Fifth: Reproduce the signal audibly by means of a loud speaker or headphones.

The parts of a receiver performing the above functions sometimes have overlapping duties. For example, the antenna circuit gives some amplification due to resonance and has some selectivity.

The simplest antenna coupling circuit is shown in Fig. 1*A*, with its equivalent. r_a and C_a are the effective resistance and capacitance of the antenna, and L_s and r_s are the inductance and resistance, of a variable inductor, in the receiver. E_a is the voltage induced in the antenna by the incoming signal. The step-up ratio of the circuit is defined as the ratio of E_s to E_a. At resonance (neglecting that component of E_s due to r_s, $E_s/E_a = j\omega L_s/r$, where $r = r_a + r_s$. The step-up at a frequency other than resonance is $E'_s/E'_a = j\omega L_s/z$, where $z = r_a + r_s + j(\omega L_s - 1/\omega C)$.

The ratio of the step-up at resonance to that at a frequency differing from resonance by a given amount is known as the selectance, or the discrimination ratio, for the given frequency difference. A curve of selectance vs. frequency difference is a selectivity curve.

To a rather close approximation the selectance is equal to $S = 1 + j4\pi f_d L/r$, where f_d measures the frequency difference from resonance. Since the only circuit constants in this expression are L and r, the figure L/r is said to determine the selectivity of the circuit. The selectivity is not changed by a change of carrier frequency if L/r is kept constant.

The circuit of Fig. 1*A* has several disadvantages. The step-up is high and reasonably constant over the tuning range, but the selectivity is poor, owing to the large antenna resistance in series with the tuned circuit. Also it is very difficult to incorporate in a unicontrol tuning system. The circuits of Figs. 1*B*, 1*C*, and 1*D* are more commonly used.

In 1*B* a tunable circuit is connected to the antenna through a small coupling condenser C_c. If C_c is quite small (as it is in practice) then the antenna resistance and capacitance may be neglected with only a slight error. By the use of Thévenin's theorem the circuit then reduces to that on the right of Fig. 1*B*. This is a simple series circuit. The step-up of such a series circuit, considered by itself, is nearly a constant over the tuning range. It is exactly constant if r_s is exactly proportional to the frequency. In practice r_s usually varies slightly more rapidly than the frequency. However, in this case the input voltage varies with frequency. As indicated in the diagram the effective driving voltage $E'_a = E_aC_c/(C_s + C_c)$. Since $C_s + C_c$ is the capacitance which produces resonance, then $C_s + C_c$ is inversely proportional to the square of the frequency. Hence E'_a is directly proportional (and the output voltage E_s is also roughly proportional) to the square of the frequency. This is the chief disadvantage of this circuit. Its advantages are its good selectivity and the ease with which it may be incorporated in a unicontrol tuning system.

In Fig. 1*C* the tunable circuit is connected to the antenna through a large inductance. If this coupling inductance were quite large the capacitance and resistance of the antenna could again be neglected. If the power factors of L_c and L_s are assumed to be equal a transformation involving Thévenin's theorem gives the equivalent circuit shown. Here, since L_s and L_c are constant, the input voltage E_a is constant. If all these assumptions are correct and r_s is proportional to the frequency, the output voltage E_s is also constant. In practice there are three effects combining to produce a marked drooping of the step-up at the high-frequency end of the tuning range. First, the inductance of L_c is usually not large enough to make the antenna capacitance negligible. Hence, the effective inductance of L_c and the antenna in series is less at low frequencies. This increases the low-frequency step-up. Second, the distributed capacitance of L_c increases its effective inductance most at high frequencies and lowers the high-frequency step-up. Third, the resistance of r_s usually varies faster than the first power of the frequency, lowering the high-frequency step-up.

An antenna circuit which is often used involves a combination of capacitative and inductive coupling in order to obtain a flat step-up characteristic. This circuit is shown in Fig. 1*D*, with its equivalent. It may consist of a tuned secondary, of the usual type, coupled to a primary of about eight times the secondary inductance. Loose inductive

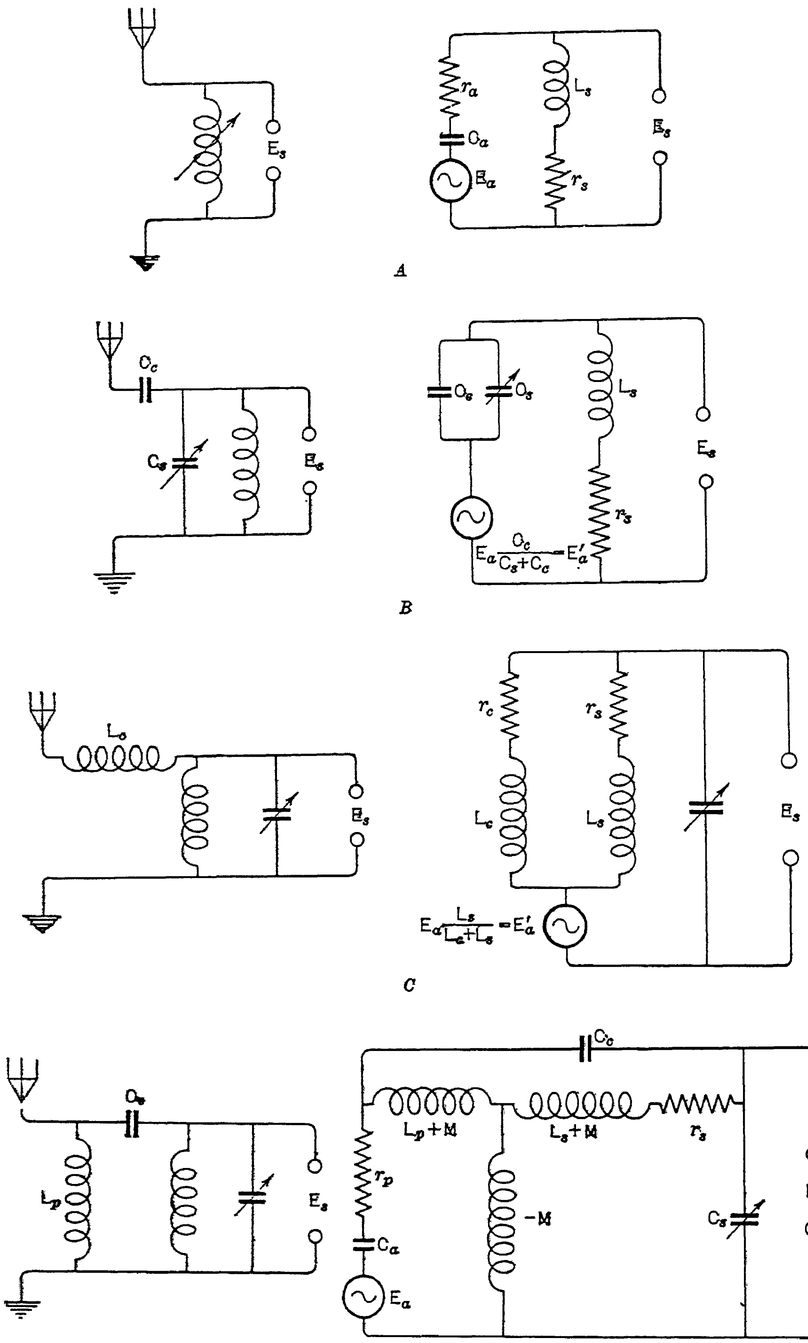

Fig. 1. Antenna Coupling Circuits

coupling is used. The capacitative coupling is adjusted to the value required to give the desired step-up at the high-frequency end of the tuning range. For uniform and maximum step-up it is essential that the inductive coupling have the proper phase, so that the capacitative coupling adds rather than subtracts. To obtain this condition the grid and antenna leads must emerge from the transformer with opposite directions of rotation. The step-up of such a transformer is practically constant over its tuning range. In a transformer for the broadcast band the value of the step-up usually lies between the limits of 3 and 10, depending on design constants. If tight coupling is used giving high step-up, the penalty is more detuning with changes in antenna constants. This results in poor tracking, with the other tuned circuits of the receiver, unless an antenna is used of the size for which the circuit was designed.

26. TYPES OF RECEIVERS

CRYSTAL DETECTOR RECEIVER. The simplest type of complete receiver is a crystal detector circuit such as shown in Fig. 2. The selectivity of this receiver is very slight, and amplification is lacking except for that due to resonance. Nevertheless local stations can be received.

For low-impedance crystals, the selectivity of the receiver can be improved by connecting the input to the crystal across a portion of the coil.

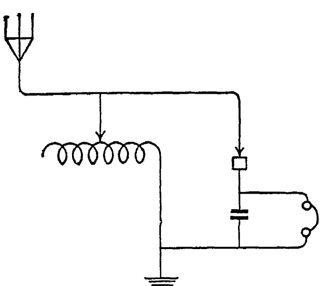

FIG. 2. Crystal Detector Receiver

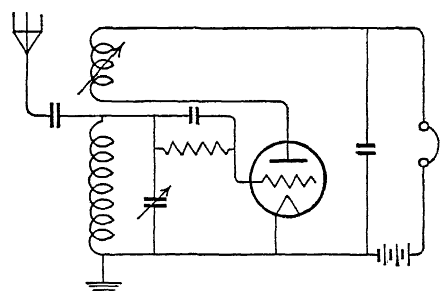

FIG. 3. Regenerative Receiver

REGENERATIVE RECEIVER. Figure 3 shows the circuit of a regenerative detector. The inductive coupling of the small coil in the plate circuit to the tuning inductance is adjustable. When the regenerative feedback is adjusted to a critical value, just less than that required to produce self-oscillation, a great amplification of signals results. The selectivity curve is much too sharp, resulting in a loss of sidebands, thus unduly impairing the fidelity of reproduction. The greatest objection to regenerative receivers is due to their ability to oscillate when the feedback is too great. This results in a radiated signal which produces very objectionable squeals, or beat notes, in near-by receivers. This type of receiver is now illegal. It can be made legal by placing a neutralized stage of r-f amplification ahead, so that it will not radiate when properly shielded.

Superregeneration of the Blocking Type. If the feedback in Fig. 3 is advanced well beyond the point of oscillation, the oscillations become self-modulated. This is due to a periodic blocking of the tube. The r-f voltage, rectified by the grid, produces a bias voltage across the grid leak sufficient to produce plate current cutoff, and oscillations die out. The charge on the grid condenser leaks off, the tube again starts to oscillate, and the blocking cycle repeats itself. The frequency of blocking depends partly on the tube but chiefly on the time constant of the grid leak and condenser. The higher the frequency of blocking, the greater the feedback required to produce the effect.

When the frequency of blocking is increased to about the limit of audibility, by decreasing the values of the grid leak and condenser, the circuit becomes an extremely sensitive receiver. It is even more sensitive than the regenerative receiver, and much less critical to adjust. The disadvantage is extremely broad tuning.

The sensitivity to weak signals is due to the fact that an oscillator cannot start oscillating in the absence of an impulse to start it. Weak impulses in the form of noise are always present. It is only necessary for the signal to exceed the random noise in order to control the oscillation. Since the peak amplitude of each block of oscillation is very closely the same regardless of signal amplitude, it is difficult to see how audio-frequency signals are produced. Probably the effect of the signal is to increase the frequency of blocking by causing oscillation to start sooner each blocking cycle. This decreases the plate current, since the tube is cut off a greater percentage of the time. Thus an amplitude-modulated signal produces audio-frequency currents, of the modulation frequency.

Superregeneration Employing One Tube Oscillating at Two Frequencies. Improved results over the above can be obtained with the circuit of Fig. 4. The tube of this circuit oscillates continuously at the quench frequency of about 15 kc, drawing grid current at one point in each cycle. When not drawing grid current the tube and circuit are in a suitable condition to oscillate at the frequency of reception. However, when only weak pulses or signals are present to trigger oscillation, the voltage does not have time to build up to full amplitude before it is quenched by grid current. Under these conditions the amplitude of the r-f voltage on the grid, when grid current starts, is proportional to the actuating signal amplitude.

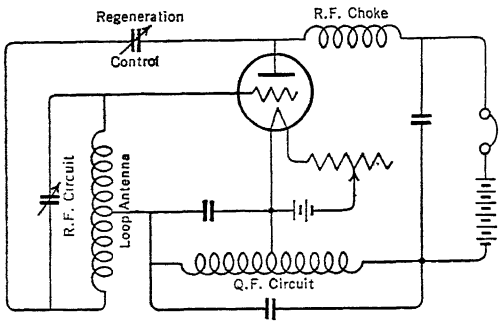

Fig. 4. One-tube Superregenerative Receiver

This circuit has a better signal-noise ratio than the blocking type, but it is almost equally broad in tuning. The chief application for these circuits is for reception at very high frequencies. For this use the broadness of tuning is frequently an advantage, helping to find and hold the signal.

THE TUNED RADIO-FREQUENCY RECEIVER. A tuned r-f receiver consists of several stages of tuned r-f amplification followed by a detector and audio amplifier.

Regeneration in Multistage Amplifiers. In a multistage tuned r-f amplifier, if capacitance exists between control grid and plate, regeneration will result. In fact, coupling of any sort between any two stages of an amplifier will result in regeneration, or oscillation, depending on the degree of coupling.

Resistance Stabilization. Since regeneration is equivalent to adding negative resistance, its effects may be largely counterbalanced, at a given frequency, by adding resistance to the input circuit. This added resistance should not be placed from grid to filament if it is desired to counteract regeneration over the whole tuning range with a fixed value of resistance. The regeneration is much more severe at the high-frequency end of the tuning range. Hence, it is desirable to place the added resistance in such a position that it will have its greatest effect at high frequencies. This is accomplished by placing the resistance in series with the grid.

The Tuned R-f Receiver with Resistance Stabilization. Figure 5 is the schematic circuit diagram for a complete battery-operated receiver, employing an untuned antenna

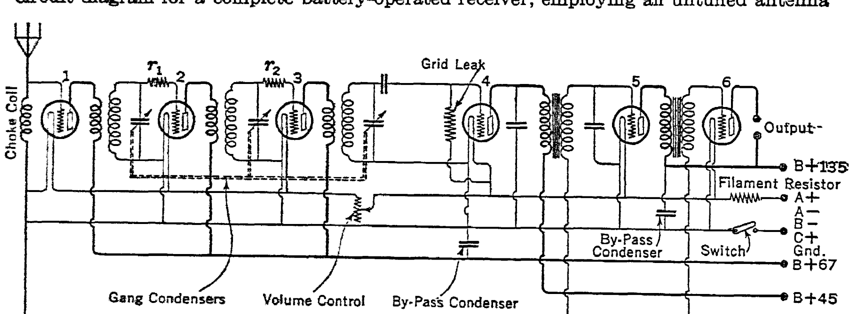

Fig. 5. Tuned R-f Receiver, Resistance Stabilized

circuit, and three r-f transformers, with resistance stabilization. Such a receiver would oscillate without the presence of resistors r_1 and r_2. When these resistors are given the proper value (usually about 800 ohms) the effects of regeneration may be approximately counterbalanced over the entire tuning range. In order to flatten the sensitivity curve the resistors are usually made large enough to overcompensate for the regeneration at high frequencies. For this reason the tuning is unduly broad at high frequencies, in this type of receiver.

The Neutralized Receiver. Another method of eliminating oscillation is by the use of neutralization. (See p. 7-29.) Receivers employing two and three stages of tuned amplification with capacitance neutralization were quite popular before the development of the screen-grid tube.

The Tuned R-f Receiver Employing Screen-grid Tubes. When screen-grid tubes are employed in a multistage tuned amplifier, regeneration of the type discussed above is not observed. The presence of the screen grid, between control grid and plate, reduces the grid plate capacitance to such a low value that regeneration is appreciable only when the stage gain is extremely high.

Nevertheless, it is necessary to take many other precautions to avoid oscillation if the overall gain is very great.

Other Sources of Regeneration. Coupling of any sort, between any two stages of the receiver, may give rise to serious regeneration. Coupling between adjacent stages is not as serious as between circuits which are one or more stages removed from each other. Capacitative, or inductive, coupling causes oscillation with equal facility because of the change in phase obtainable by tuning the intervening circuits. Incomplete shielding of grid and plate leads is one of the most prevalent sources of regeneration.

When the overall gain is high, the mutual inductance of the various sections of the gang tuning condenser becomes troublesome. Owing to the use of a common rotor shaft this coupling cannot be completely eliminated. It can be reduced to a satisfactorily low value by careful design. It is general practice to use several wiping contacts on the rotor shaft. The ground leads from the tuning inductances are brought separately to different terminals on the wiping contacts, to avoid the coupling of a common ground lead.

Objectionable coupling is often caused by the use of common voltage supplies for the cathode, screen, or plate circuits. This trouble can be eliminated by the use of small decoupling resistors in series with the voltage supply leads for each tube and with separate by-pass condensers.

THE SUPERHETERODYNE RECEIVER. The tuned r-f receiver requires extreme care to avoid oscillation, because of the high overall gain required at radio frequency. To avoid this the superheterodyne type of receiver, in which unduly high gain is not required at any frequency, is used. Part of the required amplification is obtained at the radio frequency and part at an intermediate frequency. This makes stabilization relatively easy.

The essential idea of the superheterodyne receiver is to amplify all signals at the same fixed frequency. The essential component parts are the preselector, the frequency converter, the intermediate-frequency amplifier, the audio amplifier, and the loud speaker. A typical receiver of this type is shown in Fig. 6.

The Preselector. The preselector consists of an antenna input circuit with, or without, one or more tuned r-f amplifier stages.

The operating characteristics of the preselector are identical with those of corresponding units in a tuned r-f receiver.

The preselector assists in producing discrimination against signals on adjacent frequencies, but the intermediate-frequency amplifier is so much more effective for this purpose that the use of the preselector is not warranted for this alone. Its essential function is the elimination of undesired responses at frequencies widely different from that of resonance.

The Frequency Converter. Frequency conversion is obtained by the use of the first detector and oscillator. In most receivers, the oscillator operates at a frequency higher than the signal frequency. The difference in frequency is the intermediate frequency. Voltage from the oscillator and from the signal is fed to the first detector, and the output is amplified in the i-f amplifier. Previous to 1933, a majority of receivers employed separate tubes for the oscillator and first detector, usually using a circuit in which the oscillator voltage was fed to the first detector cathode. A majority of modern receivers employ a single tube in which the two functions are combined. An example of this type of tube is the 2A7, used in the circuit of Fig. 6.

Combined First Detector and Oscillator. In the 2A7 tube the first two grids, adjacent to the cathode, comprise the oscillator elements. The voltage fluctuations of the first grid control the electron stream, not only to the oscillator plate (called second grid for convenience although it includes only two vertical rods), but also that to the remainder of the elements. The current arriving at the output plate of the tube consists of pulses, at the frequency of the oscillator. The amplitude of these pulses may be varied by the control grid. The remaining grid, or screen, acts as a shield between the oscillator elements and the control grid and output plate. It also screens the control grid from the output plate.

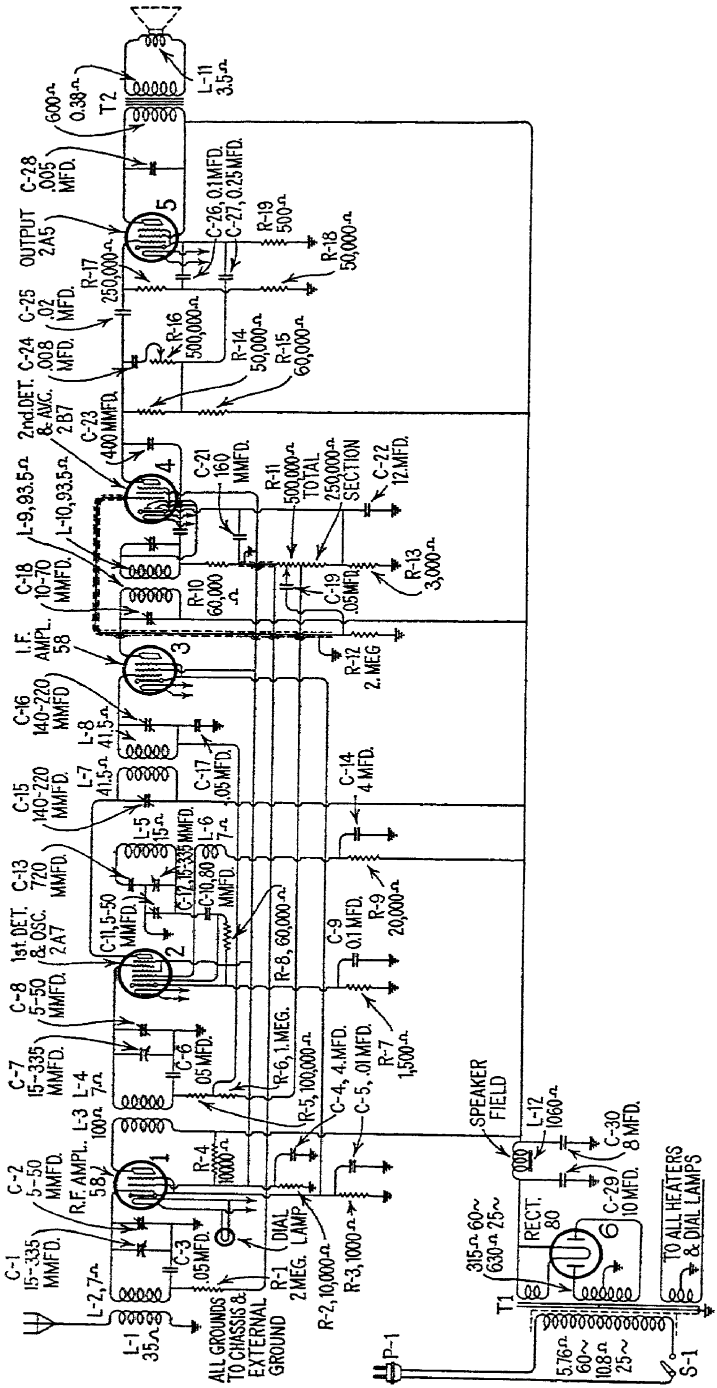

FIG. 6. Six-tube Superheterodyne

The component at the difference between oscillator and signal frequency corresponds to the intermediate frequency; it is selected and amplified by the i-f amplifier.

Tracking. One of the most important problems of superheterodyne design is tuning the oscillator and the preselectors with a gang tuning condenser. The problem is to maintain the oscillator at a uniformly higher frequency than the preselector, as the preselector is tuned over the frequency band. The frequency difference must remain equal to the intermediate frequency. Since the oscillator is operated at a higher frequency than the preselector, it has a tendency to change frequency too rapidly.

One method of correcting this is to specially shape the rotor plate of the tuning condenser which is used in the oscillator section of the gang tuning condenser. Another method is by means of fixed condensers in series and shunt with the oscillator tuning condenser. These reduce the rate of change of frequency. When the two auxiliary condensers and the oscillator inductance have the proper value, the oscillator frequency deviates only slightly from that desired, as shown in Fig. 7.

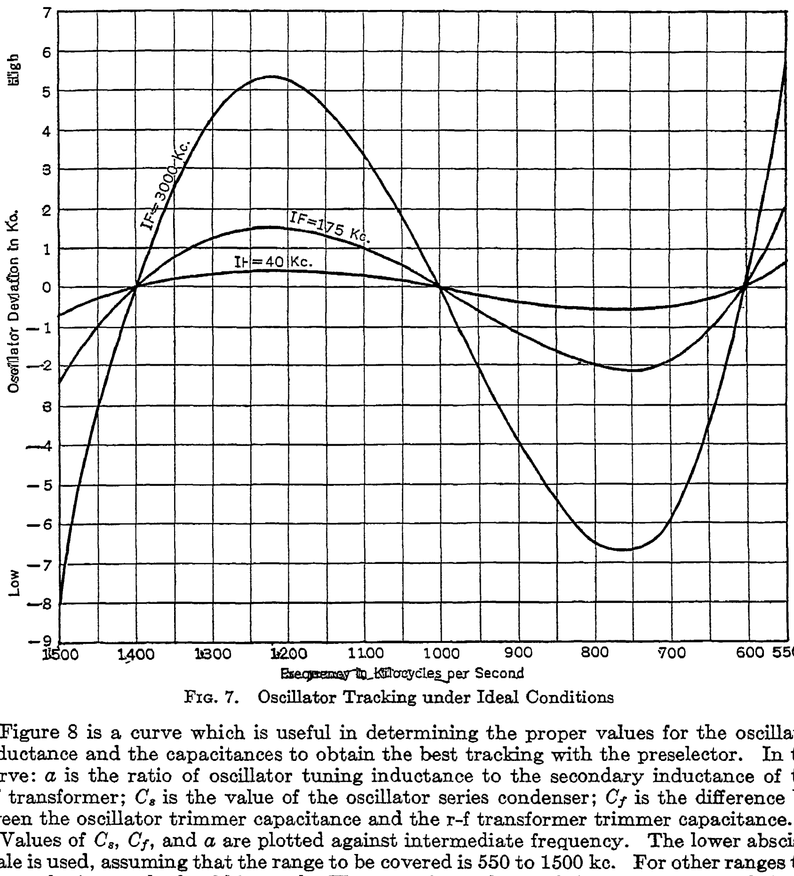

FIG. 7. Oscillator Tracking under Ideal Conditions

Figure 8 is a curve which is useful in determining the proper values for the oscillator inductance and the capacitances to obtain the best tracking with the preselector. In the curve: a is the ratio of oscillator tuning inductance to the secondary inductance of the r-f transformer; C_s is the value of the oscillator series condenser; C_f is the difference between the oscillator trimmer capacitance and the r-f transformer trimmer capacitance.

Values of C_s, C_f, and a are plotted against intermediate frequency. The lower abscissa scale is used, assuming that the range to be covered is 550 to 1500 kc. For other ranges the upper abscissa scale should be used. The curve is for the condition of 400 $\mu\mu$f total circuit capacitance at the low-frequency end of the range. If the maximum capacitance is changed, C_s and C_f change in the same ratio, while a remains unchanged.

The Intermediate-frequency Amplifier. The i-f amplifier consists of one or more stages of amplification following the first detector. The tuning is fixed at the intermediate frequency. Usually two coupled circuits are used in each i-f transformer. The frequency chosen usually lies between 100 and 500 kc per sec. High gain and good selectivity are easily obtained at these frequencies, particularly towards the lower of the two values.

The Diode Pentode Tube. In the circuit of Fig. 6, the fourth tube is a combination of a diode and a pentode in a common envelope. The diode and pentode together serve as detector and audio amplifier. This combination tube may replace two separate tubes in all circuits except those requiring different d-c cathode potentials.

Undesired Responses. Although the superheterodyne has many advantages, it is subject to a number of undesired responses and interfering beat notes which do not occur in a tuned r-f receiver. However, careful design minimizes these difficulties.

The Image Response. The most important undesired response in a superheterodyne is known as the "image." As explained above, the intermediate frequency is the difference between the signal frequency and the oscillator frequency. The oscillator is operated above the signal frequency. However, i-f signals are produced equally well by a beat

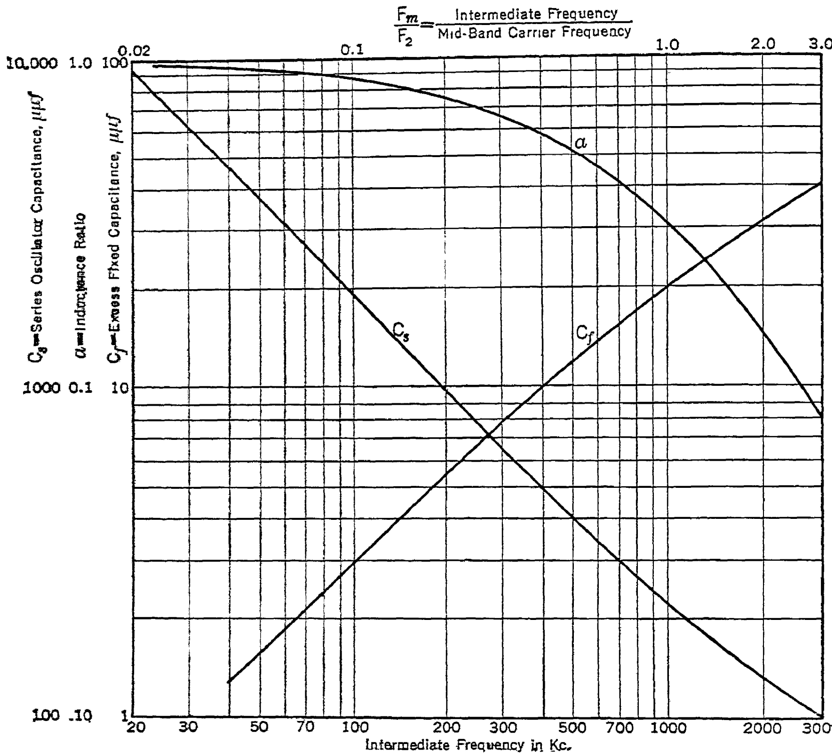

FIG. 8. Proper Values of Oscillator Inductance and Capacitances for Best Tracking with the Preselector

between the oscillator and a signal which is above the oscillator in frequency. The first detector is equally responsive to signals at either of these two frequencies. The only means of selecting the desired (lower frequency) of these two response points and attenuating the other is by means of the preselector. The higher the frequency of the intermediate amplifier, the greater the frequency separation of the desired signal and the image response; hence, the image response ratio is greater for a high intermediate frequency. With an intermediate frequency of 175 kc, the ratio of the sensitivity at the desired response to that at the undesired response can be made about 1000 at the high-frequency end of the broadcast range and about 10,000 at the low-frequency end. Although higher intermediate frequencies give higher image response ratios, other difficulties may develop from their use, as described below.

Harmonics of the Intermediate Frequency. Another source of difficulty which may be present in the superheterodyne is a beat note which occurs when reception is attempted at a frequency corresponding to a harmonic of the intermediate frequency. The reason for this beat note is that the second detector produces these i-f harmonics. If a very small amount of coupling exists between the second detector circuit and the antenna, or the r-f transformer, the i-f harmonic beats with the incoming signal producing a disagreeable squeal.

