d = above ratio at frequency F_d; r = load resistance; L = filter inductance; and C = filter capacitance. Then

$$K = \frac{a}{\sqrt{a^2 + b}} \tag{4}$$

where $a = F_0^2 - F^2$ and $b = \dfrac{4\pi^2 F^2 F_0^4 L^2}{r_2}$.

$$\frac{L}{r} = \frac{(F_0^2 - F^2)}{2\pi F F_0^2 K}\sqrt{1 - K^2} \tag{5}$$

$$F_d = F_0\sqrt{K_d + 1} \tag{6}$$

$$K_d = 1 - \frac{L}{r^2 C} \tag{7}$$

Sample Calculation. Assume that a linear amplifier requires an output of 10 kw at 15,000 volts. A filter consisting of a 15-henry inductance and 7.5-μf capacitor is provided. Determine the resonant frequency of the filter, the value of K at 30 cycles, the frequency at which distortion begins, and K at that frequency.

$$r = \frac{E^2}{W}\frac{225 \times 10^6}{10{,}000} = 22{,}500 \text{ ohms}$$

$$L = 15 \text{ henrys}$$

$$C = 7.5\ \mu\text{f} = 7.5 \times 10^{-6} \text{ farad}$$

$$F_0 = \frac{1}{2\pi\sqrt{LC}} = \frac{1}{6.28\sqrt{15 \times 7.5 \times 10^{-6}}} = 15 \text{ cycles per second}$$

$$F = 30 \text{ cycles per second}$$

$$a = F_0^2 - F^2 = 225 - 900 = -675$$

$$b = \frac{4\pi^2 F^2 F_0^4 L^2}{r^2} = \frac{4 \times 9.85 \times 900 \times 50{,}600 \times 225}{506{,}000{,}000} = 797$$

$$K = \frac{-675}{\sqrt{465{,}000 + 797}} = -0.999$$

$$K_d = 1 - \frac{L}{r^2 C} = 1 - \frac{15}{506{,}000{,}000 \times 7.5 \times 10^{-6}} = 0.99605$$

$$F_d = 15\sqrt{0.99605 + 1} = 21.2 \text{ cycles per second}$$

Thus, it will be seen that, at 30 cycles, the reduction in rectifier voltage at the peak of the audio cycle is only 0.1 per cent, and distortion due to the filter circuit will not be encountered at any frequency above 21.2 cycles. At this frequency the reduction in voltage is 0.395 per cent.

Class B Modulator. The same method of calculation may be followed for a class B modulator, except that some allowance should be made for the steady d-c component of plate current supplying the no-signal plate current for the modulator and the modulated r-f amplifier. An approximate method is to find K as above and then to find the actual ratio, use the equation $K' = 2 - f(1 - K) - K$, where K' is the ratio of load voltage at the crest of an audio cycle to the unmodulated load voltage, corrected for the unmodulated component of plate current representing the sum of the class C amplifier plate current and the no-signal plate current of the modulator; f is the ratio of peak load current to load current without modulation; and K is calculated in the same manner as for a linear amplifier. It must also be remembered that only the double frequency component of the modulating frequency appears in the rectifier circuit, and so the modulating frequency should be doubled when it is used to evaluate F_0, F_d, and F.

Filter Chokes. Methods of calculation of the inductance required for the filter choke are covered in the section on filters. In addition to inductance, it is necessary to specify the voltage insulation or type of construction, the d-c current, and the a-c voltage. In normal operation the full ripple voltage of the rectifier will appear across the terminals of the choke. Its winding insulation must, therefore, be sufficient to withstand this voltage. In addition, a short circuit in the load will subject the choke to the full d-c rectifier output voltage, so that it must be designed to withstand this strain. The voltage insulation required between winding and core for normal operation will be lowest if the choke is connected between the rectifier and ground. This does not, of course, eliminate the necessity for the provision of adequate insulation to take care of load short-circuit.