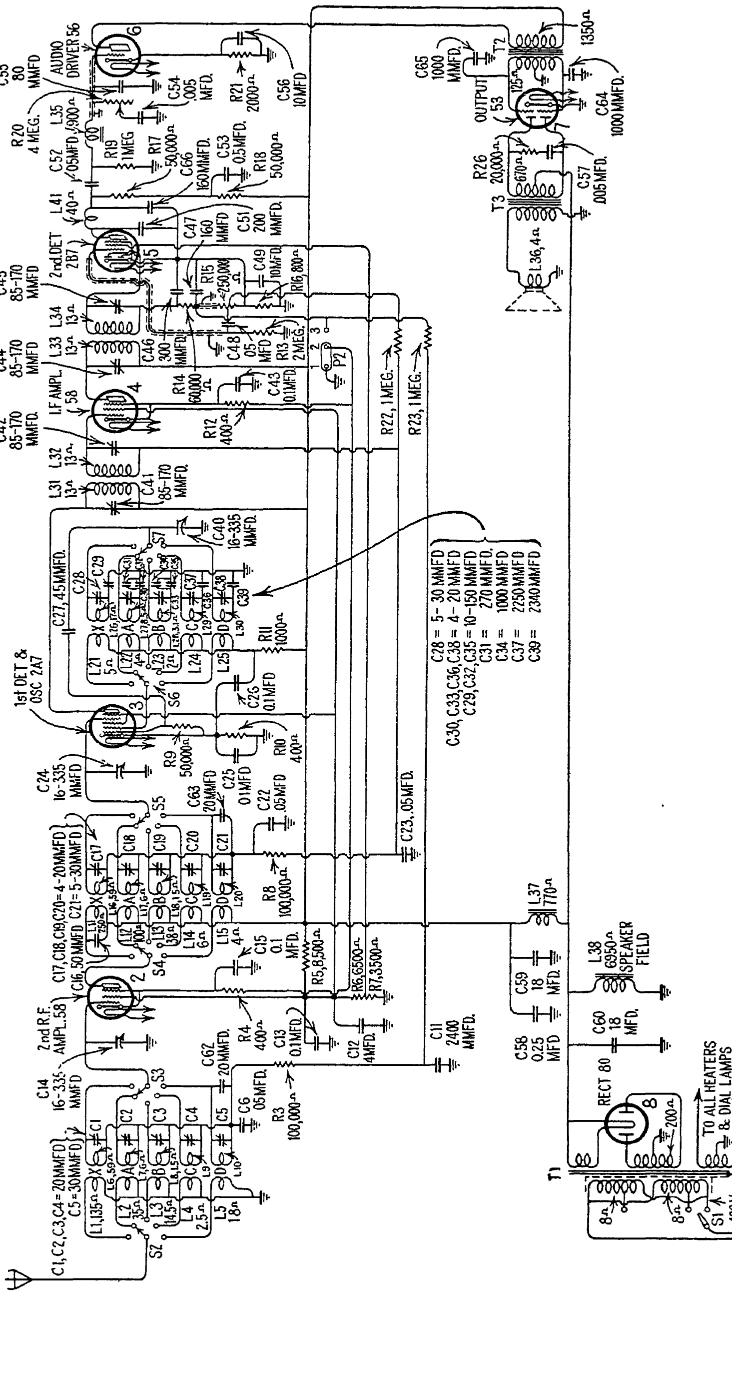

FIG. 9. All-wave Superheterodyne

The higher the order of the harmonic the less its amplitude in the detector circuit. Hence it is easier to suppress the beat note due to higher-order harmonics than that due to the second and third harmonics. The highest intermediate frequency which can be used if the third harmonic is to be kept outside of the broadcast frequency band is 175 kc. This accounts for the great popularity of this figure. When higher intermediate frequencies are used, such as 450 kc, the severity of the harmonics in the broadcast band is increased, but the number of interference points is reduced from five to two. By very careful shielding, the beat notes resulting from these harmonics may be almost completely eliminated. The greatest difficulty is obtained with the second harmonic.

Other Responses. The above are the most important of the undesired responses, but many other types occasionally give trouble. For example, two broadcasting stations may beat together to produce i-f signals independent of the local oscillator. Harmonics of the oscillator may beat with signals of various frequencies and with their harmonics, etc. A good preselector is the best insurance against all these.

ALL-WAVE RECEIVERS. The popularity of short waves increased very rapidly during 1933 and 1934. For this reason most of the commercial entertainment receivers now include provision for the reception of frequencies other than the standard broadcast band. Many of these receivers employ the name "all-wave," but this is a misnomer as none of these receivers cover the whole r-f spectrum. The circuit of a typical receiver of this kind is shown in Fig. 9. The circuit is entirely conventional, except that the preselector transformers and the oscillator transformers may be switched to any one of the five bands which it covers.

The r-f transformers for the low-frequency bands are purposely designed with restricted gain, so as to maintain approximately uniform sensitivity on all bands. This is necessary, because the gain obtainable in a single stage is limited to a low value at high frequencies.

RECEPTION OF CONTINUOUS WAVE CODE SIGNALS. In the reception of unmodulated code signals it is necessary to supply a local oscillator to produce an audible beat note with the incoming signal. In the regenerative detector circuit of Fig. 3 it is only necessary to advance the tickler to a point just beyond where oscillation starts in order to receive this type of signal. The regenerative detector may be preceded by one or more stages of tuned r-f amplification to increase the sensitivity.

The circuits of Figs. 5, 6, and 9 may be used to receive code signals by the addition of an external oscillator. In the tuned r-f receiver the oscillator must be tuned to beat with the signal directly. Hence it must be tunable over the receiving frequency range. With superheterodyne the local oscillator may beat with the signal at the intermediate frequency. Hence its tuning may be fixed. The oscillator should be coupled weakly to the detector input circuit.

TUNING INDICATORS. Because radio stations are not always modulating, it is somewhat advantageous to have a visual indication of resonance, rather than to depend on audio output as a check on the accuracy of tuning. There are many different methods for accomplishing this. One of the simplest is to place a milliammeter in the B supply lead to one of the r-f amplifier tubes which is subjected to automatic volume control. The stronger the signal, the higher the bias on this tube, and the lower its plate current. Hence the deflection of the needle downward from its peak value at no signal is a good indication of signal strength and of the accuracy of tuning.

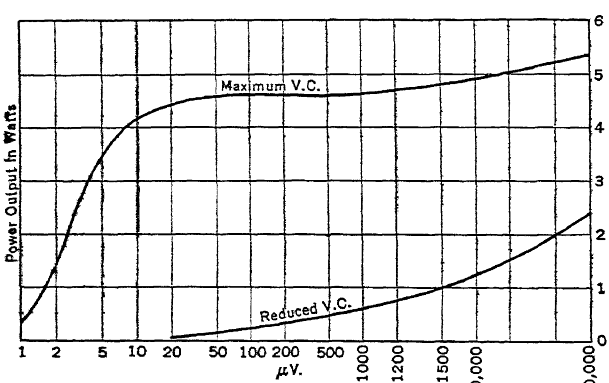

FIG. 10. Overload and AVC Curves

AUTOMATIC VOLUME CONTROL. The circuit connections for automatic volume control are shown in Fig. 6. The diode second detector develops a d-c voltage which is so connected as to increase the bias on the amplifier tubes with increased signal strength. The result of this connection is that strong signals produce only slightly greater audio response than weak ones. In Fig. 10 the audio output of a typical receiver is plotted against signal strength for maximum, and for a reduced manual volume control setting. A manual volume control, such as that shown in the diode circuit, is necessary to adjust the level of sound volume. After this adjustment is made signals come in at approximately the same volume. One of the important advantages of automatic volume control is a reduction of the effect of fading signals.

27. FIDELITY CHARACTERISTICS

The circuits affecting the fidelity characteristics are: the r-f amplifier, the automatic volume control circuit, the audio amplifier, the tone control, the output transformer, and the loudspeaker. The effect of the loudspeaker is not included in the curve of Fig. 11. Loudspeaker characteristics are discussed in Section 6.

The overall fidelity curve of Fig. 11 is the product of the fidelity curves of the component parts of the receiver.

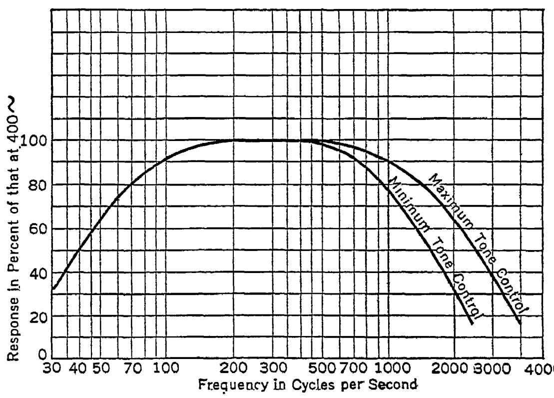

FIG. 11. Fidelity Curves Showing Effect of Tone Control

EFFECT OF R-F CIRCUITS ON FIDELITY. The r-f circuits affect the fidelity curve by cutting the high-frequency response. The modulation on a signal consists of continuous wave signals (called sidebands) on frequencies adjacent to the carrier frequency. These sidebands differ in frequency from the carrier by the value of the modulation frequency. The selectivity curve of the r-f and i-f amplifier shows quite appreciable decrease at only 2 or 3 kc from resonance. Hence the fidelity curve indicates this same decrease of the high audio frequencies.

THE EFFECT OF THE AUTOMATIC VOLUME CONTROL ON THE FIDELITY. The automatic volume control reduces the effects of fading, delivering to the detector a signal having only slight variations in amplitude, in spite of the wide fluctuations of signal amplitude on the antenna. In a similar manner the amplitude fluctuations of the signal, corresponding to low-frequency modulation, may be almost completely wiped out if the action of the automatic volume control is too fast. The action of this circuit may be slowed down by increasing the values of the resistors and by-pass condensers in the return leads of the tuning inductances. If the action is too slow the delay becomes noticeable to the ear. Shocks of static then blot out appreciable portions of the program, and the change in volume when tuning in stations may be noticeably slow. For this reason the time constant should be low enough so that there is a small but appreciable effect on the low-frequency portion of the fidelity curve.

THE RESISTANCE-COUPLED AUDIO AMPLIFIER. In Fig. 6 the diode section of the diode-pentode is resistance-coupled to the pentode section. Also, the pentode is resistance-coupled to the output tube. Neglecting the slight effect of the grid leak, the gain of a resistance-coupled amplifier is the ratio of the voltages applied to the grids of the preceding tube and the following tube. It is equal to $E_2/E_1 = \mu r/(r_p + r)$, where μ is the amplification factor of the tube, r is the load resistance, and r_p is the plate impedance of the tube. Or, if the plate impedance is very high, $E_2/E_1 = s_m r$, where s_m is the transconductance (or mutual conductance) of the tube at the operating voltages.

These formulas neglect shunt capacitance and the coupling capacitance. At high frequencies the shunt (plate-filament, grid-filament, and other) capacitances affect the result. The response is attenuated to 70 per cent of the mid-range value, at the frequency where the shunt capacitative reactance is equal to the effective resistance of r and r_p in parallel.

At low frequencies the coupling capacitance reduces the gain. The response drops to 70 per cent at the frequency where the reactance of the coupling capacitor is equal to the resistance of the grid leak. The effect of the diode resistance-coupling circuit may be calculated in a similar manner.

TONE CONTROL. The above paragraphs neglect the effect on the fidelity, of R-16 and C-24 (in Fig. 6), which constitute the tone control. At the maximum setting of the variable resistor the effect of these two units is very slight. However, when the control is turned back, high frequencies are progressively attenuated. A fidelity curve at maximum and minimum tone control setting is given in Fig. 11.

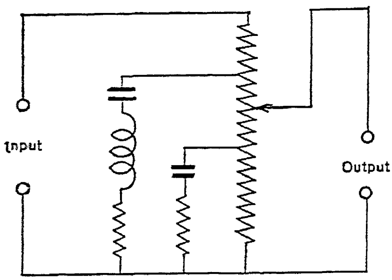

FIG. 12. Compensated Volume Control Circuit

The major use of the tone control is to improve the apparent signal to noise ratio. Noise is usually uniformly distributed over the audio-frequency spectrum, while the signal energy is chiefly contained in its lower frequency components. Hence when the tone control is turned back the signal is reduced by a smaller percentage than the noise.

The tone control may also sometimes be used to improve faulty fidelity in the transmitted signal.

THE EFFECT OF AUDIO TRANSFORMERS ON THE FIDELITY. Audio transformers of either the interstage or output type affect the fidelity by cutting both the high- and low-frequency response. However, the degree may be largely controlled by design. (See pp. 6-13 to 6-25.)

COMPENSATED VOLUME CONTROL. To the human ear the apparent loudness of sound at various frequencies changes at a different rate as the amplitude of the sound waves is changed. This makes it desirable to accentuate low frequencies and high frequencies when the volume control is turned down. A circuit employed to accomplish

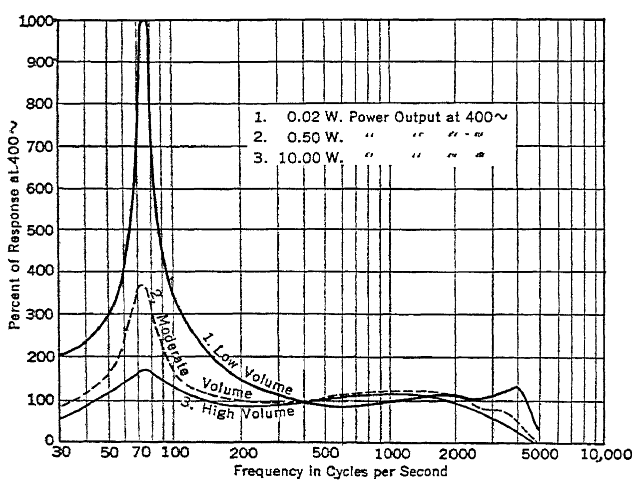

FIG. 13. Variation of Frequency Response with Setting of Compensated Volume Control

this is given in Fig. 12. Figure 13 gives the fidelity curve of a receiver incorporating this circuit. A receiver employing compensated volume control has a more natural sound at all volume levels.

NOISE SUPPRESSION. When automatic volume control is employed with a receiver of high sensitivity, the receiver automatically goes to full sensitivity when tuned between stations. The results are disagreeably strong reproduction of the static and general interference, which is always present in the background at any frequency. In order to make tuning more pleasant, circuits of various types have been developed for cutting off the audio amplifier in the absence of a signal carrier. One popular circuit for this purpose is shown in Fig. 14.

When no signal is present, no current flows in the diode circuit. Hence, no bias voltage is applied to the grid of V_2 and maximum plate current flows through r_2. The voltage developed across r_2 biases V_3 to cutoff so that it cannot amplify. The audio signals from interfering noises cannot pass this point. When an r-f signal is present, current flows in the diode circuit producing d-c and a-c voltages across the diode circuit resistor. The

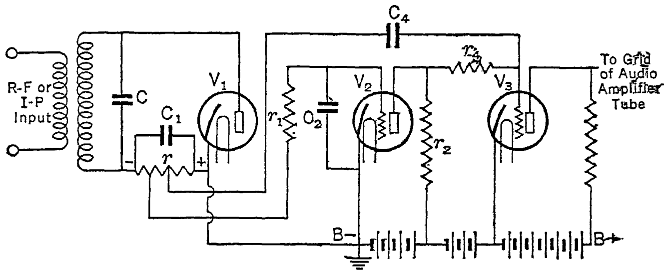

FIG. 14. Noise Suppressor Circuit

d-c voltage biases V_2 to cutoff. There is then no voltage drop across r_2, so V_3 operates with normal bias. V_3 then functions as an amplifier for the audio-frequency voltage applied to its grid through C_4.

28. RANDOM NOISE

Random noise (sometimes called fluctuation noise or Johnson noise) is a fundamental form of interference which prevents the satisfactory reception of signals below a certain level.

Random noise comes from two sources, thermal agitation in circuit resistances, and shot effect in vacuum tubes. Thermal-agitation noise comes from the random motion of electrons in a conductor due to its temperature. The open-circuit rms noise voltage across a resistor is

$$E_n = \sqrt{4KTr\,\Delta f} \tag{1}$$

where K = Boltzmann's constant = 1.37×10^{-23} joule per degree Kelvin.
T = absolute temperature in degrees Kelvin.
r = value of the resistance in ohms.
Δf = the effective noise bandwidth of the instrument used to measure the voltage.

Since the effects of shot noise are indistinguishable from those of thermal noise, it is customary to measure the shot noise of a vacuum tube in terms of the equivalent noise grid resistance. This is defined as the value of external grid resistance required to double the noise power output of the tube over that with the grid shorted. The value for a triode is approximately,

$$r_{\text{eq}} = \frac{3}{g_m}\,* \tag{2}$$

where g_m is the transconductance of the tube. The value for a pentode is approximately four times as high.*

Noise Factor. The "available power" of a signal generator is the power delivered to a load resistance under the condition of an impedance match. Thus the available noise power of a resistance considered as a noise generator is:

$$\frac{E_n^2}{4r} = KT\,\Delta f \tag{3}$$

If the resistance r is the impedance of a receiving antenna, and if no other noise sources existed, then a signal noise ratio of unity would be obtained when the signal power available from the antenna was $KT\,\Delta f$. This is the (unattainable) ideal which can never be

* B. J. Thompson, D. O. North, and W. A. Harris, Fluctuations in Space-charge-limited Currents at Moderately High Frequencies, *RCA Rev.*, Vol. IV, No. 3 (January 1940).

improved upon. Actually other noise sources always exist, so that the signal required for unity signal noise ratio is always greater than $KT\,\Delta f$. The ratio by which it is greater is called the noise factor. This ratio is usually expressed in decibels. Below 100 Mc receivers can be built that have a noise factor only a few decibels above thermal. Above 500 Mc, 10 db above thermal is considered good.

The test for "noise factor" is not yet accepted by the Institute of Radio Engineers as a standard test, but its use by the armed services during World War II became so widespread that its adoption as a standard seems inevitable.

The Nature of Random Noise. Random noise may be considered to be made up of an infinite number of sinusoidal components of different frequency. The amplitude of any single frequency component is infinitesimal, but in any finite bandwidth the rms voltage is proportional to the square root of the bandwidth though independent of the mean frequency.

Distribution of Amplitude. The actual voltage at any instant cannot be predicted, but an accurate statistical prediction can be made of the fraction of the time, taken over a long period, that the voltage will exceed any given value. This fraction of the time is identical with the probability that the given voltage V will be exceeded at a given instant and is equal to

$$P_V = \frac{1}{E\sqrt{2\pi}} \int_V^\alpha \exp\left(-\frac{V^2}{2E^2}\right) dV\,* \tag{4}$$

where E is the rms voltage of the noise.

Distribution of Envelope Amplitude vs. Time. If the bandwidth of the circuit passing the noise is small compared to the mean frequency, then the amplitude never changes abruptly from one cycle to the next. Thus, in a graph of the wave, if the peaks of adjacent cycles are connected with a smooth line the resulting line is the envelope of the wave and is a function varying much more slowly than the wave itself. The probability that the envelope will exceed a certain value A at any instant is

$$P_A = \exp\left(\frac{-A^2}{2E^2}\right)\,\dagger \tag{5}$$

The Values of Various Averages.† The average absolute value of the voltage is: $\bar{V} = 0.798E$.

The mean value of the envelope is: $\bar{A} = 1.252E$.

The root mean square deviation of the envelope from its mean value is:

$$A_r = 0.655E \tag{6}$$

The root mean square value of the envelope is: $A_{\text{rms}} = \sqrt{2}E$.

The most probable value of the envelope is: $A_p = \pm E$.

RADIO TRANSMITTERS

By J. E. Young

A radio transmitter is defined as a device for producing r-f power for purposes of radio transmission. It also contains means of modulating or varying that r-f power, designated as the carrier wave, in correspondence to the intelligence it is desired to transmit. Television transmitters or others using the pulse technique, as well as those employing frequency modulation, are discussed in other sections. See Sections 8, 9, and 20. This section will be concerned with broadcast and communications transmitters employing amplitude modulation.

NATIONAL AND INTERNATIONAL REGULATIONS. Since radio communication, broadcast or point-to-point, involves transmission through a common medium, it has been necessary to set up national and international rules defining the frequencies, or channels, frequency tolerance, and type of emission for all radio stations. In addition, the Federal Communications Commission has set up national rules and standards governing frequency assignments, transmitter power, time when testing is permitted, specifications of performance regarding distortion, noise, and fidelity, grades of operators to be employed, etc., for all types of radio transmission. Other agencies, particularly the Radio Manufacturers Association, have been active in setting up recommended standards of performance and uniform methods of writing specifications and testing for various classes of transmitters.

RADIO TRANSMITTER—SCOPE. The transmitter is usually considered to consist of all audio equipment operating above standard telephone-practice levels, and all r-f equipment from the source of the r-f oscillations to the transmission line connecting the transmitter to the antenna. Within the equipment defined by these limits is contained sufficient audio-frequency amplification to raise the input signal to a level high enough to perform the function of modulation, r-f amplification and multiplication to raise the power level and frequency of the r-f oscillations to the output level, and the necessary power supplies for these circuits. The function and application of vacuum tubes to these elements of the radio transmitter are discussed in other articles of this section; only certain general aspects of design and performance will be covered here.

FREQUENCY CONTROL. The requirements of frequency stability are virtually always too severe to permit modulating (including c-w keying) an oscillator used as a direct source of antenna power. The usual practice is to use a low-power oscillator, separated from the modulated amplifier by a sufficient number of stages to prevent interaction caused by changes in impedance of the modulated stage resulting from the processes of modulation or other variations in load.

For transmitters operating on fixed frequencies, quartz crystals are commonly used as the frequency-determining element. A frequency stability of 10 parts per million is quite easily achieved with a quartz-crystal-controlled oscillator in which the temperature of the quartz plate is not permitted to vary more than ± 1 deg cent.

Some types of transmitters, particularly those used for military applications, operate on frequencies which may frequently be changed. For these applications quartz crystals are not practical and a master oscillator in which the tuned circuit is the frequency-determining element is employed. Such oscillators, having as much as 2 : 1 frequency range, may be designed to have a frequency stability better than 1 part in 10,000 for moderate variations of temperature, humidity, and power supply voltages.

OSCILLATOR POWER. It is possible to design crystal-controlled oscillators which will produce several hundred watts of output power; however, such oscillators are difficult to adjust and somewhat less stable than those of lower power output. It is better design practice to use a crystal oscillator which has only a few watts of output, followed by high-gain shielded-grid amplifiers, to achieve maximum frequency stability, and, in keyed-oscillator circuits, freedom from chirps and frequency creepage. This practice also permits the use of small crystals mounted in compact holders, since the crystal dissipates very little heat.

29. INTERMEDIATE-RADIO-FREQUENCY AMPLIFIERS

The intermediate-r-f amplifier stages perform the triple function of increasing the power level of the frequency-controlled oscillator, multiplying its frequency, if required, and acting as a buffer between the modulated amplifier and the oscillator. In the interest of simplicity, intermediate amplifier stages usually employ high-gain, multigrid tubes so that it is not uncommon to attain all three of these objectives with one or two intermediate amplifier stages. In high-level modulated and telegraph transmitters the intermediate amplifiers are operated class C. In low-level modulated transmitters the intermediate amplifier stages following the modulated stage must reproduce the audio-modulated envelope and must, therefore, be operated as class B r-f amplifiers. (See p. 7-22.)

INTERSTAGE COUPLING CIRCUITS. Amplitude-modulated transmitters are rarely used at frequencies above 40 Mc. Up to this frequency no special precautions are ordinarily required in interstage circuits. In general, it is desirable to make the circuits as simple as possible to avoid dangerous multiple resonances and parasitics. Typical coupling circuits for shielded-grid tubes are shown in Fig. 1. Note that the grid leak is not by-passed and that grid and plate feed circuits are dissimilar. It frequently happens that the input resistance of the driven amplifier is so low that the r-f choke in series with the grid leak may be eliminated without appreciably affecting the driver power output. This should always be done where calculations so indicate, since a possible parasitic circuit is thereby eliminated. For the same reason it is desirable to use the voltage obtained by the flow of rectified grid current through a resistor as grid bias rather than to obtain this voltage from a separate source. Protection against excessive plate dissipation, if the excitation fails, may be obtained by the use of sufficient cathode bias.

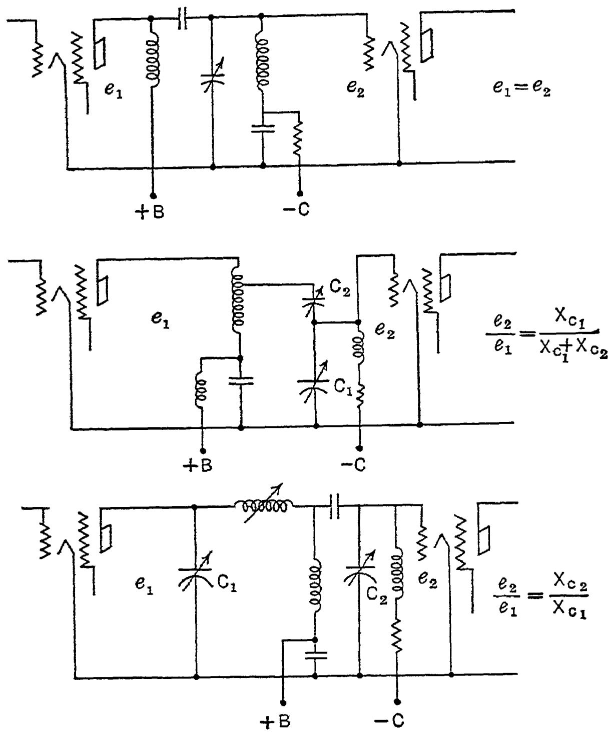

FIG. 1. Interstage Coupling Circuits

CIRCUIT Q, or KVA/KW RATIO. Unmodulated intermediate amplifier stages are not critical with respect to interstage coupling circuit Q, although it is desirable that the circuit, looking from the grid of the driven tube, be of high enough Q to insure sinusoidal wave shape in spite of the variable-impedance characteristic of the grid, as it is driven positive. Unfortunately, in the grounded filament circuits, the voltage relations are such that the driving tube puts energy into the coupling circuit almost 180° away from the time when it is absorbed by the grid of the driven amplifier. The energy storage must be sufficient to take care of this condition. The wave shape will be adequate if the circuit Q is greater than 10, unless the driven tube grid impedance at the peak of the positive grid swing is extraordinarily low. Unless the driving stage is modulated, even higher values of Q are useful and desirable, provided the concomittant coupling circuit losses are not thereby made excessive.

HARMONIC AMPLIFIERS. Because of special considerations, such as crystal activity, stability, etc., frequency multiplication is ordinarily employed where the carrier frequency is higher than 10 Mc. The necessary multiplication is accomplished in the intermediate amplifier stages. The multiplication through any one amplifier stage may be from twice to as high as five times. The plate efficiency of the amplifier tube is very nearly inversely proportional to the order of multiplication, if the most favorable conditions of loading and open angle of plate current are chosen for each multiplication. Because of the relatively low efficiency obtained when multiplying five times, this amount of multiplication is rarely used in any one stage. Because of the generally poorer plate-circuit efficiency, multiplication is usually accomplished at low power level, followed by amplifiers tuned to the output frequency, to boost the power level as required.

Optimum Angle of Current Flow. The term "angle of current flow" represents the portion of the grid voltage cycle during which plate current flows, expressed in degrees. The optimum angle of current flow depends on how nearly the plate-current plate-voltage characteristic conforms to the $^3/_2$ relation, and for a $^3/_2$ characteristic may be shown to be approximately 130° to develop maximum second-harmonic voltage in the plate circuit, 85° for the third, 65° for the fourth, and 50° for the fifth. The angle of current flow is given by the relation $\cos\frac{\theta}{2} = \frac{-E_c - E_0}{E_g}$, where θ is the angle of current flow in degrees of the excitation frequency, E_c is the grid bias, E_0 the projected cutoff bias, and E_g the grid excitation voltage. Negative bias voltages should be written in as negative numbers. Calculation will show that an open angle of 60° may be obtained with a bias voltage of not less than ten times cutoff bias. As the open angle is further restricted, the required bias voltage increases rapidly. It is not usually economical to use an open angle of plate current flow of less than 60° or to attempt to raise the frequency more than four times through a single amplifier stage. This does not hold true where the output power required is small, as in frequency-measurement work, where only milliwatts of power are usually required, and where the frequency may be multiplied many times.

30. POWER AMPLIFIERS

Power amplifiers may be either grid- or plate-circuit modulated. (See Modulators, pp. 7-73 and 7-74.) If the former, the power amplifier must be so operated as to reproduce accurately in its plate circuit an r-f envelope having the same wave shape as that of the excitation voltage. This may be accomplished by using either a linear amplifier or a

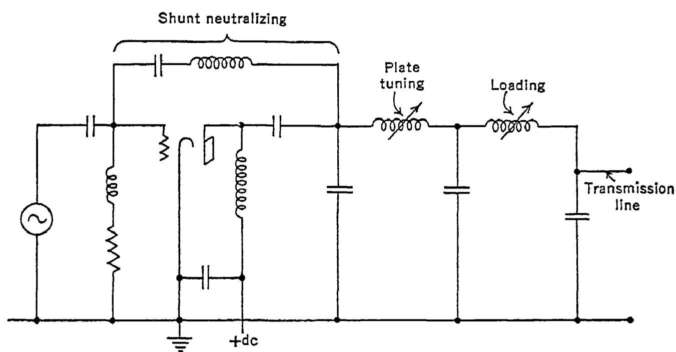

FIG. 2. Typical R-f Amplifier

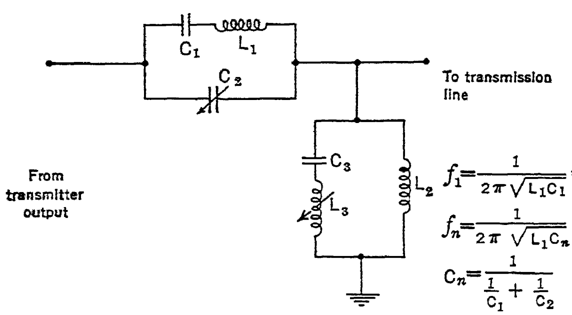
high-efficiency Doherty amplifier. The latter circuit utilizes linear amplifiers in pairs and provides for dynamic changes in drive and loading so that the average plate-circuit efficiency is several times that which may be obtained with a conventional amplifier. Two circuit paths are provided; in the first, the amplifier tube is adjusted to operate at the upper knee of its dynamic characteristic. Between its plate circuit and the load is connected a 90° phase-shifting network. The second tube is biased so that its plate current is almost zero under carrier conditions. As the drive increases during the positive excursions of the modulation cycle, the plate current of this tube, and its power output, increase in the same manner as an overbiased linear amplifier. The effective load resistance seen at the output of the 90° network connected in the plate circuit of the first tube increases as the second tube supplies power to the load. Because of the familiar impedance characteristic of the 90° network, this results in a reduction in resistance at the input terminals of this network. Therefore, the effective load resistance of the first amplifier is reduced and its power output is proportionately increased. Thus, at the peak of the positive excursion of the driving voltage, the power output of the first tube is doubled, because of its increased loading, and the output of the second tube is increased in the familiar fashion of a linear amplifier, so that it is also twice the carrier output. The total power output of the amplifier is thus four times the carrier level, fulfilling the condition for 100 per cent upward modulation. On the downward excursion of the modulation cycle the second amplifier is biased off completely, and the first amplifier functions as a conventional linear amplifier.

The envelope wave-form distortion resulting from the use of the Doherty amplifier is usually too great to be tolerable in high-fidelity systems. This defect may be remedied by applying overall feedback from the output terminals of the amplifier, through an r-f rectifier back into the audio-frequency amplifier circuits at some convenient point.

Amplifiers employing plate-circuit modulation are termed "high level." In practice the amplifier is operated class C, and the energy to perform the modulation function is provided by a class B modulator. (See Modulators, p. 7-74.) High-level amplifier output circuits must provide the necessary impedance transformation between the plate circuit of the tubes and the load and in addition must provide sufficient r-f harmonic attenuation to prevent excessive harmonic radiation. In practice, the Q of the output tank circuit is generally made quite low, from 4 to 8 for single-ended amplifiers, and additional harmonic attenuation is obtained, if necessary, by a low-pass filter inserted between the terminals of the amplifier and its load. A typical amplifier circuit employing shunt neutralization is shown in Fig. 2.

The high-level, modulated amplifier has the advantage that it is simple to adjust and uncritical in its operation. In addition, its quiescent (carrier level) efficiency is very high. Since the average percentage of modulation rarely exceeds 15 per cent in broadcast operation, the quiescent efficiency is a most important consideration in the economics of transmitter operation.

R-F HARMONIC RADIATION. Under the present conditions of crowded frequency assignments throughout the r-f spectrum, the first few multiples of the transmitter frequency—the frequencies that contain most of the harmonic energy—will often interfere



$$f_1 = \frac{1}{2\pi\sqrt{L_1C_1}} = \frac{1}{2\pi\sqrt{(L_2+L_3)\,C_3}}$$

$$f_n = \frac{1}{2\pi\sqrt{L_1C_n}} = \frac{1}{2\pi\sqrt{L_3C_3}}$$

$$C_n = \frac{1}{\frac{1}{C_1}+\frac{1}{C_2}}$$

f_1 = fundamental frequency

f_n = harmonic frequency

Fig. 3. Harmonic Attenuator

with some other radio service. Thus, because of a particular interference problem, one harmonic often must be reduced far more than the rest. The problem should first be analyzed, by making measurements to ascertain definitely that the interfering signal results from direct radiation from the station or its antenna. It frequently happens that a wire or metal surface located near the point of interference, or even the receiving antenna itself, is picking up energy from the transmitter and through the agency of an oxide-covered joint is itself producing the harmonic signal. This may be checked by field-intensity measurements made at a series of points on a line from the transmitter to the point of interference. Peaks in the harmonic signal intensity will be observed in the vicinity of such harmonic generators. The remedy is obvious but not always simple. Very often, however, a single guywire or other metal object having dimensions comparable to the wavelength in question will be found to be the source of the interfering signal.

The field-intensity meter may also be used to determine whether the interfering harmonic is radiated from the transmitter directly or from the transmitting antenna, if the two are sufficiently separated so that a directional fix may be obtained. If the radiation appears to be from the antenna, the signal energy may be carried by the transmission line from the transmitter to the antenna, or it may again result from rectification, either at an oxidized metal joint or at a tube rectifier, such as is used for remote antenna current reading or feedback. If the antenna rectifier is the offender the trouble may be cured by connecting a low-pass filter, designed to cut off just above the transmitter frequency, between the rectifier and the point where it picks up its energy from the transmitter output.

If the interfering signal emanates from the transmitter and is carried to the antenna by the transmission line, a trap, consisting of a circuit parallel-resonant to the harmonic, in series with the transmission line, and a circuit series-resonant to the harmonic in shunt with the line, will usually result in sufficient attenuation to eliminate the interference. Such a circuit may be designed so that its insertion will not affect the transmitter performance at its fundamental frequency, and it is preferably constructed so that the tuning of at least the shunt arm is variable, to permit exact adjustment to the harmonic frequency. Figure 3 shows one typical circuit.

If a balanced transmission line is used, the trap circuits should be symmetrical, with their center taps grounded to prevent in-phase transmission of the harmonic along the transmission line wires.

If the directional fix indicates that the transmitter itself is radiating the interfering signal, it may be necessary to resort to complete shielding to eliminate the trouble. More frequently, sufficient improvement will be obtained by other minor design changes, such as better grounding, more direct return of plate tank lead to filament of power amplifier or elimination of stray capacitance coupling between plate and output connection.

NEGATIVE FEEDBACK. The distortion, noise, and frequency characteristics of a telephone transmitter may be considerably improved by the application of negative feedback over all or part of the system. Two general methods of use of negative feedback are common. In transmitters using low-level modulation, followed by linear amplifiers, feedback voltage is derived from an r-f rectifier coupled to the output of the power amplifier. This signal, of the proper amplitude to secure the desired feedback, is introduced into one of the audio-frequency amplifier stages. Since the r-f rectifier is in the β loop of the feedback circuit, noise or distortion generated in it will appear in the ouput of the transmitter. It must, therefore, be carefully designed to reproduce accurately the audio envelope of the output r-f signal.

One difficulty frequently encountered in the application of this type of feedback to broadcast transmitters is that the transmitter antenna also functions as a receiving antenna for signals from other broadcast stations. Sufficient voltage may be developed in the circuit to which the feedback rectifier is connected by another broadcasting station, located in the immediate vicinity, to generate a series of cross-modulation products in the rectifier. Any of these new frequencies lying within the pass band of the α and β loops of the audio system will produce sidebands which will be radiated by the antenna and may cause serious interference. Such effects may be greatly reduced by installing a trap tuned to the frequency of the other station in the antenna system beyond the pick-up point for the feedback rectifier. Care must be used in designing such traps that they do not cause sufficient phase shift to alter the phase-shift attenuation characteristic of the transmitter seriously or instability may result.

The negative feedback will correct for distortion and noise, but only so long as there is reserve capability in the system to effect the correction. For example, it cannot correct for the distortion arising from overmodulation and, in fact, by introducing high-order harmonics back into the circuit may actually increase the distortion if the system capabilities are exceeded.

Since it is possible to keep the distortion of high-level modulated amplifiers down to a fraction of a per cent by the methods discussed under Modulators, p. 7-74, negative feedback is usually applied over the audio system, only, in this type of transmitter. This eliminates the need for the r-f rectifier and largely eliminates the effect of the output amplifier tank and load circuits on the performance of the feedback loop. The feedback voltage is usually obtained from a voltage divider, connected between the plate of each modulator tube and ground. The divider consists of capacitors, shunted by resistors. These elements are proportioned so that their impedances are equal at a frequency of approximately 100 cycles per second. The advantage of this type of divider over simple resistances is mainly that the operation of the circuit is unaffected by the capacitance of the leads connecting the network to the low-level audio-amplifier stage. Some improvement in the phase characteristic is also secured.

The use of feedback permits high-efficiency linear amplifiers to be used in services such as broadcasting, where low distortion and low noise level are essential. In high-level transmitters, feedback, applied over the audio system, including the modulator, effects a large reduction in noise and distortion and reduces performance variations due to non-uniformity of parts and tubes. It also improves the modulator efficiency, permitting the no-signal plate current to be reduced substantially to zero.

31. AUDIO AMPLIFIERS

Broadcast transmitters are, by industry agreement, provided with enough audio gain to produce 100 per cent sine-wave modulation with an audio input level of +10 db (1 milliwatt reference level) at an impedance of 600/150 ohms. Special-purpose transmitters may include more gain, although it is usually advisable to limit the gain so an input signal of at least −20 db is required. If enough gain is to be included in a transmitter to accept a lower signal level, special shielding and filtering precautions are advisable to prevent objectionable feedback.

Limiting amplifiers are generally used. A limiting stage may be designed into the audio system of the transmitter, or an external line amplifier of the limiting-compressing type may be used. Even in the latter case it is advisable to design one of the transmitter audio stages so that positive modulation greater than 125 per cent is impossible, regardless of the input signal level. Owing to switching transients or accidents, input levels 10 to 20 db above 100 per cent modulation are bound to occur, and, unless they are prevented from reaching the high-power amplifier by an absolute safeguard (such as driving the plate current of an audio stage to cutoff), serious damage may result.

Many special features are incorporated in audio systems to meet the requirements of particular services. Some of these are: automatic gain control, for circuits subject to wide variations in level; pre-emphasis of high audio frequencies, used on conjunction with complementary de-emphasis in the receiver to reduce noise; and scramblers which invert or otherwise distort speech, making it unintelligible unless a receiver provided with a complementary restorer is used.

32. TELEGRAPH TRANSMITTERS

For point-to-point transmission, telegraph code signals are often employed, since it is generally possible to secure 100 per cent transmission with a much weaker signal when telegraph is used instead of voice. Transmission may be accomplished either by tone modulation, which directly replaces the voice transmission, by keying the carrier wave directly (usually by overbiasing one of the intermediate amplifiers), or by shifting the frequency of the carrier. The last method may be accomplished by shifting the carrier a few hundred cycles back and forth at an audio rate and keying the audio signal or by shifting the carrier between two fixed frequencies, several hundred cycles apart, one corresponding to the "mark" and the other the "space." Both these systems are akin to frequency modulation and provide some advantage in noise suppression and diversity effect without the complication of diversity receivers.

33. INSTALLATION OF RADIO TRANSMITTERS

TRANSMITTER TESTING. A great deal of test equipment is now available, making it possible to examine conveniently all phases of the performance of a transmitter. Tests generally performed are as follows:

1. Circuit check—by means of click meter, ohmmeter, etc., to be sure that wiring has been done in conformance with wiring diagrams.
2. Control circuit check. Without tubes in any circuits, check the functioning of line switches, starters, time delay relays, overload relays, interlocks, and circuit breakers. No-load voltages of filament transformers may be checked at this time.
3. Transformer voltages. With filament circuits energized and tubes in place, check filament voltages, transformer tap settings, range of primary voltage control, functioning of air blower and/or water-cooling system.
4. Operational check. With all circuits tuned and functioning normally, check voltages and currents on all elements of all tubes. Check for instability and parasitic oscillation.
5. Modulation characteristics. Under normal operating conditions, check audio harmonic distortion at various modulation levels and at modulating frequencies throughout the normal frequency-transmission range. The same test equipment is required for measurement of the frequency characteristic, and residual noise level, so these tests should be performed at the same time. Figure 4 shows the equipment set-up required for this test.
6. Power output. This test should be performed using loads representing the high- and low-limit load impedances which the transmitter may be required to feed. To obtain accurate power checks, the load resistance should be accurately measured and the load

current determined by means of an accurate r-f ammeter; or the calorimetric method of power measurement may be used, in which the increase in heat content of water used to cool the dummy load is measured. The temperature rise of the water in degrees centigrade multiplied by the number of gallons flowing per minute multiplied by the constant 264 will be equal to the number of watts of power dissipated in the load.

7. Heat run. The transmitter should be run under conditions of normal operation for a period long enough for all components to reach approximately constant temperature. The procedure set up by the RMA committee on amplitude-modulated broadcast transmitters is a good example of how such a test should be run:

"The transmitter shall be operated (at rated power output) . . . long enough for all components to attain temperature stability; that is, until the hourly increment does not exceed 5 per cent of the total change under the following conditions: . . . The carrier

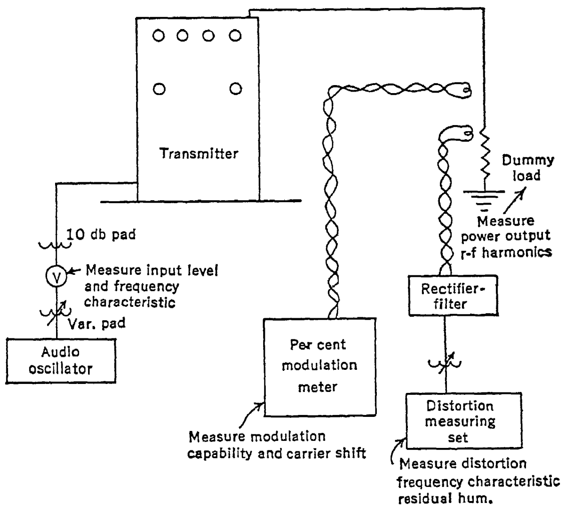


FIG. 4. Modulation Characteristics Measurements

should be continuously modulated by a 1000-cycle sine wave. The audio input level to the transmitter shall be approximately 10 db below that corresponding to 100 per cent modulation for not more than 98 per cent of the duration of the run and not less than 10 db above that corresponding to 100 per cent modulation for the remainder of the time." *

Temperature rise measurements of motor or generator windings, transformer windings, etc., should be made by the hot-cold resistance method, in which the resistance and temperature of the winding are measured after the unit has been out of operation long enough to reach a uniform, stable temperature. The resistance at the end of the heat run is then measured, and the rise in temperature is computed by the formula:

$$T = \frac{234R_2}{R_1} - \frac{234R_2T_1}{R_1} - T_2$$

T_1 = temperature at which cold resistance was measured.
T_2 = ambient temperature at end of heat run.
R_1 = resistance at T_1.
R_2 = resistance at end of heat run.
T = rise of winding temperature above final ambient.

8. Harmonic radiation. If the transmitter is tested using a dummy load, it is possible to make a rough check on harmonic intensity by coupling a field-intensity meter to the load through an attenuator, shielding the field-intensity meter so that all its pick-up is derived from the load. However, since dummy loads rarely ever even approximate the impedance characteristic of an actual radiating antenna system, such tests are of little quantitative value, and more satisfactory results will be secured if these measurements can be made on an actual field installation.

* See Radio Manufacturers Association, Engineering Department, Standards Proposal 172, Electrical Performance Standards for Standard Broadcast Transmitters.

9. Incidental phase modulation. Instruments which will measure the degree of phase modulation at frequencies below 40 Mc are seldom available. The development of commercial equipment operating in the 88–108 Mc band for the purpose of measuring the percentage of modulation of f-m broadcast stations, however, makes a handy tool available for this purpose. The signal to be measured is multiplied up to a frequency within the range of the meter by low-power harmonic amplifiers, and, since the meter is calibrated in terms of a 75-kc swing, the actual swing may be measured, and then converted into degrees of phase modulation, and divided by the multiplication ratio to determine the actual amount of phase modulation at the transmitter carrier frequency.

10. Telegraph transmitter tests. In addition to the above tests, measurements are made on the character of the keyed pulses of telegraph transmitters. The shape of the keying wave, build-up, transients, breaks, etc., may be observed or photographed on the face of a cathode-ray tube which has one pair of plates connected to a sample of the r-f output of the transmitter, and the other pair excited by a sweep voltage which is preferably adjusted to synchronize the picture of the keyed pulse on the screen. The mark-to-space ratio may be calculated by measuring the d-c current output of a rectifier energized from the r-f output of the transmitter. The percentage of mark-to-carrier is given by the ratio of the d-c current during keying to the current with key closed continuously. If the former is designated I_M, and the latter I_C, the mark-to-space ratio is

$$\frac{I_M}{I_C - I_M}$$

LOW-POWER TRANSMITTERS. Modern transmitters having a power output of 1 kw or less are usually designed as completely self-contained units. It is, accordingly, only necessary to provide power line, audio input, antenna or transmission line, and any necessary external monitor connections. Such transmitters are usually designed to operate from either a 115-volt or a 230-volt single-phase a-c source. Power and audio circuits may be conveniently brought into the transmitter through either conduits or trenches; trenches permit somewhat greater flexibility for future change or modification. External wiring and switching should be installed in accordance with fire insurance underwriters' specifications. Ground wires should be connected by as short a run as possible to a low-resistance ground, either the antenna ground system if any portion of it is installed near the transmitter or a separate ground consisting of copper plates buried in moist soil. Antenna leads or transmission lines should be insulated, not only for the normal operating potentials but also sufficiently well to protect against induced voltages caused by lightning hits. A protective gap connected between antenna and ground will discharge heavy induced charges.

HIGH-POWER TRANSMITTERS. High-power transmitters are usually designed so that the equipment is segregated in accordance with a functional grouping, so that the low-power audio-frequency equipment, for example, is well isolated from the high-power r-f amplifiers. Each of these elements has somewhat unique installation problems and will be considered separately.

Audio Equipment. If the transmitter is located some distance from the originating point of the transmitted intelligence and connected to that point by telephone line or radio relay, it is necessary to provide line terminating equipment to match the telephone line properly and to restore the signal, attenuated by the line, to its original amplitude. The necessary pads, line equalizers, line amplifier, together with the percentage-modulation meter and transmitter-frequency monitor, are usually mounted in a standard telephone-type rack in the operating room where they may be conveniently observed by the transmitter operator. It is not ordinarily necessary to provide additional external shielding for this equipment; however, it is necessary that it be adequately grounded through a low-impedance and, preferably, separate ground lead. The incoming audio-frequency circuits and the power supply wiring to the amplifiers should be carefully isolated from each other, preferably by running in separate conduits, or, if in a common trench, by running the audio circuits in conduit. Audio-frequency circuits should use twisted pair enclosed in a tight external shield.

Low-power Intermediate-radio-frequency Amplifiers. This portion of the equipment resembles a low-power transmitter and requires no special comment beyond the points already touched upon under that heading.

High-power Amplifier and Modulator. The installation of these units requires careful planning since they must be installed so that they may be conveniently serviced and so that the required high voltages, cooling air and/or water, and r-f output connections may be conveniently made. Because of the relative simplicity and ease of maintenance, the trend in design of high-power amplifiers has been toward the use of air cooling to dissipate the heat generated in the plate circuits of the r-f amplifiers. For these transmitters provision must be made for an intake for several thousand cubic feet of air per minute, and means must be provided to exhaust this air after it has absorbed the heat developed in the power amplifier tubes. Filters should be provided either in the transmitter or in the air inlet. The exhaust air is frequently piped through ducts out of the transmitter into a mixing chamber where it may either be diverted into the hot air heating system for the building or exhausted outside. Because of the large volume of air required, the inlet duct is frequently installed in the floor below the transmitter. It is possible to use this duct also to carry interconnecting wiring out, but, because of the danger of a rapidly spreading fire in case of an accidental short circuit in this wiring, this practice is not advisable.

Interconnecting wiring between the transmitter units should preferably be carried in separate raceways which may be located in the building floor or arranged as troughs on the side of the transmitter cubicles. All such raceways should be arranged so that they may be conveniently opened for cleaning purposes and to permit changes in wiring as required.

The r-f amplifier should be provided with a low-impedance ground connection preferably in the form of a wide copper strap connected directly to a ground consisting either of buried metal plates or a connection to the antenna ground system, if it is contiguous to the transmitter building.

Rectifier and Power Equipment. It is desirable that the rectifier tubes be located so that they may be observed by the operator at his normal position during the operation of the equipment. Rectifier transformers, however, should be located either in a separate vault or in a transformer yard, enclosed by a grill or fence outside the transmitter house. Fire insurance underwriters' rules should be consulted and closely followed since these rules differ from state to state and usually cover the installation of this type of equipment in some detail.

SUBSTATION. The power line terminal equipment will ordinarily be supplied by the power company having contracted to supply power. This equipment will include any transformers necessary to change the voltage from the power company distribution voltage to the voltage required at the transmitter terminals, together with necessary circuit disconnects, circuit breakers, lightning protectors, and metering equipment. To reduce the possibility of outages resulting from a failure of the power supply, it is advisable, if possible, to provide for power feeds from two separate sources. Automatic equipment is available which will switch from one line to the other in the event of a voltage failure. To secure maximum advantage from such an emergency power supply, the transmitter control circuit should be arranged so that a 1- or 2-sec voltage failure will not necessitate a complete restarting cycle. Either manual or, preferably, automatic reapplication of plate voltage should be provided after a no-voltage drop out, provided, for most rectifier tubes, that such drop out does not exceed 2-sec duration.

SECTION 8

FREQUENCY MODULATION

FREQUENCY MODULATION

FREQUENCY-MODULATION SYSTEMS

By R. D. Duncan, Jr.

In frequency-modulation systems intelligence is communicated by variation of the frequency or phase of the transmitted wave instead of its strength (as is done in amplitude modulation). Frequency modulation is used for broadcasting, for fixed-to-mobile stations, and for one- or two-way communication in services such as police, public-utility maintenance, and forest patrol. It is being introduced into the truck, bus, taxicab, and railroad fields. So-called "studio-transmitter link" equipment, which provides a one-way radio connection in lieu of telephone lines between the broadcast studio and a remote f-m transmitter, utilizes frequency modulation.

During the war, frequency modulation was much used in long-distance relay service, and it is also used in domestic microwave relay service. It is employed in the allied fields of facsimile and television broadcasting. In the latter, it provides the sound channel and has been employed for relay operation. It has also been experimentally used for power-line carrier current communication.

Frequency modulation is not well adapted to circuits subject to multipath transmission effects since serious distortion results from the simultaneous reception of several signals differing slightly in phase.

1. FUNDAMENTAL RELATIONS

The modulating signal in frequency modulation causes the carrier frequency to be systematically varied above and below the unmodulated value, the extent of the variation being determined by the strength of the signal. The number of times a second the frequency is so varied is determined by the frequency of the signal.

This process of variation of the carrier frequency produces additional frequency components, called sidebands, which lie both above and below the unmodulated carrier frequency. Theoretically, there are an infinite number of such upper and lower sidebands which differ in frequency from the carrier by the value of the modulating frequency or frequencies and integral multiples thereof. However, their amplitudes decrease rapidly as they exceed in frequency value the upper and lower limits of the maximum frequency swing imparted to the carrier so that satisfactory reception can be achieved by a transmitting and receiving pass band somewhat greater than twice this maximum swing. An important characteristic of frequency modulation is that the amplitude of the carrier component as well as of the sideband components is determined by both the amplitude of the modulating signal and by its frequency, or, in the case of a complex wave form, by its component frequencies.

Another distinctive feature of frequency modulation is that, theoretically, the power contained in the carrier and the infinite number of sideband components is a constant value. That is, the transmitted power remains unchanged during the modulation if the circuits are such as to transmit all the sideband frequencies. Practically, since only sidebands within and just greater than the maximum frequency swing are transmitted, there will be slight power variation during modulation, or a small amount of amplitude change or modulation will accompany frequency modulation.

SINGLE-FREQUENCY MODULATION. A consideration of single-frequency modulation will serve to illustrate the essential fundamental characteristics of frequency modulation and the difference between it and phase modulation (see article 8-2 for methods of generating frequency and phase modulation).

When the modulating signal is a single-frequency component, the expression for a f-m voltage may be written in the form

$$e_{\text{f-m}} = E \cos \left(\omega t + \frac{\Delta\omega}{p} \sin pt\right) \tag{1}$$

where E = the maximum amplitude.
ω = 2π times the unmodulated carrier frequency.
p = 2π times the modulating frequency.
$\Delta\omega$ = 2π times the peak frequency swing of the carrier.

The corresponding expression for a p-m voltage is

$$e_{\text{p-m}} = E \cos(\omega t + \Delta\theta \sin pt) \tag{2}$$

where $\Delta\theta$ is the maximum phase or angle variation.

The difference between the two expressions is the ($\sin pt$) term. For frequency modulation the maximum phase or angle excursion is directly proportional to the peak frequency swing, i.e., to the strength of the modulating signal, and inversely proportional to the value of the modulating frequency, whereas for phase modulation, it is proportional only to the strength of the modulating signal and is independent of its frequency.

A physical conception of the difference between frequency and phase modulation may be had from Fig. 1. This shows a voltage vector E which without modulation during an interval of time t has rotated counterclockwise through an angle (ωt). If it is assumed that an observer boards the vector, as it were, so as to rotate with it, and modulation is applied, all that will be noticed is a rocking back and forth of the vector through the angle ($\pm\Delta\theta$), or a rotation first in one direction and then in the other through the angle ($\pm\Delta\theta$), which may greatly exceed 360 deg. If the modulation is purely frequency type, it will be noted that, with a fixed signal strength, the maximum angular excursion will be greater for the low modulating frequencies than for the high ones. If modulation is of the phase type, no difference in the maximum excursion of the vector will be noted for any modulating frequency. If the modulating frequency remains fixed, there is no way of determining whether modulation is frequency type or phase type. If amplitude modulation is also present, a slow periodic shortening and lengthening of the vector would be noticed.

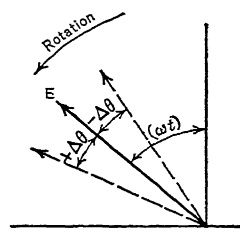

Fig. 1. Voltage Vector with Phase Modulation

In the discussion on the mathematical equivalent of discriminator action (p. 8-09) it is shown that the mathematical equivalent of f-m detection is to take the first differential, with respect to time, of the variable angle through which the vector is rotating. For eqs. (1) and (2) this angle is the argument of the cosine function. Doing this, the two following expressions result.

For frequency modulation

$$\frac{d}{dt}\left(\omega t + \frac{\Delta\omega}{p}\sin pt\right) = \omega + \Delta\omega\cos pt \tag{3}$$

For phase modulation

$$\frac{d}{dt}(\omega t + \Delta\theta \sin pt) = \omega + p\Delta\theta\cos pt \tag{4}$$

The recovered signal is proportional to the periodic term in (3) and (4). For f-m reception, the maximum value of the signal is proportional to the extent of frequency swing and is independent of the value of the modulating frequency. For f-m reception of a phase-modulated wave, the maximum value of the signal increases directly with increasing modulating frequency. By incorporating frequency-distorting circuits at the transmitter or at the receiver, phase modulation may be converted into frequency modulation, or vice versa.

The ratio $\Delta\omega/p$ of Eq. (1) for frequency modulation was originally termed the "deviation ratio" but is now referred to as the "modulation index," the last terminology also applying to the angle $\Delta\theta$ in eq. (2).

The modulation index $\Delta\omega/p$ plays an important part in the theory of noise suppression in f-m systems and involves the circuit characteristics of both the transmitter and receiver. The FCC has established ±75,000 cycles ($\Delta\omega = 2\pi \times 75{,}000$) as 100 per cent modulation for an f-m broadcast transmitter, with a channel band width of 200,000 cycles. It requires that the transmitter be capable of sustaining this maximum peak frequency swing for any aural modulating frequency between 50 and 15,000 cycles, without exceeding certain specified levels of harmonic distortion.

For this maximum peak frequency swing, the modulation index $\Delta\omega/p$ would have a value of 5 for a modulating frequency of 15,000 cycles and a value of 1500 for 50 cycles. There would be five upper and lower sidebands within the overall swing band for the higher modulating frequency and a maximum of 1500 sidebands for the lower frequency.

The standard for 100 per cent modulation for the sound channel of television broadcasting is ±25,000 cycles with the same aural frequency band as f-m broadcasting. It is suggested in the Standards, however, that the f-m transmitter be designed for satisfactory operation at a peak swing of ±40,000 cycles. In the case of point-to-point communication services, such as police, the maximum overall swing band specified by the FCC is three-quarters of the channel band. For the 30–50 megacycle band, one of the several allocated for these services, the channel width is 40,000 cycles, for which the overall swing band would be 30,000 cycles; 100 per cent modulation would then be ±15,000 cycles. Assuming 3000 cycles as the maximum modulating frequency, the modulation index would be 5.

Substituting (P) for the ratio $\Delta\omega/p$ in eq. (1) and for $\Delta\theta$ in eq. (2), the equivalent sideband form of expression may be written as follows:

$$\begin{aligned} e = E[J_0(P)\cos\omega t &- J_1(P)\cos(\omega - p)t + J_1(P)\cos(\omega + p)t \\ &+ J_2(P)\cos(\omega - 2p)t + J_2(P)\cos(\omega + 2p)t \\ &- J_3(P)\cos(\omega - 3p)t + J_3(P)\cos(\omega + 3p)t \\ &+ J_4(P)\cos(\omega - 4p)t + J_4(P)\cos(\omega + 4p)t \\ &- J_5(P)\cos(\omega - 5p)\,t + J_5(P)\cos(\omega + 5p)t \\ &+ \cdots \\ &+ J_n(P)(-1)^n\cos(\omega - np)t + J_n(P)\cos(\omega + np)t] \end{aligned} \tag{5}$$

The coefficients $J_0(P)$, $J_1(P)$, $J_2(P) \cdots J_n(P)$ are Bessel functions of the first kind, of order 1, 2 $\cdots$ n, and argument (P). Values of the argument (P) for frequency modulation, as is shown later on, may vary from approximately 1 radian to the order of 1500 radians. For phase modulation, the maximum value for broadcasting is 5 radians.

For high values of the argument (P), the approximate value of a particular order Bessel function may be computed from the expression (see also Section 1).

$$J_n(P) = \sqrt{\frac{2}{\pi(P)}}\cos\left[(P) - \frac{\pi n}{2} - \frac{\pi}{4}\right] \tag{6}$$

Values of Bessel functions here involved, of zero order, for integral values of the argument from 1 through 9, and for orders 1 through 44, corresponding to integral values of the argument of 1 through 29, are to be found in the book, *Tables of Functions* by Jahnke and Emde. Values corresponding to decimal values of the argument, increasing by increments of 0.2 from 0.2 through 6.0, and in increments of 0.5 from 6.5 through 16.0 for orders zero through 13, are given in British Association for the Advancement of Science, *Reports on the State of Science*, 1915, on The Calculation of Mathematical Tables, pp. 28–33.

For large values of the argument, the reader is referred to Tables of Bessel Functions $J_n(x)$ for Large Arguments by M. S. Corrington and W. Miehle, *Journal of Mathematics and Physics (M.I.T.)*, Vol. 24, 30 (February 1945). Argument values are presented in various incremental groupings, extending from 29 through 300, corresponding to orders zero through 10. Values of the specific function $J_n(1000)$ corresponding to order values of 935 through 1035 increasing by steps of 1 are given in Tables of Bessel Functions $J_n(1000)$ by M. S. Corrington, *Journal of Mathematics and Physics (M.I.T.)*, Vol. 24, 144 (November, 1945).

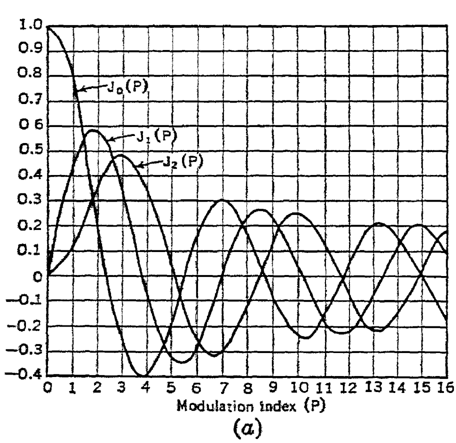

FIG. 2a. Modulation Index (P)

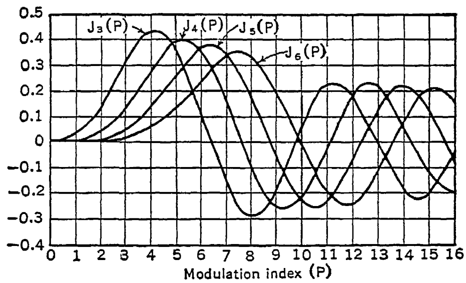
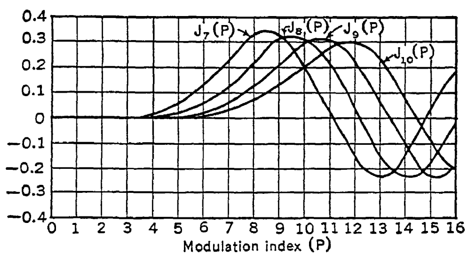
The first ten orders of the Bessel function coefficients of eq. (5) are plotted in Fig. 2. These curves show that, depending upon the value of the argument (P) or modulation indices, $\Delta\omega/p$ or $\Delta\theta$, the different order Bessel functions have both positive and negative values and therefore pass through zero. The amplitude of any sideband component and also of the carrier may be zero, that is, may be entirely missing from the f-m or p-m wave. As is shown later on, this characteristic as it relates to the carrier component provides a basis for measuring the extent of frequency swing or the degree of frequency modulation.