Rectifier-tube Operation. The hot-cathode mercury-vapor tube is used in the majority of high-voltage rectifiers for radio transmitters. In addition to the limits of peak inverse voltage, and peak and average current set up in the rating of each of these types of tubes, it is also necessary that the condensed mercury temperature be maintained within specified limits. For operation of the tubes at their maximum rated peak inverse voltage, it is usually necessary to keep the condensed mercury temperature between the limits of 20 and 60 deg cent. For temperature ranges extending from 10 to 70 deg cent, the maximum peak inverse voltage is frequently halved. To control the condensed mercury temperature a jet of air is directed against a spot on the lower edge of the glass bulb, and the temperature of this air stream is occasionally controlled by means of auxiliary heaters. It is sometimes desirable to secure additional current capacity by connecting rectifier tubes in parallel. Because of the peculiar conduction characteristics of gases, unless such tubes are identical the one in which the gas is ionized first will conduct all the current and the other will not break down. This condition may be corrected by connecting a small center-tapped choke between the two tubes or by connecting a resistance in series with each tube so that sufficient potential is available to break down the second tube after the first one has started conducting.

TUBE HEATER DELAY. Most of the hot-cathode mercury-vapor tubes use highly efficient shielded cathods or filaments in order to reduce the filament power to a minimum. Such cathodes require some time to come up to their operating temperature, and it is usually advisable to provide a time-delay relay to prevent the accidental application of plate voltage before the cathode has reached its operating temperature. For the same reason, and to prevent the adherence of any particles of mercury to the anode or cathode, each new tube should be baked out thoroughly before plate potential is applied, and then reduced plate voltage should be applied, slowly working up to the normal operating plate voltage. Unless these precautions are followed, severe arc-backs may result and the tube will be permanently damaged.

TUBE-FAILURE PREDICTION. Mercury-vapor rectifier tubes almost always fail by arcing back, that is, becoming conductive to a voltage of either sign. This condition will occur, momentarily, and then clear itself; however, as the tube ages, it happens with increasing frequency, until it cannot be tolerated, and the tube must be replaced. Each arc-back short-circuits the plate transformer and usually trips the a-c overcurrent relays. If a bank of tubes is used in a multiphase rectifier it is difficult to determine by visual observation which tube has arced back. Devices which will register the flow of reverse current, such as polarized magnetic drops, are sometimes used as indicators. However, the short-circuit current is often so great that it will cause the indicators to drop on other tubes as well as on the defective one. It is possible to predict with fair accuracy the time when a tube may be expected to fail by making a routine check of the arc-drop voltage when the tube is carrying rated current. When, on successive readings, separated by perhaps 100 hours of normal operation, the arc drop is found to be rising rapidly, the tube will probably soon fail and should be removed from service. *These tests must, of course, be made by removing the tube from its operating position, and applying the necessary test voltage, which need not be greater than 100 volts.*

RECTIFIER CONTROL SYSTEMS. Since high-power rectifiers must usually be designed to have low regulation, a fault, in the form of either a short circuit in the load or an arc-back in a rectifier tube or tank, may result in dangerously high currents in the system. To minimize any trouble resulting from this source, a high-speed breaker should be provided in the power transformer primary. The breaker should be controlled by a-c overload relays in each phase of the primary and by a d-c overload relay in the output circuit. If a short circuit should occur in the transmitter, the energy stored in the filter will be dissipated in the fault even though the primary circuit is cleared instantly. For this reason it is advisable to incorporate some series resistance in the load circuit to aid in dissipating the filter energy. A resistor of 1 to 5 per cent of the load resistance can usually be added with no bad effects. It should be remembered, in designing such a resistor, that for a gassy tube or similar fault the load resistance is virtually zero, and all the rectifier voltage will, for an instant at least, appear across the protective resistor. This should have sufficient thermal capacity to dissipate several times the energy stored in the filter and should be insulated to carry the full rectifier voltage across its terminals. As a further protection against high voltages across the power transformer secondary in the event of an arc-back, it is advisable to connect a spark gap in series with a current-limiting resistor between each high-potential secondary terminal and ground. The gap may take the form of either a horn or sphere gap and should be set to break down at about 1.5 times the normal voltage.

RADIO RECEIVERS

By Vernon D. Landon

The functions of a radio receiver are to:

First: Select a desired signal from the heterogeneous signals picked up by the antenna.

Second: Amplify the radio-frequency signal selected.

Third: Detect the signal, thereby producing audio-frequency currents. (In the case of continuous wave code signals, it is necessary to heterodyne the signal with a local oscillator before detecting.)

Fourth: Amplify the audio-frequency signal.