Further illustrative of the relative amplitudes of the carrier and sideband components and the frequency spread, as indicated in eq. (5), values of the first ten order Bessel functions are given in Table 1 for six values of the argument from 0.3 to 5. It is observed that for values of the modulation index of 0.5 and less the amplitudes of the sidebands beyond the first do not exceed approximately 3 per cent of the carrier. For a modulation index



(*b*)

FIG. 2*b*. Modulation Index (*P*)



(*c*)

FIG. 2*c*. Modulation Index (*P*)

of 1.5, the third order sideband is approximately 12 per cent, and the fourth order, 2 per cent, of the carrier. For values of 3 and 5 for the modulation index, all sidebands beyond the sixth and eighth respectively are less than 1 per cent of the carrier amplitude.

Table 1. Values of Bessel Functions

Order n	Argument or Modulation Index (P)					
	(P) = 0.3	(P) = 0.5	(P) = 1.0	(P) = 1.5	(P) = 3.0	(P) = 5.0

8						+0.01840
9						+0.00250

Equation (5) with Fig. 3 illustrates additional differences between frequency and phase modulation. Figure 3 (*a*) shows a carrier and sideband components for a modulation index equal to 5 radians, and for a modulating frequency of 15,000 cycles. All the components in this and the accompanying figures are plotted as positive regardless of their polarity. For a modulation index of 5 and a frequency of 15,000 cycles, the peak carrier frequency swing is 75,000 cycles. Figures 3(*b*) and (*c*) are for this same peak frequency swing; (*b*) is for an aural frequency of 10,000 cycles and a modulation index of 7.5, and (*c*) an aural frequency of 5000 cycles and modulation index of 15. Figures 3(*d*) and (*e*) are for a fixed value of the modulation index of 5; (*d*) is for an aural frequency of 10,000 cycles and a peak frequency swing of 50,000 cycles, and (*e*) for a 5000-cycle aural frequency and a 25,000-cycle peak frequency swing. Figure 3(*a*) is representative of both frequency and phase modulation. Figures 3(*b*) and (*c*) are representative of frequency modulation and Fig. 3(*d*) and (*e*) of phase modulation.

For frequency modulation a decrease in the modulating frequency with a fixed peak frequency swing increases the peak angle swing, alters the respective values of the carrier and sideband components, increases the number of important sidebands within the frequency swing band, and bunches the sidebands lying just outside of the swing band closer

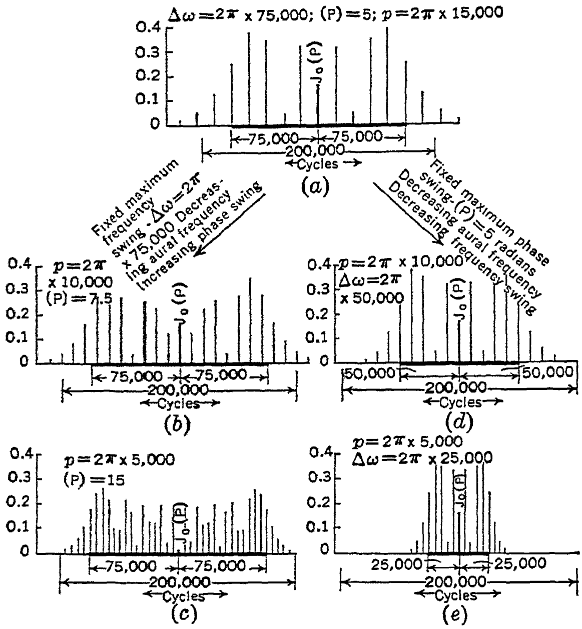

FIG. 3. Sideband Distribution for FM and PM

to the peak swing limits. For the three aural frequencies considered, the first three sidebands lying just beyond the swing limits, the outer one of which is less than 5 per cent in value of the unmodulated carrier, occupy frequency spaces of respectively 45,000, 25,000 and 15,000 cycles.

Going to an extremely low modulating frequency, for example, 75 cycles, there would be a maximum of 1000 upper and lower sidebands within the swing band with some appreciable out-of-band components bunched relatively close to the swing limits. Mathematical analysis of this particular case has shown that the fifteenth out-of-band component which would be displaced by 1125 cycles beyond the swing limits is approximately 1 per cent in amplitude of that of the unmodulated carrier, with the further outlying sidebands rapidly approaching zero.

It is to be concluded for frequency modulation that (*a*) for a given energy content the higher modulating frequencies require a somewhat greater band-pass range from a circuit design standpoint and (*b*) with decreasing modulating frequency the required band-pass range approaches the overall frequency swing band in width. This last explains why only the actual swing band need be considered when the frequency is varied at a very slow rate, for example, by manual change of the capacitance of an oscillator, even though variation is over a relatively large range. It also explains why steady-state analysis, under the assumption of a sinusoidal frequency variation at a low rate, may be employed in the study of f-m circuits yielding results which, when properly interpreted, are sufficiently accurate for design purposes (see article 2-8).

Furthermore the fact that in the usual speech or music programs the energy of these high-frequency tones is quite low keeps the modulation low and hence the magnitude of harmonics of higher order.

The practical result of these factors is that f-m systems work very well with the pass band only slightly greater than the swing band.

In the case of phase modulation, decreasing the modulating frequency, with a fixed phase swing, decreases the overall frequency swing, that is, bunches all sidebands closer together, but alters neither the number of sidebands, their respective amplitudes, nor the amplitude of the carrier.

If eq. (5) represents an f-m voltage wave, the rms value is given by

$$E_{\mathrm{rms}} = \frac{E}{\sqrt{2}}\left[J_0^2(P) + 2J_1^2(P) + 2J_2^2(P) + 2J_3^2(P) + 2J_4^2(P) + 2J_5^2(P) + \cdots\right]^{1/2} \tag{7}$$

The theory of Bessel functions shows that the quantity in the brackets approaches unity as the number of terms becomes large. That is, the rms voltage of an f-m wave or the power transmitted remains substantially at a constant value regardless of the extent of modulation if a sufficient number of sidebands are present.

TWO-FREQUENCY MODULATION. Corresponding to eq. (1), the expression for two-frequency modulation may be written in the form

$$e_{\text{f-m}} = E \cos\left(\omega t + \frac{\Delta\omega}{p}\sin pt + \frac{\Delta\omega}{q}\sin qt\right) \tag{8}$$

where E, ω, p, and $\Delta\omega$ have the same meanings as before and $q = 2\pi$ times the second modulating frequency. The equivalent sideband form of this expression is given by eq. (9), in which, as before, $(P) = \Delta\omega/p$ is the modulation index of the $p/2\pi$ frequency, and (Q), substituted for $\Delta\omega/q$, is the modulation index of the $q/2\pi$ frequency. For simplification, this expansion is limited to the third-order Bessel functions of the two arguments.

The result of two-frequency modulation is the production of major sidebands involving each of the two frequencies and, in addition, other sidebands involving the sums and differences of the two frequencies and integral multiples of the same in different combinations. The amplitudes of all sidebands are products of pairs of Bessel functions. Since, for finite values of the argument, the values of all Bessel functions are less than unity, the product of any pair will be less than the individual value of either of the pair. The change from single- to two-frequency modulation thus greatly increases the number of sideband components and the frequency spread or space occupied. However, the amplitudes of all sidebands have been decreased in value so that, while the frequency spread has increased, the outer sidebands have very low amplitudes.

A similar situation holds when more modulating components are added. That is, in going from a single sinusoidal modulating signal to one of complex wave form the number of sideband components is greatly increased, but their amplitudes automatically become readjusted, or the total modulation is in effect divided between the components, so that the overall frequency spread for all practical purposes undergoes little or no change.

$$\begin{aligned}

&+ \cdots]
\end{aligned} \tag{9}
$$

To avoid overmodulation on the peaks, the average modulation with a complex wave form must be reduced. The necessity for such a reduction is well known in broadcasting.

MEASUREMENT OF FREQUENCY SWING. In the development, testing, and practical operation of f-m equipment, it is necessary to be able to measure the extent of frequency or phase swing or modulation. The fact that the zero-order Bessel function $J_0(P)$ passes through zero with increasing values of the modulation index as shown in Fig. 2 is made the basis for one useful method of measuring the peak frequency or phase swing. In Table 2 are given the first five values of the argument (P) or modulation index for which the zero-order Bessel function $J_0(P)$ becomes zero. Other values may be obtained from the references previously given.

Table 2. First Five Values of Argument (P) for Which $J_0(P) = 0$

2.4048
5.5201
8.6537
11.7915
14.9309

In the operation of this method, a receiver of the heterodyne type is tuned to the unmodulated carrier so that a beat tone of several hundred cycles is obtained. Single-frequency modulation is then applied to the transmitter, the frequency being of a much higher order than that of the beat tone. The strength of the modulating signal is increased until the amplitude of the beat tone drops to zero, which for the first null corresponds to the first passage through zero of the zero-order Bessel function $J_0(P)$. From Table 2, the value of the modulation index for this null point is 2.4048. The value of the modulating frequency $(p/2\pi)$ being known, the peak frequency swing $(\Delta\omega/2\pi)$ is obtained from the ratio $\Delta\omega/p = 2.4048$. Further increase in strength of the modulating signal will develop additional null points corresponding to which values of the modulation index are given in Table 2.

Another method of indirectly measuring the frequency swing provides a visual observation on the screen of a cathode-ray oscilloscope, of the carrier and sideband components in their respective amplitudes and positions within a frequency band somewhat greater than twice the swing band. In this method, the f-m signal wave is heterodyned to an intermediate frequency of 2 Mc, amplified, passed through an a-m detector, and supplied to the vertical deflection plates of a cathode-ray oscilloscope. The heterodyning oscillator is itself frequency-modulated by means of a reactance tube, with a 25-cycle linear-sweep signal to peak values of plus and minus 100,000 cycles. The linear-sweep voltage is also impressed on the horizontal deflection plates of the cathode-ray oscilloscope.

In action, the f-m signal wave, which consists of its carrier and sideband components, is in effect "scanned" frequency-wise from 100,000 cycles below to 100,000 cycles above the carrier, at a rate of 25 times a second. When, during this scanning process, a sideband component or the carrier is encountered, a voltage pulse is impressed on the vertical deflection plates of the oscilloscope. As the linear-sweep voltage is also impressed on the horizontal plates, the particular component will appear in its proper location within the overall swing band.

THE MATHEMATICAL EQUIVALENT OF DISCRIMINATOR ACTION. In theoretical investigations of f-m systems, as with other communication systems, the end product usually sought is a determination of the form of the received signal in comparison with that of the signal originating at the transmitter.

An alternating voltage or current is represented by a vector of length proportional to the maximum or rms value, revolving at an angular velocity equal to 2π times the frequency, or, in customary nomenclature, $\omega = 2\pi f$. In a given time t, the vector will have rotated through an angle of $(\omega t = 2\pi\, ft)$ radians. From the elementary theory of the mechanics of planer rotating bodies, it is known that the angular velocity of rotation of any point in the body about the axis is equal to the first differential of the instantaneous angle of rotation with respect to the time. In the present case, this would be $d(\omega t)/dt = \omega = 2\pi f$; that is, the frequency is equal to the first differential of the instantaneous angle with respect to time.

In conventional a-c theory, a vector revolves at a constant velocity as the frequency has a constant value. In frequency modulation, the angular velocity varies with time, in accordance with the modulation, about a mean or unmodulated value. The frequency obtained by differentiation is therefore the "instantaneous frequency," which is what is sought. The expression for the instantaneous frequency may be a simple periodic function of the modulating frequency or it may be a complex function requiring algebraic and trigonometric operation or a Fourier analysis to break it down into the fundamental and harmonic components.

Expressions are given above for a single- and a double-frequency-modulated f-m voltage wave and single-frequency-modulated p-m voltage wave. These are as follows:

$$e_{\text{f-m}} = E \cos\left(\omega t + \frac{\Delta\omega}{p} \sin pt\right)$$

$$e_{\text{f-m}} = E \cos\left(\omega t + \frac{\Delta\omega}{p} \sin pt + \frac{\Delta\omega}{q} \sin qt\right)$$

$$e_{\text{p-m}} = E \cos\left(\omega t + \Delta\theta \sin pt\right)$$

The first differential with respect to the time of the arguments of the three cosine functions are, respectively, $(\omega + \Delta\omega \cos pt)$ and $(\omega + \Delta\omega \cos pt + \Delta\omega \cos qt)$ and $(\omega + p\,\Delta\theta \cos pt)$. With linear detection the demodulated output is directly proportional to these expressions. With square-law detection, the demodulated output is proportional to the squares of the expressions and would contain second-harmonic components in addition to the fixed and fundamental frequency components. With a balanced discriminator and differentially connected detectors, both the fixed and second-harmonic components cancel out, leaving the fundamental frequency components of double amplitudes. Linear detection is employed almost exclusively in commercial practice.

It is important to note that this mathematical method of recovering an f-m signal implicitly assumes (*a*) that there is no amplitude modulation and (*b*) a linear input-output characteristic of the hypothetical discriminator. It gives only the relative amplitudes of the frequency components but tells nothing of their absolute values. If amplitude modulation is present, the maximum voltage amplitude E in the preceding expressions is also a function of the time and must be taken into due account. Under most practical conditions, it may be assumed that the effects of amplitude modulation are removed, by some means such as limiting, leaving only the variable angle to be investigated.

FREQUENCY-MODULATION TRANSMITTERS

By J. E. Young

Transmitters for two major types of services are discussed in this section. These are frequency-modulation broadcasting, which includes the sound transmitters used for television broadcasting, and emergency communication.

2. FREQUENCY-MODULATION BROADCASTING

Frequency-modulation broadcasting has been assigned the frequency range from 88 to 108 mc. This band has been divided into 100 contiguous channels with carrier frequencies starting at 88.1 mc and ending at 107.9 mc. Transmission in each channel is permitted with a maximum frequency swing of 75 kc, which is designated 100 per cent modulation. To insure that f-m broadcasting will be a high-fidelity service, the FCC has set up the following standards for the overall transmitting system from microphone terminals to antenna:

1. Distortion: less than 3.5 per cent, 50 to 100 cycles, 2.5 per cent, 100 to 7500 cycles at 25 per cent, 50 per cent, and 100 per cent modulation; and 3.0 per cent, 7500 to 15,000 cycles at 100 per cent modulation.

2. Noise level: at least 60 db below 100 per cent modulation in the band 50 to 15,000 cycles.

3. Amplitude noise: at least 50 db below 100 per cent amplitude modulation in the band 50 to 15,000 cycles.

4. Frequency characteristic: the transmitting system shall be capable of transmitting a band of frequencies from 50 to 15,000 cycles. Pre-emphasis shall be employed in accordance with the impedance-frequency characteristic of a series inductance-resistance network having a time constant of 75 microseconds. The deviation of the system response from the standard pre-emphasis curve shall be between two limits. The upper of these limits shall be uniform (no deviation) from 50 to 15,000 cycles. The lower limit shall be uniform from 100 to 7500 cycles, and 3 db below the upper limit; from 100 to 50 cycles, the lower limit shall fall from the 3-db limit at a uniform rate of 1 db per octave (4 db at 50 cycles); from 7500 to 15,000 cycles the lower limit shall fall from the 3-db limit at a uniform rate of 2 db per octave (5 db at 15,000 cycles).

Included in the system for which performance is thus specified are the microphone preamplifier, mixers, program amplifier, studio-to-transmitter link, which may be wire or radio, transmitter line terminating amplifier, and transmitter. The Radio Manufacturers Association, working through industry committees, has specified the performance of the components of the system so that it would be possible to combine elements of different manufacture without exceeding the distortion or noise limits specified. For the transmitter, the following standards have been agreed to in the industry:

1. Distortion: audio distortion, including all harmonics up to 30 kc, shall not exceed 1.5 per cent rms from 50 to 15,000 cycles, and shall not exceed 1 per cent rms between 100 and 7500 cycles. Measurements shall be made at 25 per cent, 50 per cent, and 100 per cent modulation, for audio frequencies of 50, 100, 400, 1000, and 5000 cycles, also at 100 per cent modulation for audio frequencies of 7500, 10,000, and 15,000 cycles.

2. Noise level: at least 65 db below 100 per cent modulation in the band 50 to 15,000 cycles.

3. Amplitude noise: at least 50 db below 100 per cent amplitude modulation in the band 50 to 15,000 cycles.

4. Frequency characteristic: shall not deviate more than 1 db from a straight line, or, if pre-emphasis is used, from a 75-microsecond curve from 50 to 15,000 cycles.

F-M TRANSMITTER—SCOPE. Like the a-m transmitter covered in pp. 7-128, 7-137, the f-m transmitter is considered to consist of all audio equipment operating above standard telephone-practice level and all r-f equipment from the source of the r-f oscillation to the transmission-line terminals. Unlike a-m transmitters, f-m practice is to modulate at low power levels, multiplying the frequency and power, usually many times, before reaching the transmitter output.

FREQUENCY CONTROL AND MODULATION. Frequency control and modulation are tied together since modulation is accomplished by actually swinging the frequency back and forth in accordance with the modulating signal. To accomplish this, and still keep the center, or average, frequency within tolerance (±2000 cycles for f-m broadcasting) is one of the chief problems of f-m transmitter design.

Methods of frequency modulation may be divided into two basic systems. In one of these, phase modulation, modulation is effected at some point in the circuit following the oscillator, which is crystal-controlled. Modulation is accomplished by changing the phase of the crystal-controlled signal at a rate corresponding to the desired modulation. It is characteristic of p-m systems that the frequency shift is proportional to the modulating frequency as well as to its amplitude. To convert to true frequency modulation it is necessary to compensate the frequency characteristic of the modulator, therefore, so that the amplitude of the modulating signal is inversely proportional to its frequency. One system of phase modulation is shown in the block diagram in Fig. 1. A crystal oscillator having a frequency of approximately 200 kc is used to drive a balanced modulator in which the modulating signal is the audio frequency to be transmitted, and whose a-f characteristic has been corrected to convert from phase to frequency modulation as described above. The output of the balanced modulator consists of two f-m currents whose deviations are instantaneously in opposite directions. These two signals are multiplied in frequency 81 times through two separate channels of multipliers. One of the resultant signals is heterodyned to another frequency about 2 mc removed. The resultant frequency and the output of the second multiplier channel are then recombined and their difference recovered. It will be noted that the difference frequency is independent of the frequency of the original oscillator and depends only on the frequency of the 2-mc heterodyne oscillator. Additional multiplication of 48 times is then necessary to reach the final operating frequency.

The phase modulation, at the point of its introduction, is usually restricted to less than 30° in order not to exceed permissible transmitter distortion. In the method described

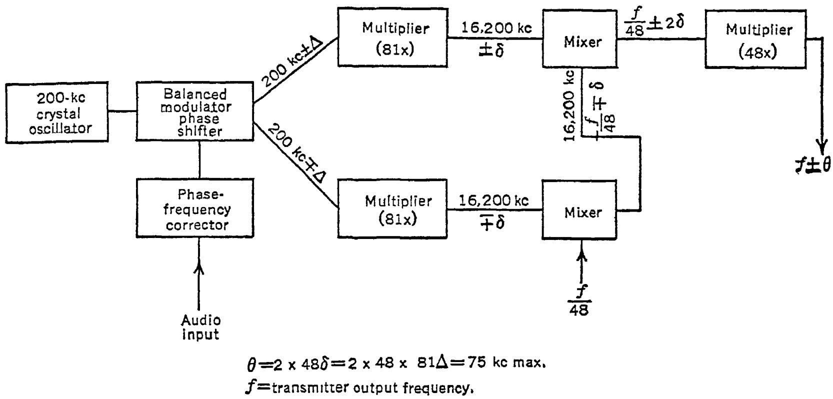

FIG. 1. Frequency Modulation by the Phase-modulation Method

above, since two outputs are obtained from the balanced modulator having phase modulation in the opposing sense, a total phase shift of 60° is possible. The multiplication necessary to convert this phase modulation to frequency modulation, having a frequency swing of ±75 kc, was, in this particular example, 3888 times. The use of dual p-m channels not only permits doubling the frequency swing but also makes it possible to cancel out the effect of the 200-kc crystal in determining the transmitter frequency stability. In the arrangement shown, the carrier frequency stability is a function only of the stability of the 2-mc oscillator. Some improvement in f-m noise level is also obtained at the same time.

Other methods of phase modulation have been developed which are quasi-mechanical in nature. One of these, for which a special vacuum tube has been developed known as the "Phasitron" tube, is used in some commercial f-m transmitters. The block diagram of the circuit is shown in Fig. 2. A crystal oscillator operating at approximately 230 kc

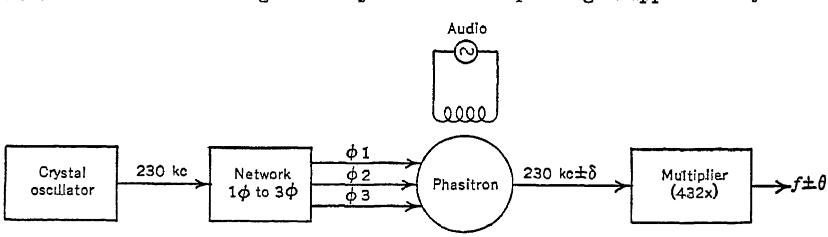

FIG. 2. Frequency Modulation Using the "Phasitron" Tube

(the exact frequency depends on the assigned station frequency) is coupled to a network which, by means of tuned circuits, produces three outputs, all of the same frequency and separated in phase by 120°. These outputs are applied to alternate wires of the deflector grid of the Phasitron tube in such a manner as to produce a rotating field. A cathode and two anodes, which are at a positive d-c potential with respect to the cathode, are arranged so that electrons are drawn from the cathode and focused into the form of a tapered thin-edged disk. This disk, with the cathode for its axis, lies between a neutral plane and the deflector grid structure and extends out to anode 1. The three-phase potential applied to the deflector grid structure deflects the electron beam so that the outer edge of the electron "disk," if it could be seen, would appear to have a sinusoidally serrated edge which rotates about the cathode as a center, at a speed determined by the three-phase voltage applied to the grid. Anode 1, located cylindrically around the cathode, outside the periphery of the deflector grids, has 24 evenly spaced holes arranged around its circumference; 12 of these are above the plane of the electron disk and 12 below. The rotating serrated edge of the electron disk impinges on this series of holes. As the serrations move around the periphery of the electron disk, the electrons alternately pass through the holes to anode 2 and as the serrations move on one-half cycle are completely blocked from anode 2. Thus the current flowing to this anode varies sinusoidally at the crystal frequency. It follows, therefore, that any variation in the angular velocity of rotation of the electron disk will result in a phase variation of the output current from anode 2.

A coil is placed around the outside of the tube so that the magnetic field resulting from the current flowing in the coil is perpendicular to the plane of the electron disk. The electrons traveling radially out of the cathode toward the anodes through this field have a force exerted on them in a direction perpendicular to their path and perpendicular to the direction of the magnetic field. Thus, an angular displacement is introduced in the rotation of the electron disk causing phase variation in the output of anode 2 as described above. Consequently, if an a-f signal current of the proper amplitude flows through this coil the output of the tube will be phase-modulated in accordance with this audio frequency. When there is no audio signal input, the serrations about the periphery of the electron disk will rotate at a constant amplitude, and the output frequency of anode 2 will be the same as the frequency of the crystal.

Phase excursions as great as 720° are possible, in this system, but if low distortion is to be achieved the phase shift must be considerably restricted.

DIRECT FREQUENCY MODULATION. Direct modulation of the transmitter master oscillator may be accomplished by several different methods. They all function by changing the reactance of the frequency-controlling part of the oscillator circuit

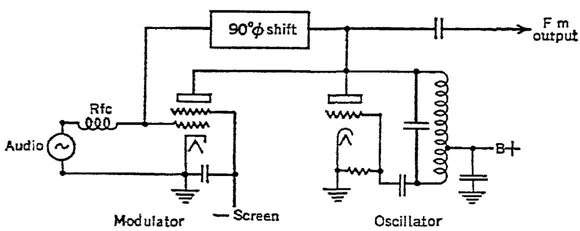

FIG. 3. Frequency Modulation by Reactance Tubes

in accordance with the modulating frequency. One of the commonest of such systems is the use of a tube or tubes having their plates connected to the oscillator circuit and their grids excited by an r-f voltage derived from the oscillator tank and shifted in phase 90° with respect to the oscillator tank voltage. Plate current drawn by these tubes will then be 90° out of phase with the oscillator output and thus has the characteristic of a positive or negative reactance. The amplitude of this plate current is then varied by means of the audio signal, which is also impressed on the grid, and, consequently, the oscillator frequency shifts in accordance with the a-f signal. The basic circuit is shown in Fig. 3.

Another method of achieving frequency shift in the master oscillator is to connect the grid circuit of the modulator in parallel with the oscillator tank. See Fig. 4. In this cir-

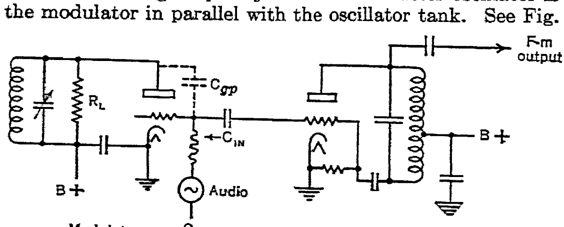

FIG. 4. Frequency Modulation by Input Capacitance Variation

cuit, frequency modulation results from the fact that the input capacitance of the modulator tube is a function of its plate circuit impedance and its transconductance, so that

$$C_{in} = C_{gp}(1 + g_m R_L)$$

It follows that, if the transconductance is varied by the audio input signal, frequency modulation in accordance with the audio input is obtained.

All the systems of direct frequency modulation have the common characteristic that the transmitter frequency control is effected with reference to a separate, highly stable oscillator. These control systems may be divided into two categories, those in which the restoring force is proportional to the deviation, and those in which full restoring force is developed regardless of the amount of deviation. In general, the latter will provide the most accurate frequency control since the transmitter output frequency will be an exact multiple of the reference oscillator frequency if the system is functioning properly. The control voltage developed by the error signal in either system may be used to correct the master oscillator frequency, either by changing the bias of the tube used to effect modulation or through an electromechanical device driving a correcting capacitor in the tank circuit of the oscillator.

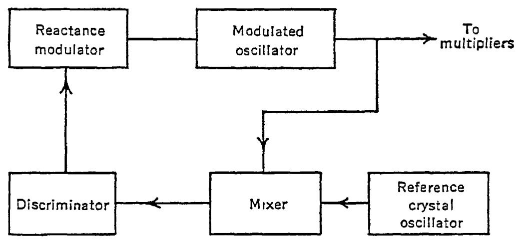

Fig. 5. The Crosby Method of Frequency Control

One of the earliest of the first type of systems is shown in Fig. 5. A portion of the output of the f-m oscillator, which is modulated by reactance tubes, is fed into a mixer, together with the signal from the reference crystal oscillator. The beat between these two signals is fed into a discriminator tuned so that it is working on the center of its characteristic when the frequency of the modulated oscillator is the exact submultiple of the transmitter frequency. As the modulated oscillator drifts away from the correct frequency, the beat signal fed into the discriminator changes frequency accordingly and a d-c voltage is developed by the discriminator. This voltage is applied to the grids of the reactance tubes in the proper sense to correct the frequency of the oscillator. This method of frequency correction may be thought of as akin to negative feedback, since the degree of correction is a function of the gain through the mixer and discriminator, and the sensitivity of the reactance tubes.

One of the several variations of the second type of system is shown in Fig. 6. The master oscillator is frequency-modulated by a reactance tube or other electronic means. A sample of its output is divided in frequency by a locked-in oscillator, or multivibrator, to a frequency low enough so that the carrier frequency will not vanish for any percentage of modulation of any audio frequency in the normal pass band. For example, in one transmitter the modulated oscillator has a center frequency of 4 Mc, requiring a 3-kc swing to achieve a 75-kc frequency swing at the transmitter output frequency. The center frequency is divided by 256 so that the frequency swing reaches a maximum of 12 cycles per second. If an audio modulating frequency of 30 cycles per second is used, the phase shift is then 0.4 radian or 24°. This modulation index reduces the carrier to 0.96 times its unmodulated value; consequently, a carrier frequency component is always present to effect synchronization. The output of the reference crystal oscillator is also divided in frequency, in order to use a crystal which can be easily manufactured, and these two outputs are fed into a balanced phase detector. If the two inputs to the phase detector are exactly 90° out of phase its output will be zero. Any shift in phase difference away from the 90° point will produce an output voltage with a positive or negative sign depending on whether the phase shift is greater or less than 90°. This voltage is then applied to the modulator tube grid to correct the frequency of the master oscillator.

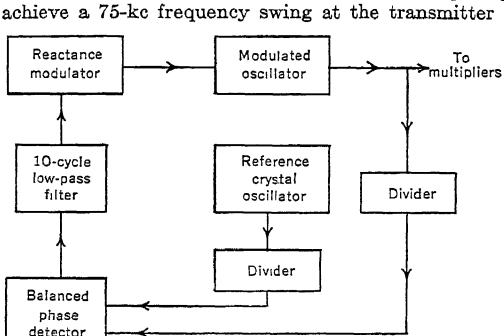

Fig. 6. Phase Detector Method of Frequency Control

A system of frequency correction utilizing an electromechanical circuit is shown in block diagram in Fig. 7. In this circuit the oscillator is modulated by reactance tubes in the conventional manner. A sample of the output of the modulated oscillator is divided by 240 and then fed into the grids of a pair of balanced modulators. The output of the reference crystal oscillator is divided by 5 and then split through two phase-shifting networks, arranged to provide a 90° phase difference between the two branches. One of these branches is fed into the grid circuit of one of the balanced modulators and the other to the grid circuit of the second balanced modulator. If the divided down signal from the f-m oscillator is in phase with the divided signal from the reference oscillator there will be no a-c output from the balanced modulators. However, if there is any frequency difference, an a-c voltage will be developed in the plate circuits of each of the balanced modulators and the two voltages thus obtained will differ in phase by 90°. These

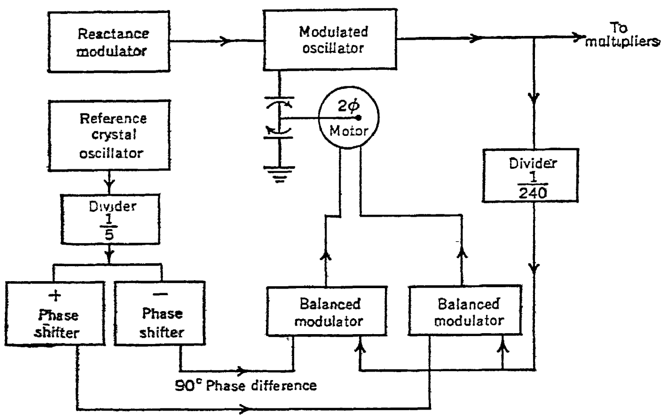

FIG. 7. Electromechanical Frequency Control

two outputs are connected to the two windings of a two-phase motor, and the shaft of this motor is arranged to drive a small capacitor connected in the tank circuit of the f-m oscillator. The a-c outputs of the balanced modulators, resulting from a frequency deviation in the modulated oscillator, produce a rotating field in this motor which tends to rotate the variable capacitor in the proper direction to correct for the frequency error. As soon as the frequency of the modulated oscillator has been restored to the point where its submultiple is in exact synchronism with the submultiple of the crystal oscillator, the a-c output of the balanced modulators drops to zero and the tuning capacitor comes to rest.

Another frequency-control circuit operating on a different principle is shown in the block diagram, Fig. 8. In this circuit the outputs of the master oscillator and the crystal oscillator are combined in a pair of mixers, in one of which the input from the crystal oscillator differs in phase by 90° from the input to the other. The output of one of the

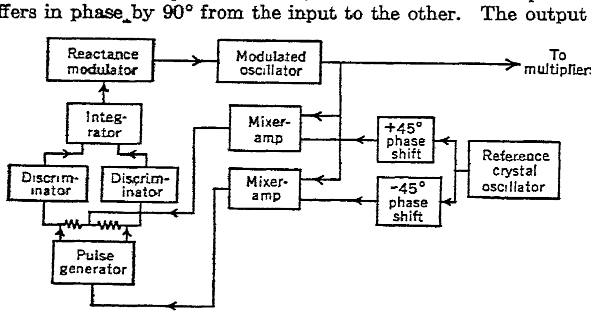

FIG. 8. Pulse Counter Frequency Control

mixers is fed through a pulse generator and thence through a pair of discriminators. The discriminators are biased diodes. The bias on these diodes is set just above the peak value of the output of the second mixer. The result is that, when the pulses add to the sine-wave output of the second mixer, the bias is overcome and the pulse is passed through the diode. When the pulse subtracts from the sine wave the bias prevents the diode from conducting and the pulse is not passed. This arrangement serves to separate the pulses into two circuits; one circuit is energized by one pulse for each cycle of beat between the master oscillator and the crystal oscillator when the signal frequency is high, and the other circuit is energized by one pulse for each cycle of beat when the signal frequency is low. The outputs of the two discriminators are fed to an integrator, which is simply a large capacitance and thence to the grid circuit of a cathode follower. The output of this tube is connected to the tube which effects frequency modulation, and thereby controls the frequency of the master oscillator. This circuit will tend to hold the center frequency so that the frequency swings higher and lower than the correct frequency by the same total number of cycles. The correction is continuous, and the speed at which a frequency shift is reflected in a correcting voltage is a function of the time constant of the integrating capacity.

3. FREQUENCY MODULATION FOR EMERGENCY TRANSMITTERS

Phase modulators, corrected to obtain frequency modulation, are used almost exclusively for this class of service. The necessary degree of phase modulation can be achieved with relatively few stages of multiplication of the f-m signal. This results from the combination of two requirements that greatly restrict the necessary p-m angle. The first of these is that a comparatively narrow frequency swing is used, varying from ± 12.5 kc in the 25 to 30 Mc band to ± 22.5 kc in the 152 to 162 Mc band. The second is that the lowest unattenuated modulating frequency need be no lower than 500 cycles per second. Thus, if a phase swing of 1 radian can be obtained in the modulator, a multiplication of only 45 is necessary to achieve a frequency swing of 22.5 kc. Since considerable distortion is tolerable before any loss of intelligibility results, phase modulators having much more inherent distortion may be used for this class of service than for f-m broadcasting. Overall distortion as high as 10 to 15 per cent has been found to have no effect on the intelligibility of the signal. Since most transmitters of this type are portable, the most important characteristics are small size and weight, and the minimum number of tubes.

4. TRANSMITTER CIRCUITS

Because of the many times the f-m signal must be multiplied, in f-m transmitters, to obtain the necessary frequency swing, the low power

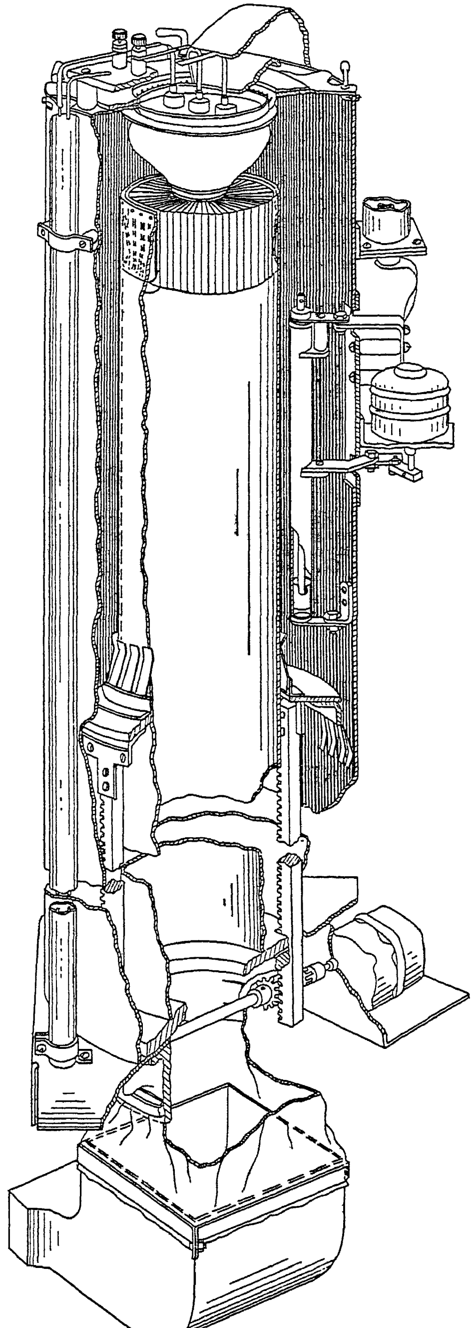

FIG. 9. Coaxial Tank Circuit

stages operate through the frequency range covered by the section on a-m transmitters. Additional care is required in f-m transmitter design to avoid high-Q circuits, since the band widths required are greater than in other transmitters. For the same reason, it is desirable to use circuits that have symmetrical phase-shift characteristics about the center frequency.

Output amplifiers for transmitters of power above 250 watts usually employ tubes having internal capacitances great enough to necessitate the use of transmission-line-type tanks. To avoid stray fields which might affect the operation of the exciter stages, and to simplify the problem of keeping the transmitter enclosure and outer conductor of transmission lines at ground potential, these circuits are preferably made in the form of concentric lines. One such typical circuit is shown in Fig. 9. In this illustration a triode is used. To avoid interaction between plate and grid circuits, the grid is grounded for r-f voltages, and excitation voltage is applied between ground and the filament of the tube. A three-quarter wave tuned transmission line is used and is in turn coupled to the output of the driver by a small, single-turn loop. The plate circuit is a coaxial line, in which the anode of the tube forms a continuation of the inner conductor. The line is tuned by moving a by-pass capacitor provided with fingers which make contact with the inner and outer conductor, along the line. Output coupling is obtained by positioning a loop in the space between the inner and outer conductors. Control of the tightness of the coupling is effected by changing the angle of the loop. Maximum coupling is obtained when the loop lies along a radius of the outer conductor.

FREQUENCY-MODULATION RECEIVERS

By Leslie F. Curtis

5. COMPARISON WITH AMPLITUDE-MODULATION RECEIVERS

Conventional f-m receivers use the superheterodyne principle and differ from a-m superheterodynes mainly in the i-f amplifier and in the second detector.

The intermediate frequency is chosen to give adequate image reduction depending on the service. An intermediate frequency of 10.7 Mc is suitable, and is specified as an RMA standard, in receivers for f-m broadcasting in the assigned band from 88 to 108 Mc since the image response then falls outside the bands having assigned services which are liable to interfere. A higher intermediate frequency of the order of 21.7 Mc is required for the sound channels of television receivers to avoid interference. The higher frequency is favored in receivers incorporating both f-m broadcast and television facilities since the same components may then be used for both.

The i-f band width should be sufficient to pass the side frequencies at the maximum system frequency deviation without excessive attenuation of the power in any of them to preserve the fidelity of the modulation. A band width of at least 150 kc for a reduction of not over 50 per cent on the overall response curve at maximum deviation is required in receivers for f-m broadcasts. (See Section 7, article 12.) This applies even when an amplitude limiter follows the i-f amplifier, since, although a limiter removes amplitude modulation, it cannot remove the phase distortion introduced in the tuned circuits. A flat or slightly rounded i-f response curve is preferred since double-peaked curves increase the phase distortion within the receiver. The uniformity of response over the required band should be as good as can be obtained with overcoupled or stagger-tuned i-f circuits if no limiter is used. Receivers for special purposes which utilize narrow system deviations commonly use limiters, and operate on the portion of the i-f response curve which is above 50 per cent of maximum.

It is possible to reduce the frequency deviation, and therefore the band width necessary for the i-f stages, by feeding back some of the demodulated audio output to a reactance tube associated with the superheterodyne oscillator to cause it to follow partially the original frequency deviation. The distortion in the receiver and the overall noise-to-signal ratio are reduced thereby, although the system is rather expensive.

The overall gain in an f-m receiver is usually greater than in an a-m receiver since satisfactory reception may be had at very low levels of input to the antenna terminals, and since, when a limiter is used, the input voltage at its grid terminals must be at least 1 volt. In general, gain is uneconomical in the r-f stages at the frequencies assigned for f-m broadcasting, and practically all the gain is usually obtained at intermediate frequencies. The usual i-f plus converter gains are of the order of 10,000. The band width required lowers the gain per stage, and usually one or two more i-f stages are required in an f-m receiver than in an a-m receiver using the same types of tubes.

The frequency detector directly or indirectly converts the frequency modulation to amplitude modulation and then recovers the audio signal by amplitude detection (see, however, last paragraph of article 8-7). Some means of reducing or preventing response to spurious amplitude modulation due to noise and due to the variation in amplification as the frequency is deviated over the i-f pass band is usually associated with the frequency detector. This may be an amplitude limiter preceding the frequency detector, or the frequency detector itself may be of a type which is non-responsive to amplitude modulation.

A frequency detector with a balanced output, that is, one in which the net rectified output is zero at the mean intermediate frequency, is preferred since spurious audio output can then be produced only during deviation of the frequency due to the desired modulation and is masked considerably by the latter. The d-c output of a balanced frequency detector may be used to control the bias of a reactance tube associated with the oscillator and thereby furnish automatic frequency control. De-emphasis circuits to compensate for the pre-emphasis at the transmitter (corresponding to the voltage across an inductance in series with a resistance when the combination has a time constant of 75 microseconds), and tone-control circuits, are usually included in the a-f system.

Antenna input systems, the superheterodyne oscillator, and the first detector are usually the same in f-m receivers as in a-m receivers for about the same transmitted frequency except that there is more tolerance in tuning and in frequency drift in f-m broadcast receivers than in narrow-band receivers.

Automatic volume control may be incorporated and is desirable to keep the voltage applied to the input of the limiter or non-amplitude-responsive detector at a level which prevents overall response to rapid variations of the net antenna input voltage over as wide a range as possible.

Certain types of f-m broadcast receivers are difficult for a novice to tune by hand since there are multiple tuning positions where there is almost equal volume of response to the desired program. Minimum harmonic distortion is obtained in only the position which corresponds to the most linear portion of the frequency detector characteristic. The program is demodulated in the other positions by the slope of the sides of the i-f response curve and sometimes by the reverse slope of the skirts of the frequency detector characteristic. A greater volume of even-harmonic distortion than fundamental often is produced between the several tuning positions for maximum response. Accurate tuning is also required for the most effective reduction of response to impulse noise.

A zero-center-indicating meter operated by the d-c output of a balanced frequency detector makes an excellent tuning indicator. It indicates zero for the proper tuning position, and the direction of the deflection shows the direction of any mistuning. Twin electron-ray tuning indicators, in which the illuminated portions of the opposite halves are unequal except in the proper position, are sometimes used in broadcast receivers.

Receivers for operation in both the a-m and f-m broadcast bands generally use many of the circuit components in both bands. The intermediate frequency for the f-m section is much higher than for the a-m section, but transformers incorporating tuned circuits for both frequencies are quite satisfactory. The r-f and converter stages tolerate a minimum of switching because of the high frequency and are often separate for the two bands in the more expensive receivers. The audio amplifier and power-output stages are usually common to both sections. Particular care in the design of the audio amplifier and sound reproducer is justified since low harmonic distortion and excellent signal-to-noise ratio are realizable with frequency modulation.

Figure 1 is the circuit diagram of the r-f, i-f, and detector portions of a low-priced fm-am receiver. The desired band is selected by a ganged switch for the r-f, oscillator, converter, avc, and detector circuits. Both bands are tuned with a two-gang condenser having separate stator sections for the two ranges. The f-m section includes a broad-band input transformer for a 300-ohm transmission line, a tuned input circuit to the converter, and delayed avc to obtain the proper input level for the ratio-type frequency detector. The a-m section includes a condenser-tuned low-impedance loop and series loading coil, means

for additional antenna input from the leads of the 300-ohm line in parallel, and an untuned input stage for the converter.

Crosstalk between common-channel f-m stations is reduced in receivers incorporating good a-m rejection means to a point where only the modulation of the stronger of two stations is audible. Cross-modulation in the stages of an f-m receiver due to the nonlinearity of tube characteristics is relatively small, whereas in a-m receivers it is one of the major causes of interference at certain input levels.

Phase modulation differs from frequency modulation only in the manner in which the frequency modulation index (deviation ratio) is caused to vary with the modulating frequency. In phase modulation it is proportional to the product of the amplitude and frequency of a modulating component, whereas in frequency modulation it is proportional to the amplitude of the component. Receivers for phase modulation are therefore like receivers for frequency modulation, designed with an i-f band width suitable for the maximum frequency deviation from the center frequency, but with an audio filter following the frequency detector to restore the original amplitude of the modulating component for the output. Pre-emphasis of the higher audio frequencies, as specified by the FCC for f-m broadcasting, gives some of the characteristics of phase modulation to this portion of the transmission.

6. FREQUENCY DETECTORS

Frequency detectors usually consist of some form of i-f slope filter which has a linear variation in output voltage with frequency deviation to the maximum assigned deviation, preferably fed with constant current from the last i-f amplifier, and followed by a conventional amplitude detector. Detectors employing a phase shift between the voltages applied to separate grids of multielectrode tubes corresponding to the frequency deviation have been described but are not commonly used. Circuits which provide frequency detection in a single tube and which are substantially unresponsive to amplitude modulation are in the developmental stage. The detectors described herein have had commercial application.

SIMPLE SLOPE FILTERS. A loosely coupled i-f transformer tuned to one side of the mean intermediate frequency and operated at a point on the side of the resonance curve where the response is about 72 per cent of maximum provides a simple slope filter. The conditions differ with the coupling, but, for example, when the coefficient of coupling between primary and secondary windings is $0.3/Q$, where Q applies to both primary and secondary windings, the variation in amplitude is substantially linear over the range in frequency in which the amplitude varies from 50 to 95 per cent of the maximum for that stage alone. The frequency characteristic for this condition is shown in Fig. 2. The Q of the circuits is reduced by loading so that Qf/F is 0.2, where f is the expected frequency variation from the mean and F is the mean intermediate frequency. The frequency for maximum response for the stage is separated from the mean frequency by $0.35\ F/Q$ and may be either above or below it. Full use of the most linear portion of the characteristic results in 22.5 per cent amplitude modulation, whereas a single tuned circuit provides only 15 per cent. The i-f amplifier is tuned to flatness to operate about one of the operating points mentioned. Final demodulation is obtained in a conventional diode rectifier following the filter.

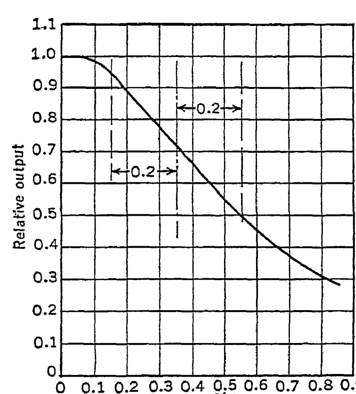

FIG. 2. Frequency Characteristic of Slope Filter

This type of frequency detector is not often used since it provides no inherent balance against spurious amplitude modulation. The output due to impulse noise in this type of frequency detector is much more disturbing than in one which is balanced for zero output at the mean intermediate frequency.

DISCRIMINATORS. Discriminators as shown in Figs. 3(a) or 3(b) are used widely as frequency detectors since they provide an inherent balance against amplitude modulation at the mean intermediate frequency and require only a minimum number of components and adjustments. The i-f voltages applied to the two diodes are respectively the sum and difference of the primary voltage and one-half the secondary voltage of the transformer, which is tuned to the mean intermediate frequency. Since these voltages differ in phase by 90° at the mean frequency, the diode voltages are then equal. The rectified voltages are opposed so that there is no net output at the mean frequency. The voltage applied to one diode increases, while that applied to the other decreases, at higher instantaneous frequencies since the secondary voltage then lags by more than 90°. The reverse is true at lower instantaneous frequencies, and a directional output substantially proportional to the instantaneous frequency deviation over a considerable range is obtained. Thus an audio voltage is available at the output terminals which has an amplitude proportional to the frequency deviation of the applied signal. A d-c output which depends on the difference between the mean applied frequency and the frequency to which the unit is tuned is also developed if these are unequal.

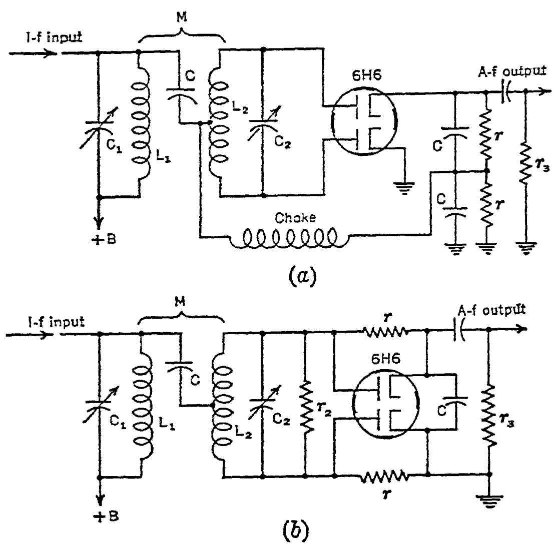

FIG. 3. Discriminator Circuits

Figure 4 illustrates typical shapes of characteristic curves obtained in a discriminator stage when the primary and secondary inductances and Q's are equal. The curves are plotted in terms of Qf/F, where f/F is the ratio of the instantaneous frequency deviation to the center frequency. The actual output is obtained by multiplying the relative output by $\sqrt{2}eQL\omega I$, where e is the rectification efficiency of the diode, L is the inductance of the windings, ω is the mean intermediate angular frequency, and I is the rms value of the current supplied by the last i-f stage. The linearity and the magnitude of the output are near optimum for the conditions shown when the product of the Q and the net coefficient of coupling between windings is about 2.7 although many similar curves may be obtained when the primary and secondary inductances and Q's are unequal.

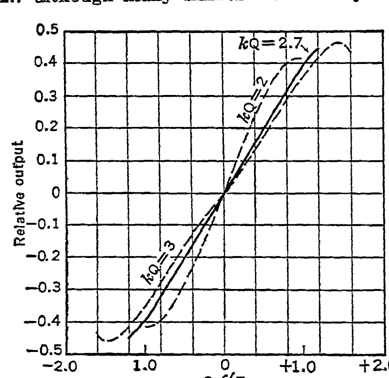

FIG. 4. Discriminator Characteristics

It is important in obtaining a symmetrical characteristic curve that the secondary winding and circuit be symmetrical with respect to ground. This requires that the center tap on the secondary be placed properly, that the coupling between the halves of the secondary be close, and that the leads to the diodes be short and have no spurious couplings to other parts of the circuit. The diode capacitances should be equal since that of one aids, while that of the other opposes, the magnetic coupling between the windings. The required Q, which includes the effects of diode loading, and which may be reduced by circuit loading if necessary to obtain the proper band width, may be estimated from the abscissas of Fig. 4 over which the linearity is satisfactory for the expected ratio of f/F. The coupling and by-pass condensers C are made only large enough to have low impedance at the intermediate frequency while their impedance at audio frequencies is large. The current through each diode load resistance r should be only that rectified by the individual diode. Any shunt resistance across the output terminals, such as r_3, is made large so that the current through it and the two resistors r in series will not bias appreciably the diode delivering the smaller instantaneous output.

The i-f choke shown in Fig. 3(a), which is effectively in parallel with the primary inductance, may be omitted if the diode loads are connected as in Fig. 3(b). This is permissible if the desired Q can be obtained with the increased loading effect which the diodes present for this connection. Each individual diode presents a load of $r/1.8$ in Fig. 3(a) and $r/2.8$ in Fig. 3(b), where r is as indicated in the figures, and the diode rectification efficiency has the usual value of about 90 per cent. The desired Q may be obtained either by loading the windings, as with r_2, or by designing the individual windings with the diameter and spacing of turns which result in the required value.

The frequency at which the response is zero is adjusted by tuning the secondary circuit of the discriminator. The symmetry of the response curve about the zero point is adjusted by tuning the primary circuit. This procedure is easier than adjusting each individual circuit for resonance at the center frequency.

Some special-purpose receivers are arranged to respond to either frequency modulation or amplitude modulation in the same transmission band by providing a reversing switch for one of the diodes of the discriminator. When one is reversed from the polarity indicated in Fig. 3, the sum, rather than the difference, of the rectified voltages is applied to the output, which is proper for the demodulation of a-m waves.

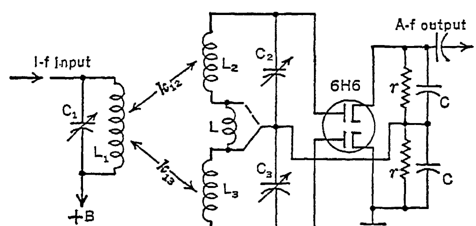

Fig. 5. Frequency Detector with Side-tuned Circuits

SIDE-TUNED CIRCUITS AS FREQUENCY DETECTORS. Another frequency detector which has zero output at the mean intermediate frequency consists of separate tuned circuits C_2L_2 and C_3L_3 individually tuned slightly above and below the center frequency and connected as shown in Fig. 5. The response curve is shown in Fig. 6. The stage is tuned by adjusting the peaks of the S curve, each of which depends chiefly on the tuning of one of these circuits but is influenced slightly by the tuning of the other. An alternative tuning method is to transfer the connection between the two tuned circuits from the full-line to the dotted-line connection after tuning both circuits to the center frequency. The incremental inductance L is chosen to shift the resonance by the proper amount in opposite directions.

Neglecting the coupling between the two side circuits caused by the common primary circuit C_1L_1, to which they are individually coupled, the best linearity of the characteristic is obtained when $f_1/F = 0.75/Q$, where f_1 is the frequency displacement of either resonant side circuit from the center frequency. The relative output for this case is shown in Fig. 6 plotted against relative instantaneous frequency deviation Qf/F. The actual output depends on the coupling to circuit C_1L_1. The capacitance C_1 of the driving tube may be tuned out at the center frequency, and the effects of the primary circuit over the band may be minimized by loading it with resistance. The presence of the tuned primary circuit slightly improves the linearity of the S curve near its peaks by an amount not shown in Fig. 6, and depending on its coupling with the side circuits. To obtain the best linearity for both positive and negative deviations it may be necessary to use slightly different Q's in the two side circuits and slightly different coefficients of coupling between the primary and these circuits. Such expedients compensate for the fact that the resonant peaks of the side circuits are not at the same frequency.

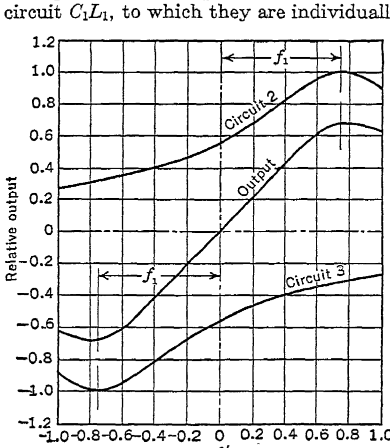

Fig. 6. Frequency Characteristic with Side-tuned Circuits

RATIO-TYPE FREQUENCY DETECTORS. One type of frequency detector which can be made to be non-responsive to any undesired amplitude modulation has been called a ratio detector, since the net output is approximately proportional to the ratio of the i-f voltages applied to the two diodes, although the process by which this is accomplished is indirect, and a more complete analysis shows that the ratio of the circuit impedances rather than the voltages is involved. Two of many possible arrangements are illustrated in Figs. 7(*a*) and 7(*b*). In Fig. 7(*a*) the filter is quite similar to the discriminator previously described except that the components are designed to tolerate a greater a-c load current. In Fig. 7(*b*) the side-tuned circuits C_2L_2 and C_3L_3 are in series with no magnetic coupling to the choke feed L_1, while capacitance C_1 is as small as possible to reduce the undesired coupling between these circuits. In both arrangements condensers C are only large enough to have low impedance at the intermediate frequency.

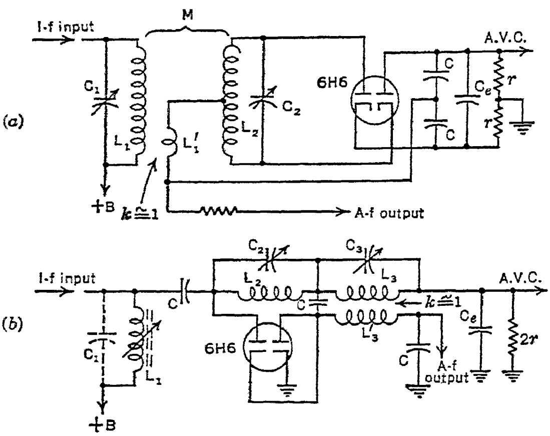

FIG. 7. Ratio-type Frequency Detector Circuits

The diodes are in series and are therefore forced to carry the same rectified load current which charges a large electrolytic condenser C_e to a voltage which depends on the mean i-f signal level. During desired frequency modulation or undesired amplitude modulation, this voltage, all or a part of which may be used also for automatic volume control, remains constant and establishes conditions for the mean rectification efficiency of the diodes and for a voltage drop in the a-c impedance of the source. The action is illustrated by the diagrams of Fig. 8 which are not to scale but show, diagrammatically, superimposed regulation curves for the diodes (one inverted to show the division of the electrolytic condenser voltage E) for several conditions. Figure 8(*a*) shows the relations between the output current and the component voltages which lead to operation at a particular value of output current at one input level and frequency. The peak voltages applied to the input terminals of the diodes are E_1 and E_2 respectively. They have maximum values for no rectified current since the a-c diode input current is from 1.67 to 2.0 times the rectified current, depending on the rectification efficiency of the diodes. The rectified voltages, whose sum is E, are the input voltages multiplied by the individual rectification efficiencies and are e_1 and e_2 respectively. The diodes are in series, and the common-current operating point is shown by the marked intersection.

The a-c diode input current is in phase with the input voltage, but the filter networks carry substantial reactive components of current. Furthermore, the relations between the diode input and output currents and voltages are non-linear. Therefore the characteristics cannot be expressed readily in terms of the circuit constants. However, each circuit and associated diode has a definite regulation curve for each frequency and for each current level supplied by the last i-f tube. The effective impedance which determines the output voltage drop in terms of the output current depends primarily on the impedance of the tuned circuits and secondarily on non-linear functions of the current and voltage.

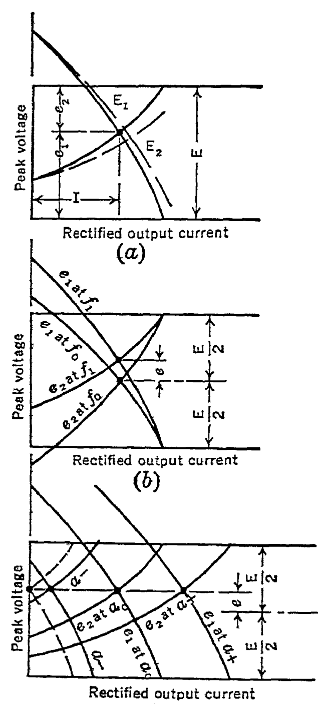

FIG. 8. Regulation Curves in Ratio-type Frequency Detectors

Figure 8(*b*) shows the effect of deviating the frequency. This changes the filter impedances and consequently the effective output impedance and the slope of the regulation curves. The difference between either diode output voltage and its mean value, $E/2$, varies at the modulating frequency and represents the desired audio output.

Figure 8(*c*) shows the effect of amplitude modulation of the input signal at a given frequency. The voltage E remains constant at its mean value by virtue of the charge on the electrolytic condenser. The output current varies instantaneously with amplitude modulation although its mean value is substantially constant. If the degree of inward modulation is sufficient to reduce the rectified current to zero as illustrated by the dotted lines, rectifying action is lost and intolerable distortion results. The resistance r is made smaller than in conventional discriminators to allow for a margin in inward modulation without reaching these limits. The ratio of the uniform signal to the instantaneous signal which will produce cut-off is the overdrive and should be at least 2 to 1. It is particularly important that the relations be so chosen that the detector is not cut off when the instantaneous voltage swings to its lowest value as the frequency is deviated over the selectivity response curve of the receiver.

It can be shown that with ideal diodes with rectification efficiencies of 100 per cent, and with non-reactive source impedances, the output voltage e is independent of amplitude modulation when the short-circuit currents I_s, as shown by the regulation curves, are the same for the two diodes. The output is then $e = 0.5E(Z_1 - Z_2)/(Z_1 + Z_2)$, where Z_1 and Z_2 are the impedances of the two filter sections. In actual ratio-type frequency detectors the phase angle of the filter impedance varies with the frequency deviation and the diode efficiency depends on both applied voltage and rectified current. It is therefore difficult to compensate perfectly for amplitude modulation over a wide range of either signal level or deviation. The best combination of impedances is determined by trial. For the circuit of Fig. 7(*a*), for example, optimum values of coil inductance L_2 and L_1', mutual inductance m, resistance r, and capacitance C will be found for a particular type of tube and range of operating levels for the best linearity of desired output and reduction of amplitude modulation.

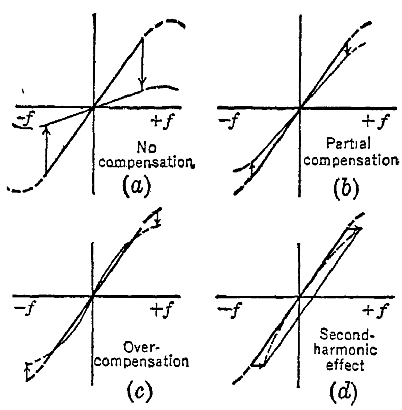

Fig. 9. Amplitude Compensation in Ratio-type Frequency Detectors

Some of the possible detector characteristics for simultaneous amplitude and frequency modulation are illustrated in Fig. 9. The curves drawn with heavy lines show the output during maximum outward amplitude modulation. Figure 9(*a*) is for a conventional discriminator without the compensating effect of the ratio-type detector. Figures 9(*b*) and 9(*c*) are for partial and overcompensation respectively. In (*c*) high input level produces less output over a portion of the deviation range than lower input.

The diodes carry components of current at the second-harmonic frequency as well as at the fundamental frequency. This current returns through the filter sections and produces a small second-harmonic voltage which shifts the effective phase of the peak voltage to be rectified. This effectively detunes the filter sections synchronously with the amplitude modulation and accounts for an unbalanced characteristic as illustrated in Fig. 9(*d*) between two signal levels. When the variation in input level is due to deviating over a non-uniform selectivity response curve of the receiver, the resulting characteristic may be as shown by the dotted line.

The demodulated signal rises and falls with the applied signal when it is varied slowly, as in tuning. This is an advantage, since the proper tuning position is then indicated by maximum volume.

Since a large degree of reduction of amplitude modulation is obtained in the ratio-type detector stage itself, limiting in the previous stages is not always required, and the signal level at the last i-f tube need not be as high as in receivers using limiters. Automatic volume control may provide sufficient control of signal level.

Multipath transmission through space of the signal applied to the antenna terminals of the receiver may result in amplitude modulation sufficient to reduce the instantaneous input to the diodes in a ratio-type detector below their cut-off level, and in this case a receiver having high i-f gain followed by limiter is superior.

7. LIMITERS

An ideal limiter or limiting system for operation at the intermediate frequency of an f-m receiver delivers an rms output which is independent of the input when the input is above a threshold level. (However, a proposed type "dynamic limiter" gives output proportional to the *average* input but wipes off any a-f amplitude modulation.) It should operate instantaneously and therefore should not include time-constant circuits which delay its recovery after being subjected to a high input voltage, as, for example, a burst of impulse noise. The loading effect of the limiter on associated tuned circuits should not change with signal level.

The greatest value of a limiter is in reducing amplitude modulation, synchronous with the desired frequency modulation, which may be introduced by the deviation of the frequency over symmetrical but slightly rounded i-f response curves. It is also of value in reducing random or impulse noise which occurs while the carrier is deviated from the mean.

GRID-BIAS LIMITERS. Limiters in which the operation is controlled by the bias developed by grid rectification are more commonly used than other types. The fundamental component of the plate current of a grid-bias limiter is maintained substantially constant over a considerable range of input (usually about 10 to 1) by a proper correlation of the bias developed at these levels with the bias necessary to cut off the instantaneous plate current, thereby compensating for the change in angle in each cycle over which the plate circuit is conducting. This relation is most easily obtained in a pentode tube since its plate current is nearly independent of the plate load. A typical circuit is shown in Fig. 10. The output is applied to a circuit tuned to the fundamental frequency (usually the discriminator), and the harmonics are filtered out. A sharp-cutoff tube is used since limiting may then be obtained at low input levels.

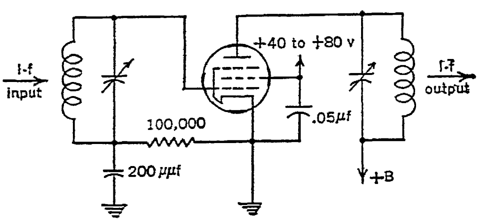

FIG. 10. Grid-bias Limiter

A typical grid-bias limiter static characteristic is shown by the solid line in Fig. 11. If the grid resistor is too small, the efficiency of grid rectification and the developed bias are too small, so that the angle of plate conduction is not reduced sufficiently at high input levels, and the output current rises, as shown by the upper curve. Conversely, if the grid resistor is too large, the output falls as shown by the lower curve. At very high input levels the proper relations cannot be held for any proportions and the output again rises. Although the static characteristic of a grid-bias limiter may be made flat over a wider range than shown by placing resistors by-passed to ground in the plate- or screen-supply circuits, the overall operation in the presence of impulse noise is not satisfactory since the conditions following a burst of noise are not normal and the output suffers during the recovery time of the plate or screen circuits.

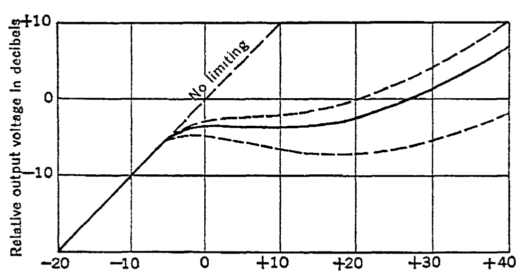

FIG. 11. Grid-bias Limiter Characteristics

An approximate rule for flat limiting which holds for pentode tubes may be used if the coefficient a in the expression $i_g = ae^{3/2}$ for the grid current i_g in terms of the instantaneous applied grid voltage e is known. The product $arE_c^{1/2}$ should be 35 or 40, where r is the grid resistor in ohms and E_c is the d-c grid voltage necessary to cut off the plate current with the screen voltage selected. The rms plate current is then approximately $0.5g_mE_c$ in the range of rms input voltage from 0.7 to $7.0E_c$, where g_m is the transconductance of the tube with small negative bias at the screen voltage selected. The level at which limiting occurs with common tubes is ordinarily between 1 and 3 volts but may be adjusted over a small range by selecting the screen voltage.

Cascaded limiters are often used to cover a greater range of input signals over which limiting is effective. The voltage applied to the grid of the last limiter from that developed in the tuned output circuit of the previous limiter is made to fall at a point below the final upward curvature of the static characteristic so that an additional 10-to-1 range in level may be handled. All the i-f tubes may act as limiters when the i-f amplifier is used only for f-m signals. The rectified d-c voltage in the grid resistor may be filtered and used for avc bias.

The time constant of the r-C combination in the input circuit of a grid-bias limiter should be as short as is consistent with little loss of i-f gain. The recovery time is then fast enough so that the program is not eliminated for an audible interval after a burst of impulse noise.

PLATE LIMITER. A plate limiter operates when the plate voltage of a triode or pentode swings downward to that portion of the plate-current plate-voltage characteristic where an increase in grid voltage in the positive direction produces no increase in plate current. The stage is operated with very low plate-supply voltage and with a high-impedance plate load. During negative grid voltage swings the plate current is cut off. The instantaneous output current swings between the maximum and zero, and tends to deliver a rectangular wave at high input levels. The rms output voltage increases slightly with increase of input level until the output current has assumed the rectangular wave form, and is then somewhat less than half the plate-supply voltage. The harmonics of voltage in the output are eliminated in the tuned circuit.

Heavy grid current loads the input circuit of a plate limiter during positive grid swings. This may be restricted by a resistor in series with the grid lead but may still influence the selectivity and gain of the input tuned circuit. A plate limiter has the advantage of rapid recovery time if the plate- and screen-supply voltages are not influenced by the tube load but is more often used in clipping and shaping pulses than in amplitude limiting in f-m receivers.

LOCKED-IN OSCILLATOR. An oscillator operating at the intermediate frequency or some submultiple thereof may be used to cause the receiver to be non-responsive to amplitude modulation and may be synchronized or locked in by the i-f signal and then follow its deviation. An oscillator remains in synchronism over a wider band, and its output is slightly greater, for high signal inputs than for low. It has been found to be most satisfactory when operated at a submultiple of the intermediate frequency. It then has the advantage of having an output frequency which will not feed back to the previous i-f stages. However, it requires an input signal above 1 volt and in this respect is no more satisfactory than a grid limiter. Discriminators for use with synchronized oscillators must be specially proportioned to take care of the interaction with and the loading of the oscillator circuits.

A frequency detector which operates as a locked oscillator in which the frequency is controlled over the deviation range by quadrature feedback from the plate circuit of a heptode tube, and which simultaneously provides an audio output in the plate circuit, has been described. The output is linearly proportional to the frequency deviation and is independent of i-f amplitude, provided the latter is great enough to maintain synchronism.

DISTORTION AND INTERFERENCE IN F-M SYSTEMS

By B. D. Loughlin

In f-m systems, just as in a-m systems, distortion can result from a non-linearity of the input-output characteristic of the modulator or frequency detector. However, the modulator of the transmitter can generally be properly designed to have a substantially linear input-output characteristic over the operating range. In the commonly used phase modulators which are inherently non-linear for large phase deviations, satisfactory linearity is obtained by restricting the operating range to use small phase deviations at the modulator, followed by frequency multiplication to obtain the desired frequency modulation. It is also relatively straightforward to obtain linear frequency detection from the commonly used f-m detectors when they are receiving an ideal f-m signal of constant amplitude. Thus the commonly used frequency modulators and detectors are generally designed so that they contribute only a small amount of distortion to the f-m system.

This section treats the special forms of distortion which are unique to an f-m system and which arise from translating the f-m signal through the amplifiers of the transmitter and receiver and through the transmission medium. When the f-m signal passes through the amplifiers of the transmitter or receiver, f-m distortion can result because of inadequate band width or non-linear phase characteristic. Also, if the transmission characteristics of the amplifiers are not flat over the frequency deviation of the applied signal, spurious amplitude modulation synchronous with the frequency modulation is introduced, which may cause distortion if there is incomplete rejection of amplitude modulation by the f-m detector system. Another serious form of f-m distortion, producing both spurious amplitude and frequency modulation, results from multipath transmission between the transmitter and receiver.

8. F-M DISTORTION FROM NON-UNIFORM AMPLITUDE AND PHASE CHARACTERISTICS

When an f-m signal is translated through an amplifier or network having a non-uniform amplitude or phase characteristic, some spurious frequency modulation (in other words, f-m distortion) results. The f-m distortion results because the various sideband components of the f-m signal are translated with different amplitude and delay and thus do not correctly combine in the output. The first approximation to the distortion can be obtained by a quasi-steady-state analysis. In a quasi-steady-state analysis, it is assumed that at any instant the f-m signal is translated with an amplification and delay determined by the steady-state amplitude and delay characteristics measured at a frequency equal to the applied instantaneous frequency. The delay used is, of course, the envelope delay, that is, the slope of the phase characteristic at the particular frequency.

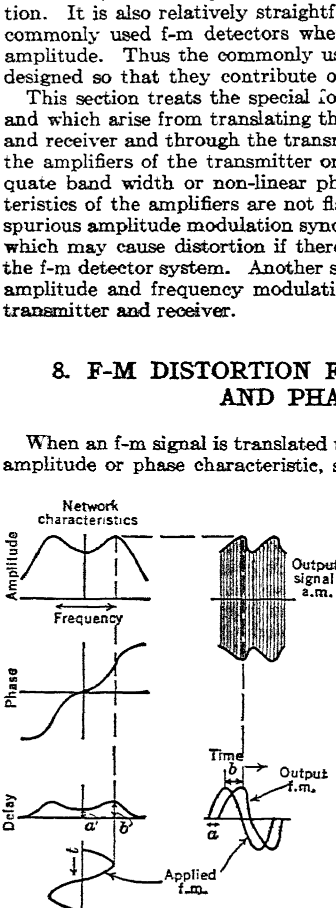

FIG. 1. Quasi-steady-state Approximation for F-M Distortion

To illustrate the quasi-steady-state solution, assumed amplitude and phase characteristics, with the resulting delay characteristic, are shown in Fig. 1. An applied f-m signal with a sine wave of modulation is shown together with the resulting output signal instantaneous frequency and amplitude modulation. It can be seen that the non-uniform amplitude characteristic introduces spurious amplitude modulation and no f-m distortion but that the non-uniform delay results in an f-m distortion due to different delay for different parts of the audio cycle. The resulting distortion can be found by a graphical Fourier series analysis, or a Fourier series expansion of the output f-m equation. In accordance with this approximate analysis method the output frequency modulation would be:

$$\text{f.m.} = a \sin p(t - t_d) \tag{1}$$

where a = maximum frequency deviation, p = angular modulation frequency, and t_d = delay of circuit (a function of instantaneous frequency). In this $t_d = t_0 + F(a \sin pt)$, Practical matters, such as ease of alignment, tolerance of manufacture, and adequate selectivity, frequently dictate the use of undercoupled circuits in commercial f-m receivers, thus resulting in a non-uniform amplitude characteristic. Even receivers designed to have a flat selectivity curve are frequently in trouble as the result of spurious amplitude modulation when the receiver is not accurately tuned or when the set drifts out of alignment. Thus it is desirable that the f-m detector system have fairly complete rejection of amplitude modulation in order to reduce distortion.

The amount and type of harmonic distortion produced by the spurious amplitude modulation is determined by the manner of the detector response to it. As indicated by Figs. 9(*b*) and 9(*d*) (p. 8-23), the response of the detector to amplitude modulation may be in a balanced or an unbalanced manner, or a combination of the two. As shown here, by Fig. 3, a receiver having a rounded-top selectivity curve, and correctly tuned, gives predominantly third-harmonic distortion when the detector has a balanced response to

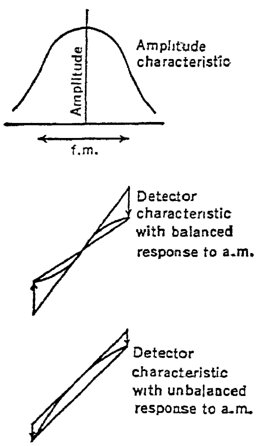

FIG. 3. Distortion from Amplitude Modulation

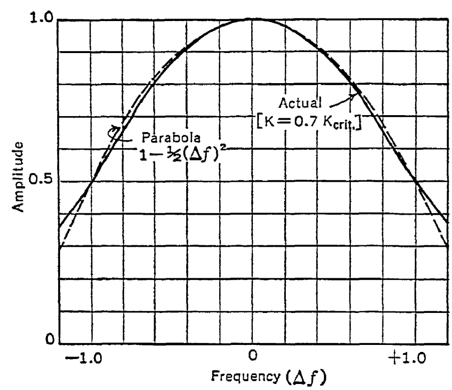

FIG. 4. Amplitude Characteristic for Two Cascade Double-tuned Transformers

amplitude modulation and gives predominantly second-harmonic distortion when the detector has an unbalanced response to it.

The harmonic distortion can be calculated by writing the equation for the f-m detector input-output characteristic in terms of both input signal frequency and amplitude. Then, the equation for the signal amplitude vs. the signal frequency is found from the selectivity curve. By considering the input signal to be frequency-modulated by a sine wave, the resulting output from the detector can be written as a trigonometric series. Substitution of suitable trigonometric expansions will give the fundamental and harmonic output signals.

As an example, consider a receiver with an i-f amplifier system including two coupled circuit transformers having 0.7 of critical coupling and a band width such that the response is down 6db at full system deviation (at ±75 kc for broadcast frequency modulation). Figure 4 shows that the amplitude characteristic of such an i-f system can be closely approximated by a parabola, giving: $A_1 = 1 - {}^1/_2\,(\Delta f)^2$, where $\Delta f = 1$ corresponds to full system deviation. Now the response of a balanced discriminator can be represented as $E_0 = A_2 k(\Delta f)$, where A_2 is the applied signal amplitude, and k relates to the f-m detector slope. If the amplitude modulation of the signal applied to the detector is effectively reduced by some a-m reduction factor (a), then the amplitude modulation due to the i-f selectivity is effectively reduced to $A_2 = 1 - \frac{a}{2}(\Delta f)^2$. Then the detector output is:

$$E_0 = \left[1 - \frac{a}{2}(\Delta f)^2\right] k\,(\Delta f) = k\,(\Delta f) - \frac{a}{2} k\,(\Delta f)^3 \tag{3}$$

Applying a sine wave of frequency modulation, $\Delta f = \sin pt$ (for 100 per cent modulation), then $E_0 = k \sin pt - \frac{a}{2} k \sin^3 pt = k\left(1 - \frac{3}{8}a\right)\sin pt + \frac{ak}{8}\sin 3pt$, thus giving: Per cent third-harmonic distortion $= \dfrac{100a}{8(1 - {}^3/_8\,a)}$. For an a-m reduction factor (a) of 0.35, this relation can be seen to give approximately 5 per cent of third-harmonic distortion.

It can be seen from the above that the exact amount and the harmonic order of the distortion will be affected not only by the selectivity and the manner and degree of the f-m detector response to amplitude modulation but also by the alignment of the detector relative to the intermediate frequency and by the tuning of the center frequency of the f-m signal relative to the center frequency of the intermediate frequency. In particular, it is possible to obtain regions of high audio output and large distortion when, as the signal is detuned, the carrier level at the detector system falls below that necessary for good a-m rejection and when the carrier, at the same time, is tuned on the steep side-slopes of the i-f response. Such distorted side responses can be considerably reduced by using a rounded-top i-f selectivity in conjunction with a well-designed ratio f-m detector.

10. DISTORTION DUE TO MULTIPATH RECEPTION

When the same radio signal is received over several paths having different delay times, the several signals may combine to give increased or decreased amplitude and/or an advance or delay in the resulting carrier phase. For fixed differences in time delay of the paths, the relative phase of the signals will vary with frequency of the signal. Thus multipath reception of an f-m signal will result in spurious amplitude and spurious phase modulation relative to the desired signal. The various signals can combine so that a substantial null in transmission exists at certain frequencies. As the carrier deviates through such a null frequency, a sudden downward amplitude modulation results in conjunction with a rapid change in phase. The sudden change in phase can result in significant spurious frequency modulation. It appears that, where multipath transmission is expected, it is of primary importance that the f-m detector system have good a-m rejection, particularly in terms of rapidity of action and amount of downward amplitude modulation that can be accommodated. In general, the resulting f-m distortion cannot be eliminated; however, a large amount of amplitude modulation is generally produced before such distortion is severe. Thus, good a-m rejection helps considerably but cannot eliminate multipath distortion effects.

Although numerous examples of multipath transmission distortion have been cited on the higher frequencies of 50 to 100 Mc,* it does not appear to represent a serious threat to the f-m broadcast industry. However, multipath transmission distortion virtually makes voice communication by frequency modulation impractical on the long-distance short-wave bands of 5 to 30 Mc.† The many paths of transmission occurring during "skip" transmission on these frequencies result in the familiar selective fading frequently producing serious f-m distortion, particularly as the deviation is increased.

11. CROSS-TALK AND BEATNOTE INTERFERENCE

Interference in f-m systems may arise from other generated signals, such as communication f-m or a-m signals, either received directly or through spurious receiver responses, or it may arise from noise signals of such form as fluctuation noise or impulse noise. The response of an f-m system to such interferences is, in general, quite different from that of an a-m system. For example, cross-modulation on amplitude modulation, where the modulation of a strong undesired a-m signal produces amplitude modulation of a desired signal, has no exact equivalent in an f-m system. The non-linearities which produce cross-modulation in amplitude modulation produce some spurious signals in an f-m system which can have the frequency modulation of both signals, but no direct cross-modulation of one carrier modulation upon the other carrier is produced.‡

If two carrier signals of different frequency exist in a linear system, the resulting signal (see Fig. 5) has amplitude and phase modulation at the difference frequency rate. When the ratio of the two signals is substantially different from unity, the fractional amplitude modulation and the radian phase modulation are equal to the fractional signal ratio, that is, the ratio of the weaker signal amplitude to the stronger signal amplitude. The average frequency of the resulting signal, being the average number of cycles per second, is the frequency of the stronger signal. Since the instantaneous frequency modulation is determined by taking the differential of the phase modulation, the resulting signal has a frequency modulation that is not only proportional to the signal ratio but also directly

* Frequency-Modulation Distortion Caused by Multipath Transmission, M. S. Corrington, *Proc. I.R.E.*, Vol. 33, 878 (December 1945).

† Observations of Frequency-modulation Propagation on 26 Megacycles, M. G. Crosby, *Proc. I.R.E.*, Vol. 29, 398 (July 1941).

‡ Two Signal Cross-modulation in a Frequency-modulation Receiver, H. A. Wheeler, *Proc. I.R.E.*, Vol. 28, 537 (December 1940).

proportional to the frequency difference between the carriers. Thus, if the two carriers are applied to an ideal f-m detector system, the average detector output will be determined by the average frequency of the stronger signal and an f-m beatnote will occur in the detector output having a frequency equal to, and an amplitude proportional to, the difference in frequency between the carriers.

When the ratio of the two beating signals is far from unity, the a-m, p-m, and f-m beatnotes are all substantially sinusoidal. However, as the ratio approaches unity, the beatnote wave forms depart from sinusoidal, as shown in Fig. 6. In particular, the f-m beatnote approaches a pulse wave form as the signal ratio approaches unity.

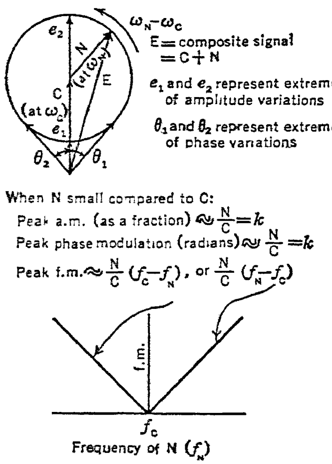

FIG. 5. Addition of Two Carrier Signals

In an ideal f-m detector system, the detector responds only to the frequency modulation of the stronger signal, resulting in substantially no cross-talk from a weaker signal.* This applies to co-channel as well as adjacent channel signals, if the desired-to-undesired-signal ratio is measured just preceding the circuit which effectively reduces or which is effectively non-responsive to the amplitude modulation of the signal. For co-channel interference, an f-m beatnote, of variable frequency, results which has considerably less amplitude within the audio spectrum (owing to the triangular f-m beatnote spectrum as shown in Fig. 5) than would exist in an a-m system. The direct audible beatnote interference does not exist for adjacent-channel interference in a conventional f-m receiver.

In practical f-m receivers the ideal performance in regard to co-channel and adjacent-channel interference is not realized because of inadequate a-m rejection. The amount by which the signal ratio can approach unity is generally limited by the downward a-m rejection capability of the system. This generally means that the signal ratio can get to within only 3 to 6 db of equality before cross-talk results, even with good f-m detectors. When considering the signal-to-interference ratio for the adjacent channel case, the most adverse condition during modulation must be taken. This exists when the undesired signal has maximum deviation toward the center of the i-f pass band, and, owing to the sharp skirt selectivity, this condition may differ considerably from the unmodulated case.

Another practical limitation results from inadequate rejection of superaudible amplitude modulation produced in adjacent-channel interference, where the beatnote generally exceeds 200 kc. The grid-bias limiter plus balanced discriminator type of f-m detector system suffers from this limitation. The usual limiter grid-circuit and diode load time-constants do not permit following of the superaudible amplitude modulation, resulting in an effective unbalancing of the discriminator and a change in average output of the limiter. This limitation frequently requires a signal-to-interference ratio of about 20 db to eliminate cross-talk from adjacent channel signals, when this f-m detector system is used. Detector systems not including the equivalent of this time-constant limitation are generally able to tolerate a 3- to 6-db signal-to-interference ratio to eliminate adjacent channel cross-talk.

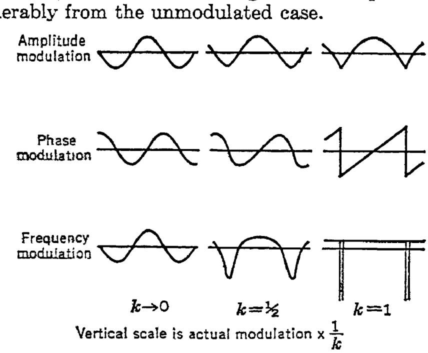

FIG. 6. Beatnote Wave Forms

12. FLUCTUATION NOISE INTERFERENCE

Fluctuation noise, such as thermal noise of resistive impedances, and shot noise and divisional noise of vacuum tubes, can be considered equivalent to a uniform spectrum of

* Common Channel Interference between Two Frequency-modulated Signals, H. A. Wheeler, *Proc. I.R.E.*, Vol. 30, 34 (January 1942).

energy in which the components have random phase or timing. When the noise is small compared to the signal, any individual noise component will beat with the carrier to give an f-m beatnote as illustrated in Fig. 5. Thus the resulting audio noise consists of predominantly high audio-frequency components giving a characteristic high-frequency hiss for f-m noise as compared to the uniform spectrum with considerable low-frequency rumble for a-m noise.*

To find the rms value of the audio noise, the output noise spectrum can be squared, the resulting squared spectrum can be integrated over the audio band, and the square root of the integral taken. Using this for the simple case of an audio system with uniform response and sharp cut-off, the f-m signal-to-noise ratio to the a-m signal-to-noise ratio (called the f-m improvement ratio) is found to be $\sqrt{3}\, f_d/f_a$, when f_a is the maximum audio frequency and f_d is the maximum frequency deviation of the system. For 15-kc audio and 75-kc deviation this gives an f-m improvement of 18.8 db.

By including a de-emphasis low-pass filter in the receiver, which is compensated for by a complementary pre-emphasis circuit at the transmitter, the f-m signal-to-noise ratio can be further improved. In this case the f-m signal-to-noise ratio including de-emphasis to the a-m signal-to-noise ratio not including de-emphasis is given by:

$$\frac{f_d}{f_0\sqrt{1 - \dfrac{f_0}{f_a}\tan^{-1}\dfrac{f_a}{f_0}}}$$

where f_0 is the frequency for 3-db attenuation of the de-emphasis filter. For broadcast frequency modulation with 15-kc audio, 75-kc deviation, and 75-microsecond de-emphasis time constant ($f_0 = 2.12$ kc), this gives an f-m improvement of 32 db.

The above relations are derived on the assumption that the noise is small compared to the carrier signal. In the region where the peak noise is almost equal to the peak carrier, the simple relations are inadequate, and actually the f-m improvement is rapidly lost as the signal is made weaker. The approximate threshold for f-m improvement is when the peak carrier equals the peak noise.

Signal-to-noise ratios are frequently expressed in terms of the rms audio signal output for 30 per cent frequency modulation to the rms audio noise when the carrier is unmodulated. Using this definition and applying the approximate equations at the f-m improvement threshold (where peak carrier equals peak noise after selectivity), the signal-to-noise ratio for broadcast frequency modulation with 150-kc i-f pass band is about 40 db at the threshold. Thus, in this case, the frequently used 30-db signal-to-noise ratio is near the knee of the improvement threshold, and when the receiver has good a-m rejection it is determined by the signal level which approximately gives peak carrier equal to peak noise. For broadcast f-m receivers with 150-kc i-f pass band, a 300-ohm antenna, and an assumed receiver noise factor of 6 db, the threshold level (peak carrier = peak noise) is at about 104 db below 1 volt. This would represent a very well-designed set. Normal design receivers have an improvement threshold around 90 to 100 db below 1 volt.

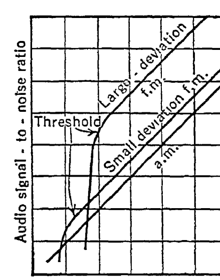

FIG. 7. Small- vs. Large-deviation Ratio FM

When the peak carrier greatly exceeds the peak noise, the signal-to-fluctuation-noise ratio of an f-m system is improved by using a larger deviation ratio. However, a small-deviation-ratio system can have narrow receiver selectivity resulting in less total peak noise and thus a lower threshold signal level, as illustrated in Fig. 7. Thus, entertainment f-m systems where signal-to-noise ratio is important are built using a large deviation ratio, while communication networks where range of coverage is important use a small deviation ratio.

13. IMPULSE NOISE INTERFERENCE

When an impulse, such as automobile ignition interference, is applied to a receiver, a transient carrier pulse results having a duration determined by the band width of the receiver and a frequency determined by the center frequency of the i-f selectors. When this transient is added to a desired carrier, an amplitude and phase modulation of the desired carrier results, depending upon the relative amplitude, frequency, and phase of the carrier and the transient. If the carrier amplitude is larger than the peak amplitude

* Frequency-modulation Noise Characteristics, M. G. Crosby, *Proc. I.R.E.*, Vol. 25, 472 (April 1937).

of the transient, the maximum phase modulation that can result is a pulse of less than 1 radian. In this case the audible interference produced, particularly in large-deviation-ratio systems, is very small.

In the case of most interest, which occurs very frequently, the transient impulse amplitude greatly exceeds the carrier amplitude. If the desired carrier has a frequency equal to the center frequency of the selector, then the transient and the carrier have a fixed phase during any one pulse. This results in a pulse of phase modulation which can have a maximum phase displacement of approximately 180° when the transient and the desired carrier are almost out of phase.

If the desired carrier has a frequency different from the center frequency of the selector, then the transient and the carrier will slip in phase between the beginning and end of any one transient pulse. For certain conditions of starting phase, this case will still result in a pulse of phase modulation as shown in Fig. 8. However, there are certain conditions of starting phase such that the resulting signal vector snaps back to its original phase after going through 360° of phase displacement during the pulse (see Fig. 8). This produces a step of phase modulation instead of a pulse of phase modulation. Thus, when the desired signal is not exactly on tune either a pulse or a step of phase modulation can result from a strong impulse noise, with the probable occurrence of the phase step becoming greater as the signal is further detuned.

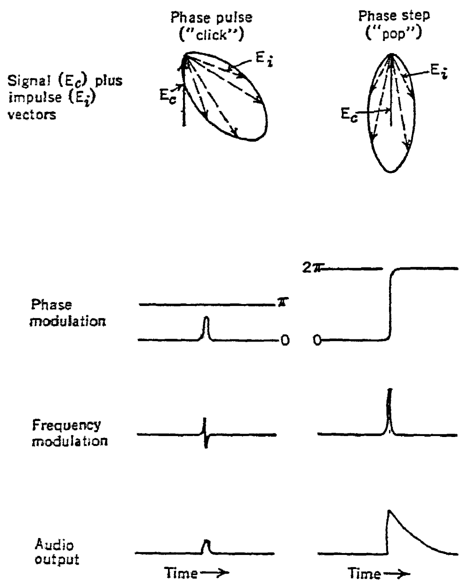

FIG. 8. Impulse Noise Interference

When a phase pulse is applied to an ideal f-m detector, the output signal is a double-polarity pulse. This double-polarity pulse applied to the de-emphasis filter and audio system results in a unipolarity pulse having relatively little energy and a short duration determined by the cut-off frequency of the audio system. This weak audio output noise is sometimes called a "click." When a phase step is applied to an ideal f-m detector a unipolarity pulse results. This pulse applied through the de-emphasis filter and audio system gives a pulse with an exponential decay determined by the de-emphasis time constant and thus having relatively more audio energy. This louder audio noise is sometimes called a "pop." *

Thus, when a strong impulse is applied to an f-m receiver, either a noticeable pop or weak click may result in the audio output, with the probable occurrence of the "pop" being directly related to the detuning of the desired carrier relative to the center frequency of the selector. In broadcast f-m with 75-kc deviation and 75-microsecond de-emphasis time constant, the click may have a peak amplitude between zero and about 6 per cent of full modulation, and the "pop" will have a peak amplitude of about 18 per cent of full modulation. The amplitude and probability of occurrence of the pop is almost independent of the amplitude of the impulse after it exceeds the carrier level by several times.

To obtain the performance described above, the f-m receiver must have good a-m rejection; otherwise the large amplitude modulation resulting from the impulse noise will be heard. Also, care must be taken to see that the receiver recovers immediately after a strong impulse; otherwise the absence of a signal immediately after an impulse may result in a large audio output due to inadequate downward a-m rejection. This trouble can result particularly in a grid-bias limiter with an improper grid time constant. Another limitation preventing ideal performance can be spurious phase modulation produced within the receiver, during the impulse, from such causes as change in input capacity of amplifier tubes.

PULSE TECHNIQUES

PULSES AND PULSE SYSTEMS

By Harold A. Wheeler

1. INTRODUCTION

The various uses of pulses in signaling and measurements were greatly advanced during World War II with the advent of numerous devices for aiding navigation, detecting and locating enemy craft, and performing difficult measurements and computations. It is the purpose of this section to give a broad perspective on the many applications of electronic pulse techniques and their limitations, together with a few of the more common circuits and a large bibliography for further reference.

Pulse coding is exemplified by the time-honored telegraph codes, which were originally operated slowly enough for crude mechanical devices, manual transmission, and auditory reception. Electronic pulse techniques were adapted to code systems for amplifying weak signals and expediting the various processes.

Pulsed radio waves date back to the original spark transmitters of Hertz and others, which set the pattern of early radio communication. With the obsolescence of spark transmitters began the evolution of electronic pulse transmitters, which had their greatest use in "radar" during the war. They now develop as much as a megawatt of pulse power at frequencies around 3000 megacycles (wavelength 10 cm). In some cases, the old rotary spark gap has been revived to key the new magnetron pulse transmitters.

2. COMPARISON OF CONTINUOUS WAVES AND PULSED WAVES

Various kinds of information, such as voice or music, are transmitted by corresponding modulation of a carrier wave. (See Section 5, Transients in Networks, and Section 17, Telephone Systems.) In the simplest form, the carrier is a continuous wave of a fixed frequency, and its amplitude is modulated in accordance with the sound wave or other information to be transmitted. Amplitude modulation is unique in that the modulated wave can be transmitted within the narrowest bandwidth in the frequency spectrum. Other forms such as frequency modulation and pulse modulation require excess bandwidth but in return they secure some advantages which may justify the cost in bandwidth.

The continuous waves used in amplitude or frequency modulation on one hand, and pulsed waves on the other hand, have entirely different properties which require different points of view in their application. These differences are most pronounced in the selection of one signal out of several signals or noise of comparable amplitude.

Figure 1 shows the principles of selection between two signals, regardless of their relative amplitude. As modulated continuous-wave signals are coextensive in time, frequency selection must be used for each channel by means of band-pass filters. Pulsed signals, however, can be separated in time, and so it is possible to use time selection as well as frequency selection for filtering one channel from another. The "skirt selectivity" in frequency selection denotes the attenuation just outside the desired frequency band; in time selection it denotes the rate of damping of one pulse to clear the way for the next pulse of another channel. Frequency selection is subject to harmonic interference, as shown in dotted lines in Fig. 1; the analogous interference in time selection is caused by pulse echoes in the transmission paths in enclosed circuits or open space.

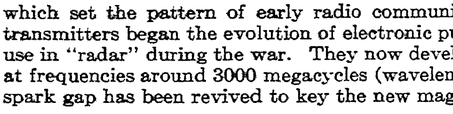

FIG. 1. Selection in Frequency or Time

In any system including several signals with the same form of modulation, some severe requirements have to be met in order to avoid interference between signals. Continuous-wave signals require that the response be very nearly linear in order to avoid harmonic interference or cross-modulation of one signal by another. This is not a requirement for pulses separated in time, because they are not coexistent. Instead, the pulse signals require that each pulse be damped out immediately after its occurrence and that later echoes be avoided.

The rating of equipment for pulse modulation places the emphasis on peak values rather than average values. For example, small vacuum tubes can be made to tolerate high peak values of current and voltage if they occur during only a small fraction of the time. Accumulative effects, such as heating and the decomposition of the glass, become less important because they depend on average values.

3. TYPES OF PULSE MODULATION

The many possible ways of modulating pulses involve three basic types of modulation as illustrated in Fig. 2. Height modulation (*a*) corresponds to amplitude modulation of a continuous wave. Width modulation (*b*) and spacing modulation (*c*) involve only the time dimensions and are therefore not critically dependent on the pulse amplitude.

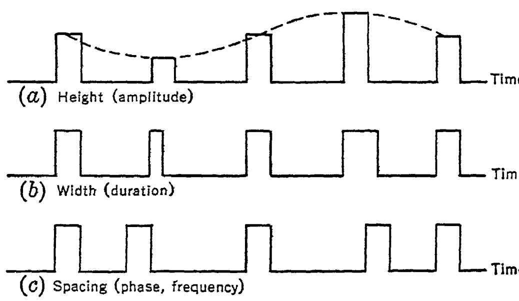

FIG. 2. The Three Basic Types of Pulse Modulation

The greatest advantages of pulses are realized in time modulation (*b*) or (*c*) as distinguished from amplitude modulation (*a*) in Fig. 2. The telegraph codes are an example of width-and-spacing modulation. It is permissible to use amplitude clipping or limiting circuits, since the amplitude need not be preserved. Also the detectors are made responsive to timing and can be made unresponsive to amplitude fluctuations such as power-supply ripple.

Pulse echo systems, such as radar, utilize the timing of the echo to determine the distance. Some pulse systems use directive antennas which receive alternately on two crossed lobes of the directive pattern. In this case, the relative amplitude of echo pulses must be preserved and the direction of reception is observed at the intersection of the two lobes by equalizing the echo-pulse amplitudes.

Some kinds of information, such as numbers, can be transmitted by grouping together a number of pulses in succession. Each group can be evaluated by a pulse counter. Multiple-pulse coding is essentially similar to pulse-width modulation but has some advantages in handling and in reliability of decoding.

The modulation of pulses of uniform width is similar to the modulation of a subcarrier, which in turn modulates a carrier. The pulse frequency is intermediate between the modulation frequencies and the carrier frequency, as is a subcarrier frequency. In the case of pulses, however, several sets of short pulses of the same frequency can be superimposed for multiplexing simply by displacement in time, whereas each continuous-wave subcarrier would need a different frequency. The pulse pattern can be subjected to any method of modulation applicable to a carrier or subcarrier, notably amplitude modulation as in Fig. 2(*a*) and phase or frequency modulation as in Fig. 2(*c*).

4. SPEED OF INFORMATION

A time variation of a quantity (such as current or voltage) may be regarded as comprising a succession of contiguous pulses of varying amplitude (see Fig. 4, p. 5-28). The speed of information that can be transmitted through a signal channel by such a variation may be conceived as the maximum frequency of such pulses whose presence or absence can be individually detected. (A space is regarded as an absent pulse, or one of zero amplitude.) Therefore the speed of information is limited by the frequency bandwidth. In the case of a low-pass channel (or one-half of a double-sideband band-pass channel), the nominal minimum bandwidth is one-half the maximum pulse frequency as here conceived, but somewhat greater bandwidth is needed for insurance of pulse damping and for skirt selectivity against adjacent frequency channels. Figure 3 shows the nominal bandwidths required for a speed of information equal to $2f_c$. (The maximum pulse frequency as here used is twice the maximum frequency of discrete pulses separated by intervening spaces of equal width; for those separated pulses the nominal minimum bandwidth becomes equal to the pulse frequency.)

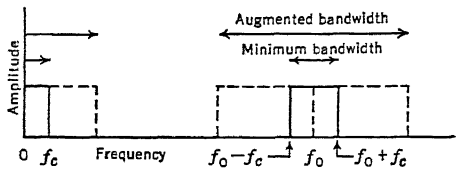

FIG. 3. Frequency Bandwidths Required for a Certain Speed of Information

The foregoing relation is based on the assumption of adjacent non-overlapping pulses, although some overlap is permissible in practice. The particular needs of the system determine how much the actual bandwidth must exceed the nominal minimum bandwidth. Figure 4 shows the distortion of a discrete square pulse which is caused by reduction of system bandwidth.

In Fig. 4 the square pulse (*a*) represents the voltage pulse or the current pulse produced by a system with a very wide bandwidth. In the remaining cases the nominal bandwidth of the system (f_c) is successively reduced to show its effect on the output pulse caused by a square input pulse. Case (*b*) shows a system bandwidth (f_c) approximately four times that of the nominal pulse bandwidth. This limitation causes sloping sides but retains a flat top over part of the pulse width. In (*c*), the system bandwidth is reduced to twice the nominal pulse bandwidth, just leaving a peak at the original amplitude. A system bandwidth equal to the nominal bandwidth of the square pulse (*d*) leaves the pulse slightly reduced in amplitude and considerably widened. Further, halving of the bandwidth (*e*) reduces the amplitude of the output pulse to less than one-half of the value in (*a*) and increases the width to more than double. Cases (*c*) or (*d*) may be regarded as practical compromises.

Like frequency modulation or subcarrier modulation, pulse modulation unavoidably increases the bandwidth requirements for the same speed of information, in the manner of the augmented bandwidths indicated by dotted lines in Fig. 3. The greater bandwidth inherently increases the average power of background noise caused by thermal agitation of electrons. It also makes possible a proportional increase in the peak power by pulsing, while maintaining the same average power.

If the signal amplitude is comparable with the noise amplitude, a change to pulsing with its greater bandwidth is no advantage. If the signal is somewhat stronger than the noise, however, and if the pulses are modulated in time, it is found possible to secure an advantage in signal-to-noise ratio which is comparable with that obtained in wide-band frequency modulation over the same bandwidth. Therefore, if the augmented bandwidth is available, pulse modulation is another way to take advantage of it.

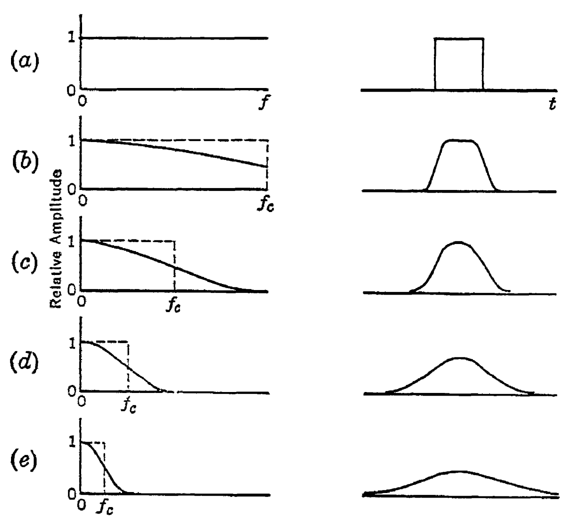

FIG. 4. The Widening of a Square Pulse by Reduction of Frequency Bandwidth

It may happen that, for some reason, more bandwidth is available than the minimum needed for the desired speed of information. At very high frequencies, the accidental frequency fluctuations of the signal may require an augmented bandwidth in the receiver. Some of this excess bandwidth may then be utilized to advantage by pulse modulation.

5. COMMUNICATION

The various types of pulse modulation have long been used in low-speed and high-speed code transmission of word messages (see Sections 17 and 18, Telephony and Telegraphy), but the greatest advance in pulse techniques has been utilized more recently in the multiplex transmission of several voice channels on a single microwave beam as a carrier. This system is taken as an example of the communication possibilities with pulse modulation.

The carrier is modulated in short pulses, and the pulse spacing is modulated by sound waves. This is the type of modulation shown in Fig. 2(*c*) above. The multiplex operation is accomplished by interspersed pulses as shown in Fig. 5. A single group of pulses comprises a sequence including one pulse assigned to each channel. One channel is reserved as synchronizing pulses to initiate each counting sequence in reception. Each of the remaining channels is modulated by shifting its pulses in time in accordance with the sound wave to be transmitted. The amount of time modulation of each pulse is limited so that the modulation of one pulse will never encroach on the time allotted to the modulation of the adjacent pulses.

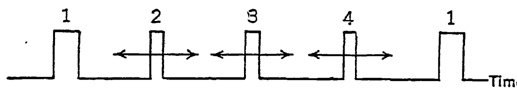

FIG. 5. Multiplex Operation of Several Channels by Pulse-time Modulation

In the transmitter, the pulses belonging to each channel are synchronized by the first channel but are otherwise separately generated and modulated. Then all channels are combined with pulses interspersed, and the composite pulse pattern is used to modulate the carrier wave.

In the receiver, the modulated carrier wave is amplified and detected, then each sequence of pulses is distributed among the several channels under guidance of the synchronizing pulses of the first channel. The distribution of each sequence may be accomplished by some form of counting or time selection. As long as the successive pulses are separated in time, there is no interference between channels. The time selection of multiplex channels offers some advantages over frequency selection, unless there are strong echoes with enough delay to overlap succeeding pulses, a condition that can be avoided by highly directive beam transmission.

Reliable reception is generally possible if the desired pulse peaks are received somewhat stronger than the peaks of noise or other interference. By amplitude limiting and clipping, the pulse peaks are flattened and the lower parts of the pulses (in the noise background) are discarded. The result is a succession of square pulses with the same timing as the edges of the received pulses. These reconditioned pulses are distributed to the separate channels for recovery of the modulation.

Since the sides of each pulse are sloping, the timing of the reconditioned pulse is still subject to some disturbance by background noise, as illustrated in Fig. 6. The noise causes some vertical displacement of all parts of the pulse, while there is no change in the level which determines the reconditioning and subsequent detection. Therefore the vertical displacement is translated to a minor amount of time displacement, always less than the pulse width. The time modulation caused by noise may be compared to the available time modulation by the signal, to determine its disturbing effect. Increasing the frequency bandwidth proportionately increases the slopes and thereby decreases the response to background noise (as in wide-band frequency modulation). Increasing the available time width for modulation (as by decreasing the number of channels) decreases the ratio of the noise modulation to the signal modulation.

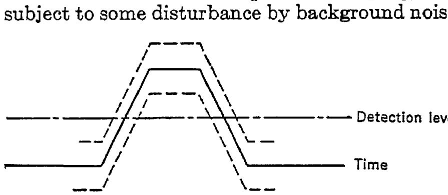

FIG. 6. Pulse Detection with Background Noise

The ultimate effect of the noise on the pulse slopes in Fig. 6 depends on the kind of detection. The simple detectors of time modulation operate on one edge of every pulse, either the leading or the trailing edge. Such detection retains the full effect of the background noise on the sloping edge of each pulse. The time detection may be designed to operate on the center of the reconditioned pulse, in which event there is approximate cancellation of those noise components that merely shift the pulse up and down, as illustrated in Fig. 6, leaving only the effect of those components that distort the shape of the pulse. The choice of the kind of detection depends not only on the noise but also on other factors which may be more important.

A common form of interference in pulse transmission is echoes caused by reflection of waves from objects in space or from irregularities in transmission lines. In communication between aircraft, the principal cause of echoes is ground reflection. Figure 7 shows how an echo may distort the trailing edge of a pulse. A direct pulse is interfered with by a slightly later echo pulse (shown in dotted lines) which is considerably weaker (below the detection level). The diagram shows only the envelope of the pulsed wave. As the relative phase of the carrier wave of the two pulses may have any angle, the echo may add or subtract on the trailing edge, as shown. Between fixed transmitter and receiver, the effect of the echo is fairly steady, varying slowly with frequency drift and environment; therefore it contributes little or no disturbance in the receiver. If the distance is variable, as between aircraft. the relative phase of the two pulses varies at random, and so an echo causes noise if the time detection operates on the trailing edge.

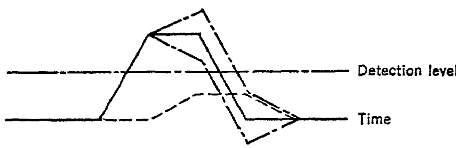

FIG. 7. Pulse Detection with Echo

Pulsed waves are most commonly obtained by pulse modulation of a carrier-frequency oscillator which delivers the required power directly to the antenna. At the beginning of each pulse, the oscillation has to build up from the noise level. Therefore the oscillator acts as a superregenerative amplifier of the background noise. The resulting noise on the leading edge of the pulse is illustrated in Fig. 8. The modulator pulse is shown in dotted lines. At the beginning of the modulator pulse, the oscillation starts to build up exponentially from the noise level and soon reaches equilibrium at the power level of the oscillator. However, the fluctuation of the noise causes a variable delay in the build-up of successive pulses, which appears as a "jitter" in the leading edge. If the time detection operates on the leading edge, the result is noise in the receiver. This effect is absent on the trailing edge because the latter is determined by exponential damping from the stable level of the oscillator on the peak of the pulse. (The noise on the leading edge can be avoided if the pulse modulation is applied to an amplifier following a continuous carrier-frequency oscillator, but this method has other disadvantages.)

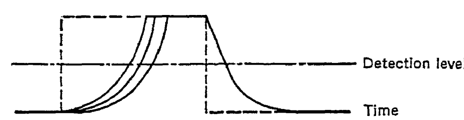

FIG. 8. Output Envelope of Pulsed Oscillator

The use of a very short pulse, shifted in time with modulation, appears to be the most economical of power while realizing the advantages of pulse modulation. The pulse duration should be nearly the least that can be transmitted within the available bandwidth in the frequency spectrum. Then the available average power can be utilized to secure greatest pulse amplitude for overcoming noise. Since the detection operates on the edges of the pulses, greater pulse duration is no advantage and greater amplitude is a proportionate advantage.

Detection on the leading edge, the pulse center, or the trailing edge, is a choice that depends on the nature of the system. In beam transmission along a fixed path, echoes are unlikely, so detection on the trailing edge is preferable to avoid the oscillator noise on the leading edge. Broadcast transmission, especially between moving stations, is subject to echo interference, which gives the advantage to detection on the leading edge; the oscillator is then designed to minimize the superregenerative noise. If both the echoes and the superregenerative noise are less than the random background noise, center detection would give the best performance and its complication might be justified.

The potentialities of multiplex pulse transmission are indicated by the studies which show that the entire broadcast services for a large city could be transmitted from a single microwave system centrally located on the highest building, with a service area limited by the optical horizon.

6. PICTURE TRANSMISSION

In picture transmission by scanning methods (see Section 19, Facsimile, and Section 20, Television), pulses are relied on not only for reproducing the picture elements but also for timing and synchronizing the scanning process. Since the common systems for picture transmission utilize scanning methods, many examples of pulse circuits and their applications are found in both facsimile and television.

Figures 9 and 10 show respectively the essential components of a picture transmitter and receiver with scanning by deflection of an electron beam, as in present-day television.

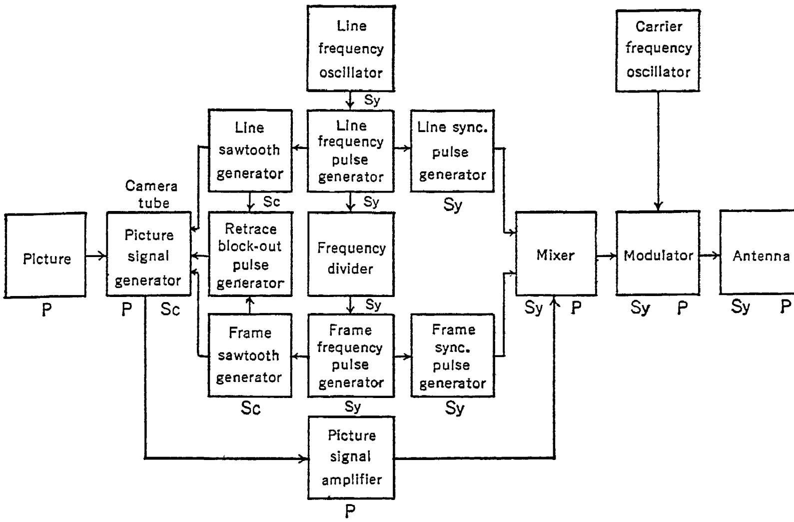

FIG. 9. Block Diagram of Picture Transmitter

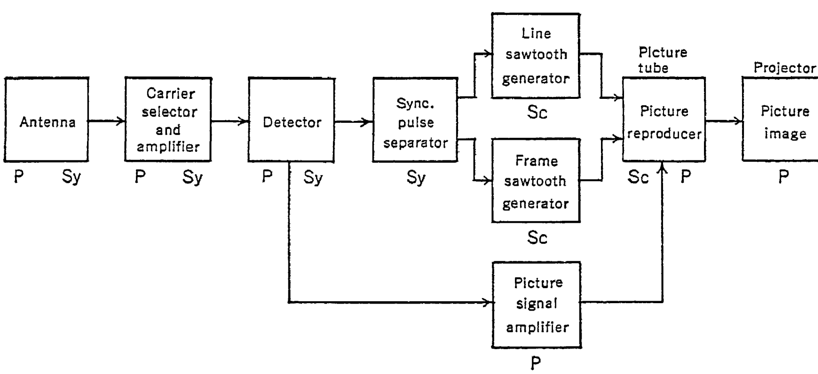

FIG. 10. Block Diagram of Picture Receiver

In these block diagrams, the various functions are coded:

P = picture channel.
Sc = scanning functions.
Sy = synchronizing functions.

The picture signal is generated in the transmitter and converted back to an image in the receiver. The scanning function is individual to transmitter or receiver. The automatic synchronizing operation is initiated in the transmitter by the line-frequency oscillator and used directly to time the scanning in the camera tube; it is maintained by transmitting timing pulses along with the picture signal, which are selected in the receiver for holding in step the scanning in the picture tube.

Figure 11 shows an example of the pulses involved in the scanning of a single horizontal line in a picture. This line is located at the dotted line in the pattern (a). The graph (b) shows in the period P the picture signal for the line. As the scanning line crosses the circular line, a black pulse is generated; as it crosses each edge of the black disk a step is generated, two steps making a wide pulse. The line signal is preceded and followed by a synchronizing pulse *Sy* which times the successive lines. The sync pulse is communicated at an "infra-black" (blacker than black) level and so it does not appear in the retrace lines back across the picture between lines. The graph (*c*) shows the sawtooth wave of voltage or current which is used to deflect the cathode ray or electron beam, in the camera tube or picture tube, from one end of the line to the other.

The transmission of the picture involves the communication of many pulses, each having an amplitude proportional to the brightness of a small element of the picture. The "speed of information" may be expressed as the number of "independent" picture elements that can be transmitted per second, or the number of pulses per second. It ranges from hundreds in facsimile up to millions in television. Completely independent transmission of adjacent picture elements by successive pulses is never attained because the electrical circuits and other devices cause distortion resulting in overlapping of adjacent pulses. One of the principal problems is therefore the design of the circuits to reproduce the short pulses with clean edges by minimizing amplitude and phase distortion over the requisite frequency bandwidth in the circuits. Both kinds of distortion are usually more prevalent at frequencies near the limits of the frequency band required for reproduction of the pulses and steps. The higher frequencies play the major part in reproducing vertical lines or edges; the lower frequencies, in reproducing long pulses or background.

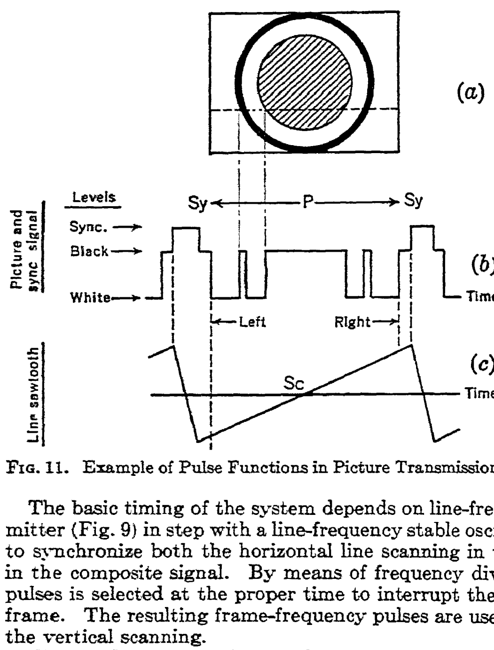

FIG. 11. Example of Pulse Functions in Picture Transmission

The basic timing of the system depends on line-frequency pulses generated in the transmitter (Fig. 9) in step with a line-frequency stable oscillator. These pulses are used directly to synchronize both the horizontal line scanning in the camera tube and the sync pulses in the composite signal. By means of frequency dividers or pulse counters, one of these pulses is selected at the proper time to interrupt the vertical scanning at the end of each frame. The resulting frame-frequency pulses are used in a similar manner to synchronize the vertical scanning.

The synchronizing pulses need to be specified and preserved in shape only to the extent required by precision of timing in the scanning operation. Since they are selected from the signal at a certain infra-black level which may fluctuate with picture content, it proves necessary to hold the edge of a sync pulse nearly as steep as the edge of a step in the picture signal. As sync pulses need not be modulated in amplitude, they can be subjected to limiting or clipping action to remove accidental changes in amplitude. A practical television system may have rather complex sync pulses for facilitating the separation of line and frame sync signals, and for minimizing their susceptibility to interference from the picture signal or other disturbances.

7. COMPUTERS

The solution of certain problems, such as the trajectory of a missile, requires elaborate calculations, which are laborious even when done on mechanical computing machines. Electronic computing machines can increase the computing speed by a factor of 1000 or more, so that a compilation of tables which would take years on a mechanical computer would be done in a few hours or days on an electronic computer. The addition of a digit in electronic computing requires a few microseconds as compared with a few milliseconds in mechanical computing.

An outstanding electronic computer is one of the products of World War II, the "electronic numerical integrator and computer" (eniac).

An electronic analog of the mechanical counter or electromechanical stepping relay may be made up of a number of flip-flop relaxation circuits connected to be switched consecutively by successive pulses. A single flip-flop circuit is analogous to a toggle switch, snapping from one condition to the other and remaining there until an external force snaps it back. In the block diagram of a two-digit ring counter, Fig. 12, each input pulse snaps the "on" switch "off" (to the left), which in turn snaps the next above switch "on" (to the right), increasing the indicated number by one. If the units column indicates nine, and a unit is added, the units "nine" switch is snapped off, the units "zero" switch is snapped on, and the tens column receives a pulse, increasing its indicated number by one. In the eniac, when going from "nine" to "zero," a "carry" switch stores the pulse for the next column. Simultaneous addition in all columns is thereby made possible. The "carry" switch is snapped off after addition in the columns is complete.

An electronic computer may consist of the following:

1. A number of counters to add and store numbers represented by pulse groups.
2. A generator of suitably timed standard pulse signals.
3. Devices for converting numbers supplied to the computer into pulse groups representing the numbers.
4. Devices for printing numbers stored in counters.
5. Devices for combining the quantities in the counters in different ways to add, multiply, divide, etc.
6. Devices to produce automatic repetition of required computations, as in numerical integration.

A basic decade ring counter was described above. The decade counter may be so arranged that, when supplied with a standard sequence of pulses from the timing generator, a number of pulses corresponding to the number stored in the counter is transmitted to another counter which adds it to its own stored number.

Various groups of pulses from the timing generator may be selected and combined by switching to produce pulse groups corresponding to numbers to be supplied to the computer. The numbers stored by a counter may be indicated by neon lamps energized by "on" flip-flops, as indicated by the black dots in Fig. 12. Card punching or printing devices may be similarly actuated to record a stored number.

Rapid switching is accomplished by means of triple-grid tubes, keying pulses being applied to one control grid and information pulses being transferred via another control grid.

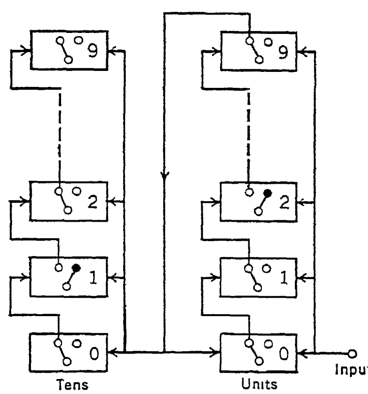

FIG. 12. Two-digit Decade Counter

The flexibility of an electronic computer as regards physical location of components, number of interconnections possible, and the large tolerances in amplitude possible, facilitates the design of computers to perform very elaborate computations with lightning speed.

Where absolute numerical precision is not required, the step counter may be replaced by simpler devices relying on continuous integration. In one type, each pulse delivers an incremental charge to a capacitor whose stored charge is indicated on a meter scale. In another type, the pulse rate is indicated by conducting the incremental charges through a d-c meter so that the current is proportional to the number of pulses per second. Examples of these types are found in Geiger counters, long in use for recording pulses of radioactive radiation.

8. DISTANCE MEASUREMENT

Distance can be measured by timing pulses transmitted through a medium in which the wave velocity is known. In the interest of precision, the duration of each pulse should be much less than the time required for the wave to cover the distance in question. The three basic methods used in operating systems are described in Section 22.

Diverse Waves. Observations of distance by this principle are based on the reception of a pulse by two kinds of waves, over the same distance, having different velocities so that the time difference in reception is a measure of the distance. Examples of light and sound waves originating in simultaneous pulses and traveling over the same distance are found in lightning and thunder or in the seeing and hearing of a distant steam whistle. In these cases, the only appreciable delay is in the sound wave, and so the computation of the distance is based on the velocity of sound in air. An example of different types of waves in the same medium is given by the seismograph of an earthquake. The pulses are transmitted through the earth by longitudinal waves (pressure waves, like sound) and transverse waves, having different known velocities so that the difference in time of reception permits computation of the distance. (See Section 22, article 9.)

Pulses from Diverse Locations. One of the outstanding radio navigational systems (loran, gee, and shoran, Section 22, article 10) also utilizes pulses spontaneously transmitted to the observer, but from widely spaced points and carefully synchronized in time. The time difference in their reception by radio waves permits precise computation of the differential distance relative to each pair of spaced points, and such observations on two different pairs determine the position of the receiver.

Reflection or Return of Pulse. The more versatile systems employ pulse waves transmitted from the observer to a distant point and back again to his receiver. The elementary sonar and radar systems utilize short pulses of sound or radio waves transmitted toward an object and reflected back to a receiver (Section 22, article 10). Special radar systems for beacons or identification rely on a pulse repeater at the object, which receives and retransmits the pulses with coding of some kind (radar beacons, Section 22, article 10; and Lanac, Navar, and Teleran, Section 22, articles 6 and 11). In any case, the round-trip time at known velocity determines the distance.

Table 1. Wave Velocity

Kind of Wave	Medium	Velocity
Electromagnetic (light, radio)	Free space (and air)	300 m/μs
Sound	Air (atmospheric pressure, 20 deg C)	344 m/sec
Sound	Water (20 deg C)	1464 m/sec
Seismic (longitudinal, sound)	Earth	4–14 km/sec
Seismic (transverse)	Earth	3–10 km/sec

Table 2. Characteristics of Radar

Carrier frequency	30–30,000 Mc
Carrier wavelength	10–0.01 meters
Pulse width	10–0.25 μs
Pulse repetition frequency	60–4,000 cps
Pulse power	10–1,000 kw

Table 1 shows various values of the wave velocity in different mediums. Table 2 shows the approximate range of pulse characteristics in radar systems of the reflection type. Since the error of time measurement may be reduced to a fraction of the pulse width, the corresponding distance error may be reduced to the order of 1–0.01 mile. The range of echo reception varies from a few miles to above 200 miles.

9. PULSE MEASUREMENTS

PULSE AMPLITUDE. A simple pulse of voltage or current can be displayed on an oscilloscope and its various properties determined from the calibration of the scope. Such a display is shown in Fig. 13. The small pulses or "pips" are superimposed marker pulses carefully timed to provide a time scale. A representative scale might have small marker pips every microsecond, and every fifth one enlarged. In Fig. 13 the pulse under observation is 1 division wide at the peak and about 2 divisions at the base; it might be rated 1.5 divisions wide at half amplitude.

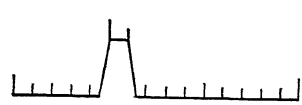

FIG. 13. Oscilloscopic Observation of Pulse Characteristics

A pulsed wave having many cycles of the carrier in a single pulse presents a special problem if the scope cannot give a calibrated display of the actual carrier cycles. The wave must be rectified for display, and the performance of the rectifier is difficult to predict or measure. If the rectifier responds quickly, the rectified pulse may be displayed as in Fig. 13, which is adequate for observing its width or duration.

An indirect method is usually employed for rough measurement of the amplitude of a repeating pulsed wave, the pulse power, for example. The average power is measured by a thermal device such as a thermocouple or bolometer. The pulse duration is observed as in Fig. 13. Then the ratio of peak to average power is equal to the ratio of the period of repetition to the pulse duration. This method is accurate if the time occupied by the sides of the pulse is much less than the duration of its peak. Otherwise the pulse width is indefinite, usually approximated by the width between the points at one-half the peak power or the peak amplitude. (This same method is applicable to simple pulses if there is no background of direct current or voltage, but it is not usually needed in this case.)

In the case of a pulsed carrier wave, some care is required in expressing the peak values during the pulse. The peak power is the mean power of the carrier wave at the peak of the pulse. If there are minor ripples on the flat top of a pulse, the pulse power is stated at the level of the flat top. The peak voltage may be stated as the peak value of the carrier voltage at the level of the peak or flat top, since that is the value significant for voltage breakdown. The pulse current in a vacuum tube carrying a pulsed wave is usually stated as the average value of the current during the peak or flat top of the pulse, since that is the value readily measured by means of an oscilloscope.

The pulse amplitude of a pulsed wave is best measured by comparison with a continous wave of known amplitude, since such a wave presents no unusual problem. The "notch" method shown in Fig. 14 is based on this principle. The comparison wave is cut off or notched for the duration of the unknown pulse. Then the pulsed wave is superimposed thereon, and the composite wave is rectified and displayed on the scope. The two amplitudes are equalized to give the appearance of Fig. 14; then the pulse amplitude is known. This method is independent of the rectifier and scope characteristics and has been found very useful. Measurements have been made as low as 200 μw peak pulse power and 2 μw average power.

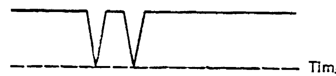

FIG. 14. Measurement of Pulse Amplitude by Comparison with Continuous Wave

PULSE DURATION. The simplest method of observing pulse width or duration is that shown in Fig. 13.

Another method is based on the frequency spectrum of a pulse, illustrated in Fig. 15. (The method of observing the spectrum is to be described below.) The frequency spectrum of a pulse has a width inversely proportional to the width or duration of the pulse. Furthermore, if the pulse has steep sides, the spectrum has a sharply defined minimum value at a frequency differing from the maximum by $2f_c$, as shown in Fig. 15 for a pulse or a pulsed wave. The frequencies of minimum response can easily be observed by a sharply tuned receiver. f_c having been determined, the pulse duration is $1/2f_c$. For example, f_c is $^1/_2$ megacycle for a pulse width of 1 microsecond, and the minimum response is displaced 1 megacycle from the maximum response.

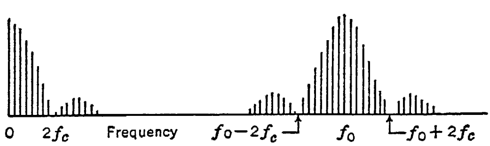

FIG. 15. Frequency Spectrum of Pulse

If it is convenient to measure the peak and average values of the power or voltage or current of a repeating pulse, the duration may be computed. The ratio of the pulse duration to the period of repetition is equal to the ratio of average to peak values, commonly called the pulse "duty cycle."

AVERAGE VALUES. A repeating pulse has a definite average value of power or voltage or current. Any one of these average values may be significant in determining the heating or other accumulative phenomena in a circuit or vacuum tube. For voltage or current, it is important to specify whether the average or root-mean-square value is to be measured.

The average power, or the rms value of voltage or current, can be measured by a thermal instrument with a time constant much greater than the period of repetition of the pulses. The peak voltage during the pulse is abnormally large for the usual instrument of this type, and so voltage breakdown may occur, in which event this defect may be corrected by redesign.

The thermal instruments in common use include the thermocouple, the bolometer bridge, the lamp with photometer, and the resistor with calorimeter. The most severe requirements are met in measuring pulsed waves of ultra-high carrier frequencies, say 1000 megacycles and upward.

The bolometer bridge is a d-c four-arm bridge with a temperature-sensitive resistor in one arm which receives the pulse power to be measured. This device has been improved by the use of a composition resistor very sensitive to temperature, called the "thermistor." Since it is desirable for the measuring circuit to present constant resistance, the bridge is rebalanced by decreasing the d-c level in all arms to restore the variable resistor to the same temperature, establishing a d-c calibration of the power sensitivity in normal operation. The device is sensitive to low power of the order of 1 milliwatt and also can be adapted to greater power.

The lamp is useful for medium power of the order of 1 watt. The radiation from the lamp is indicated by a nearby photocell and meter. It has two great advantages: it requires no electrical connections between the pulse circuit and the indicating circuit, and it can be calibrated by direct current. Its one great disadvantage is its large variation of resistance at the high temperatures incidental to radiation of light.

The calorimeter is useful for high power of the order of 1 kilowatt. It can be designed for nearly constant resistance at very high frequencies, since resistance variation is not essential in its operation at moderate temperatures.

A possible alternative to the thermal meter is a square-law rectifier, which may be approximated by proper design of a vacuum-tube rectifier. It is important to hold the peak value within the range of square-law operation, which severely limits the utility of this type of instrument.

The average value of current or voltage of repeating pulses, assuming zero between pulses, can be measured in an ordinary magnetic d-c meter having a time constant much greater than the period of repetition. In a voltmeter, care must be taken that the pulse voltage is not excessive.

PULSE FREQUENCY. Repeating pulses commonly have a steady value of the pulse repetition frequency (prf). However, a receiver or a replying transmitter may have a random pattern of repetition, depending on the traffic, and then it may be desirable to have a continuous indication of the average pulse frequency over a short period such as 1 sec in order to be aware of overloading.

A constant pulse frequency is easily observed. It is usually an audible frequency and can be compared with a calibrated audio frequency. The integrating type of frequency meter which is used for direct-reading audio-frequency meters may be designed for pulse-frequency measurements. It gives the continuous indication desirable for monitoring a varying pulse frequency. If the pulse amplitude and width are uniform, the same result can be obtained by inserting a d-c or average-power meter in the circuit where it will indicate an average value proportional to the pulse frequency.

PULSE DETAILS. A critical analysis of the details of a repeating pulse or group of associated pulses may require a display on the oscilloscope with a greatly expanded time scale. For example, the entire width of the scale may be only a few microseconds, even though the pulse groups may be separated by a millisecond.

The synchroscope is a special oscilloscope designed for this purpose. Each trace or sweep is triggered by the first edge of the pulse pattern to be observed, and so close registry of successive traces is assured, hence the name "synchroscope." At the end of each trace, the spot waits for the signal to start the next trace. Care is taken to insure that each trace starts at the same point and proceeds at the same rate. Any failure of registry then indicates variations in the pattern.

FREQUENCY SPECTRUM. A simple pulse or a pulsed wave has a frequency spectrum as illustrated in Fig. 15, the former centered on zero frequency and the latter on the carrier frequency. The significance of the spectrum is the ability to excite a circuit which selects a bandwidth much less than the width of the spectrum.

The spectrum analyzer is a device for displaying the frequency spectrum on the scope in the form shown in Fig. 15. As the trace progresses horizontally along the frequency axis, a narrow-band receiver is tuned over the frequency range. The repeating pulse is applied to the receiver, and the rectified output is shown by vertical deflection. The pulses therefore appear as successive vertical lines whose heights show the relative amplitude of the frequency spectrum. The spectrum is a measure of the frequency bandwidth required for reproduction of the pulse, as well as the interference that may be caused in adjacent frequency channels. In the case of a pulsed wave, a symmetrical spectrum indicates pure amplitude modulation free of frequency modulation.

As appears from the width of the frequency spectrum, a pulsed wave does not give a sharp indication of resonance in a sharply tuned wavemeter. The carrier frequency is best defined by the center of a symmetrical spectrum. Therefore it is customary to provide the analyzer with a very sharply resonant calibrated circuit whose frequency can be adjusted to put a narrow gap in the center of the spectrum and thereby to determine the carrier frequency. The calibration of the trap circuit is made on the narrow spectrum of a continuous wave or long pulses of known carrier frequency.

(For oscilloscope technique, see Section 11, Wave Analysis, and Section 20, Television.)

PULSE CIRCUITS

By J. J. Okrent

10. FREQUENCY MULTIPLIERS, DIVIDERS, AND COUNTERS

The abrupt changes in amplitude associated with pulse phenomena give rise to a wide-band frequency spectrum, as indicated above (see Computers, article 7 above; also Section 11, Frequency Measurements). The frequency spectra of certain periodic wave forms, as

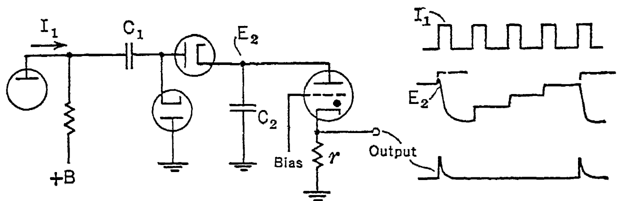

FIG. 1. Counting Type of Frequency Divider

expressed by Fourier series, are well known. Periodic pulses have strong components of high-order harmonics. These are produced for frequency comparison by making a stable sinusoidal oscillator synchronize a relaxation circuit which produces the high-order harmonics of the stable frequency. The harmonics are compared (by zero beat, for example) with a signal whose frequency is to be standardized. Substantial output of a harmonic frequency is obtained by making the relaxation pulse excite a circuit sharply resonant at a chosen harmonic frequency. Pulse circuits incidentally radiate interfering power at harmonic frequencies unless they are adequately shielded and filtered.

Frequency division may be accomplished by synchronizing a relaxation oscillator at an integral submultiple of the synchronizing signal frequency. The natural period of the relaxation oscillator is made somewhat longer than the interval occupied by the selected number of synchronizing pulses, and so the pulses expedite the relaxation in each cycle.

Another method of frequency division utilizes a "ring-counter" circuit which counts the required number of pulses and then generates a trigger pulse and starts counting over again. In Fig. 1, successive pulses of current I_1 increase the charge on the capacitor C_2 and thereby its voltage E_2, for each pulse until the output thyratron conducts, discharging C_2 and producing an output pulse.

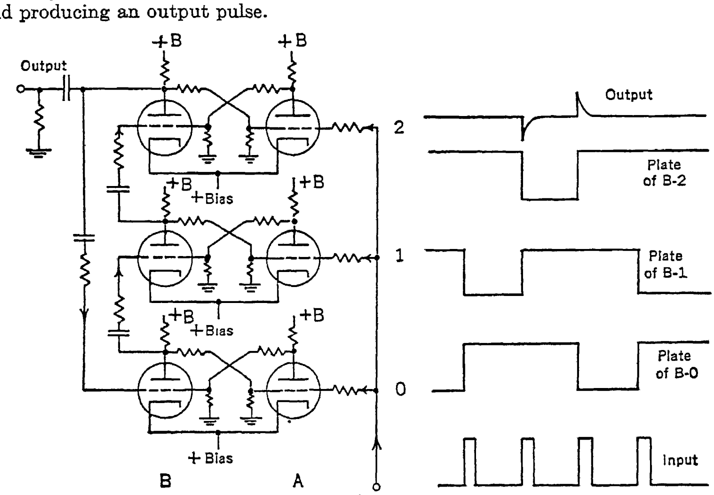

FIG. 2. Flip-flop Circuits in a Counter

Figure 2 shows flip-flop circuits of a type used in counters and computers. Successive input pulses, not necessarily at regular intervals, switch successive flip-flops to an indicating position. In each flip-flop, either triode, A or B, may conduct; the other triode is then cut off. Also, if triode A-0 is cut off, triodes A-1 and A-2 are conducting. A positive input pulse will then switch triode A-0 into conduction, and the coupling between the plate of B-0 and the grid of B-1 will switch triode A-1 into conduction. The control grid of triode A-1 is thus made sensitive to the next input pulse, and the high plate voltage on B-1 may actuate for that digit an indicating device such as a neon lamp. The coupling between triodes B-2 and B-0 completes one ring, so that the cycle is repeated every three input pulses. Output pulses with a frequency one-third that of the input pulses are thereby obtained.

11. PULSE AMPLIFIERS

The requirements to be met by pulse amplifiers are generally similar to those of television carrier-frequency and video-frequency amplifiers (see Section 7, Wide-band and I-f Amplifiers). The amplifiers must pass the essential frequency components of the signal to be amplified, with uniform gain and time delay. Any excess bandwidth passes needless background noise. A compromise choice made in radar systems allows a video bandwidth (in megacycles per second) equal to the reciprocal of the pulse duration (in microseconds), and double this bandwidth for the modulation sidebands of a pulsed carrier. This is twice the nominal minimum bandwidth defined on p. 9-11. Some additional carrier-frequency bandwidth is added for tolerance of detuning from various causes such as frequency drift.

The amplitude-and-phase spectrum concept (see Section 5, article 13) is useful in specifying low-pass and band-pass amplifiers for pulses and pulse-modulated carrier waves.

Fast recovery of normal operation after overloading by strong signals is required in systems like radar, in which a weak pulse may immediately follow a strong pulse. Figure 3 shows an i-f amplifier stage having quick recovery. The grid bias returns to normal

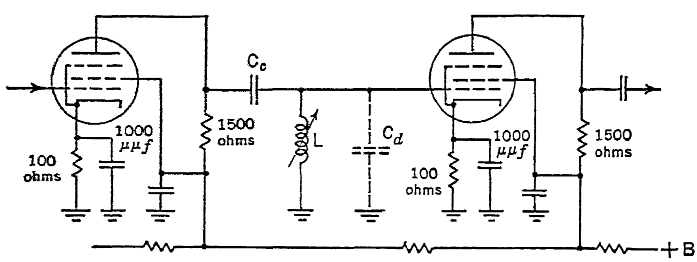

FIG. 3. Intermediate-frequency Amplifier

immediately after a strong pulse because there is negligible d-c resistance between grid and ground, and the cathode-circuit time constant is only 0.1 microsecond. The cathode-circuit time constant is made the minimum consistent with sufficient bias and bypassing. Plate current is supplied through the damping resistor for the stage. Fast recovery of normal plate voltage after a strong pulse is relatively unimportant because the operation of a pentode tube does not depend critically on plate voltage. The inductance L is made to resonate the distributed capacitance of the wiring and tubes, C_d, without any added lumped capacitance, in order to obtain maximum stage gain with the required bandwidth.

Video pulse amplifiers are frequently specified in terms of the permissible distortion of rectangular pulses by the amplifier, rather than by amplitude and phase characteristics. Thus, it may be required that a specified input pulse after amplification shall have a certain maximum rise time, fall time, ripple ratio, etc.

Resistance-coupled stages are used for voltage amplification. Because high video frequencies are usually involved, high-transconductance pentodes and relatively small coupling resistors are used. The product of the coupling resistance by the shunt capacitance places a lower limit on the time of rise and fall of output pulses. Shunt capacitance of un-bypassed components and wiring should be made as small as practicable.

In Fig. 4, an input pulse having zero rise time would produce at the following grid an amplified pulse having a leading edge rising exponentially with a time constant $\dfrac{r_1 r_2 C_d}{r_1 + r_2}$ (in ohms, microfarads, and microseconds). The amplified pulse would reach 90 per cent of peak amplitude in 2.3 times the time constant. The plateau of the pulse across r_2 decays exponentially with the time constant $(r_1 + r_2)C_c$, ordinarily much longer than T, the duration of the pulse. If, for example, less than 1 per cent decay is permissible from this coupling alone, make $(r_1 + r_2)C_c$ greater than $100T$.

The high-frequency response of resistance-coupled amplifiers may be improved by compensation and filter techniques discussed elsewhere in this book (see Section 7, Wide-band Amplifiers, and Section 20, Television).

When power amplification or impedance change is required, transformer coupling may be used. High-power pulses are economically obtained from tubes having low average-power ratings by permitting space current to flow only during pulses. The control grid

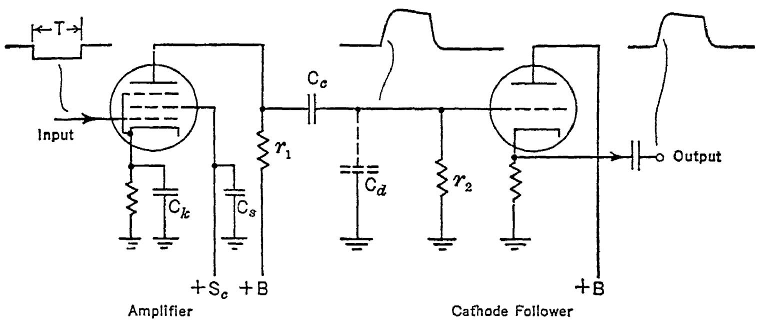

FIG. 4. Video-frequency Amplifier

in a high-power amplifier is therefore biased negative and driven positive during the pulses. Transformers may be used to provide the polarity inversion which may be required in successive high-power stages and also to permit impedance matching. Pulse transformers will be described below.

Cathode followers (see Fig. 4) are useful in obtaining high-voltage positive pulses across low impedance such as the coaxial lines commonly used. In successive stages of high-power pulse amplifiers, cathode followers make transformers unnecessary for polarity inversion. However, transformers are necessary if voltage amplification is required in addition to the current amplification obtained in a cathode-follower stage.

12. PULSE SHAPING CIRCUITS

Many of the wave forms used in pulse work are obtained by means of exponentially changing voltages and currents and by clipping or limiting action in the tubes. In sharp contrast with linear-amplifier practice, the operating conditions of the tubes in pulse shaping circuits are so chosen that grid current may flow or plate current may be cut off in order to distort a pulse or to reconstruct a clean pulse.

Clipping or Squaring. In Fig. 5, a sinusoidal voltage is applied to the grid of a tube through a high resistance. As the grid goes positive, the grid-to-cathode resistance falls

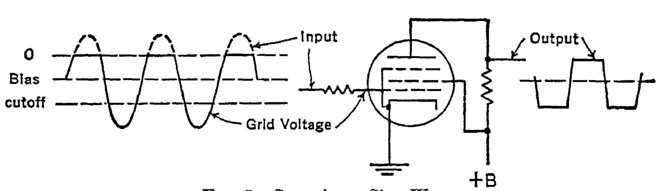

FIG. 5. Squaring a Sine Wave

abruptly, flattening the positive peak of grid voltage. As the grid goes negative, the plate current is cut off, flattening the negative peak. The output wave form is approximately square and can be squared further by added stages.

Pulse Narrowing. In Fig. 6a the time constant r_1C_1 is short as compared with the duration but not as compared with the time of rise and fall of the applied pulse, e_1. The voltage across r_1, from the step at each edge of the pulse, decays exponentially. The pulse is said to be differentiated, because the voltage across r_1 is approximately proportional to the derivative of the applied pulse voltage. Either the leading or the trailing edge may be used by the following stage. If the bias on the tube T_2 is large enough to cut off the plate current, only the positive (leading) impulse is amplified. If the bias is zero and r_2 is large, only the negative (trailing) impulse is amplified.

Long pulses may be shortened to a predetermined duration by application through a high resistance (in Fig. 6b the plate resistance of the pentode) to a delay line which is in

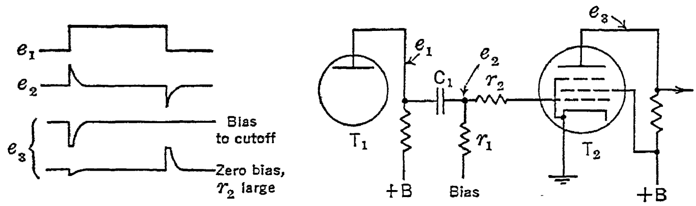

FIG. 6a. Narrowing a Pulse by *R-c* Differentiation

parallel with a resistance equal to the characteristic impedance z_0 of the line. The far end of the line is short-circuited, so that the pulse at the input end of the line is canceled by a reflected pulse of opposite polarity in twice the one-way delay time, t_d, of the line. The undesired pulse of reverse polarity which occurs at the end of the input pulse is clipped in a succeeding circuit.

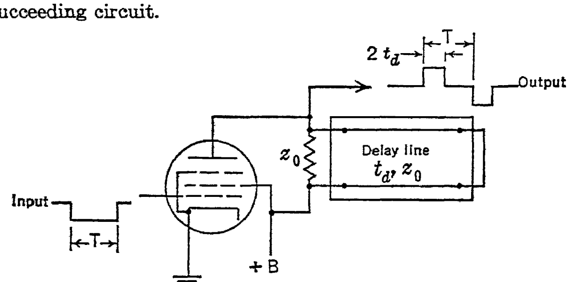

FIG. 6b. Narrowing a Pulse by Use of a Delay Line

Another arrangement for obtaining a short pulse of predetermined duration from a long pulse is shown in Fig. 6c. A half sine wave of short duration is produced in the plate circuit by the application of a long pulse. The period of the half sine wave is determined by the inductance of the coil and the distributed capacitance across it. The diode damps the oscillation on the second half cycle, reducing the oscillation after the first half cycle to a negligible level.

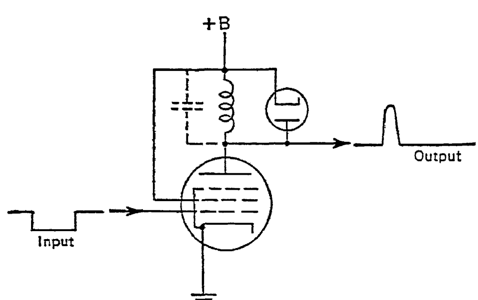

FIG. 6c. Narrowing a Pulse by Use of an Oscillatory Circuit

Pulse Widening. Integration is said to occur in Fig. 7. A positive pulse on the grid of tube *A* quickly discharges capacitor C_1, which recharges exponentially with the time constant r_1C_1. Resistance r_2 is assumed large as compared with r_1, and r_2C_2 large as compared with r_1C_1. Tube *B* is cut off during enough of the exponential discharge to provide the required pulse duration. The wave forms in solid line are typical of the circuit shown. By connecting r_2 to a positive voltage instead of to ground, a shorter duration and time of fall is obtained, as shown by the wave forms in broken line.

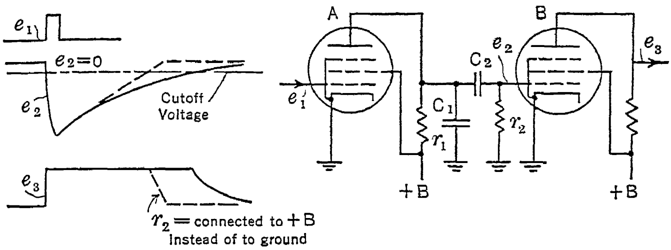

FIG. 7. Widening a Pulse

Clamping or D-c Reinsertion. When it is required that the baseline of a pulse wave form remain at a fixed voltage in spite of capacitive coupling and changing wave form, the arrangement shown in Fig. 8 may be used. If the two wave forms shown are coupled by capacitor C and resistor r_1 without the diode, the voltage limits vary as shown because the average voltage must remain zero. The use of a diode results in a short coupling time constant for negative voltages, so that the wave extends almost wholly in the positive direction. The resistance of r_1 is much greater than the resistance of the diode in the conducting direction (r_d). If no grid current flows, the rectifying action of the diode maintains on the capacitor a sufficient charge to hold substantially the entire wave positive

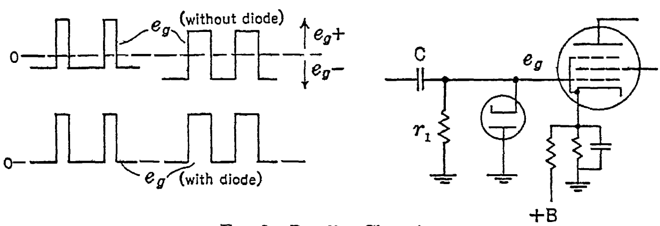

FIG. 8. Baseline Clamping

relative to ground. The diode also permits fast recovery of normal bias if grid current is drawn by a large positive pulse, because a negative voltage is quickly discharged through the diode.

13. RELAXATION CIRCUITS

Relaxation circuits are oscillators in which little if any energy is stored from one relaxation cycle to the next. The circuits have two conditions in which they are at least temporarily stable. When one condition becomes unstable, the oscillator shifts abruptly to the other condition.

An example of a circuit which has two permanently stable conditions is shown in Fig. 9. One tube is conducting and the other cut off in each of the stable conditions. Conduction

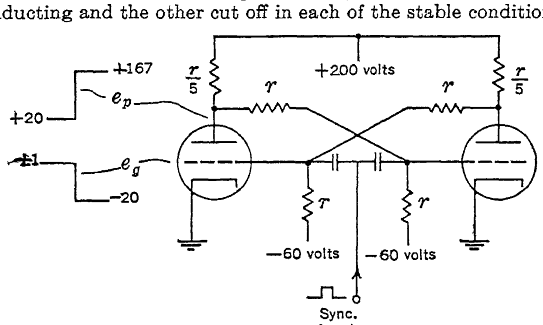

FIG. 9. Flip-flop Circuit Stable in Either Condition

is switched back and forth by successive trigger pulses, hence the designation "flip-flop" circuit. Typical voltages are shown in the figure.

In Fig. 10, a capacitor replaces one of the plate-to-grid coupling resistors, and direct coupling is used between the other plate and grid. Plate current cut off in tube T-2 and conduction in tube T-3 make a permanently stable condition. A trigger pulse through tube T-1 makes tube T-2 conduct and tube T-3 be cut off in a temporarily stable condition

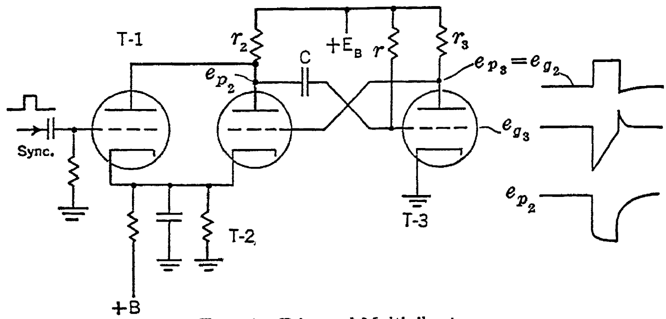

FIG. 10. Triggered Multivibrator

which ends when C discharges sufficiently through r. The circuit then switches back to the permanently stable condition. The circuit is known as a triggered or one-pulse multivibrator, or a "univibrator."

The circuit shown in Fig. 11 has only temporarily stable conditions and therefore runs free. It may be synchronized at the trigger frequency or integral submultiples thereof.

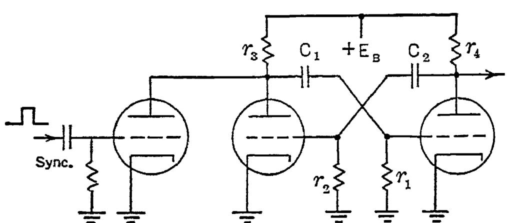

FIG. 11. Free-running Multivibrator

A transformer is used (instead of a second tube) for feedback polarity reversal in the one-tube blocking oscillator circuit shown in Fig. 12. It is free running unless the C bias is increased to limit the oscillation to one pulse. A temporarily or permanently stable condition exists between pulses while the grid capacitor is charged negative beyond cutoff. The other extreme condition exists during the pulse while the rate of increasing

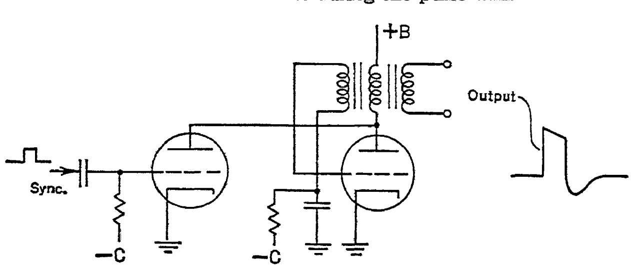

FIG. 12. Blocking Oscillator

plate current is limited by the inductance in the plate circuit; this condition causes grid current to charge the grid capacitor ready for the blocking period. Because plate current flows only during the pulses, the blocking oscillator works economically with the low impedances and high currents necessary for short pulses across the inherent capacitance.

Ionizing discharge tubes, such as thyratrons and gas diodes, are used in generating trigger pulses and sweep voltages by periodic discharge of a capacitor each time the capacitor is charged to the ionizing potential of the discharge tube. The capacitance and the charging impedance are chosen to give the desired period of pulse repetition.

A number of relaxation circuits particularly adapted for different applications are shown in other parts of this section.

14. PULSE TIMING CIRCUITS

Various timing problems arise in pulse systems. Pulse repetition rate, duration, and delay relative to a reference pulse require measurement and control.

Voltage wave forms frequently used for pulse timing are the sinusoidal, the exponential, and the rectangular. The three wave forms may be compared for basic stability resulting from their use.

With a sinusoid, if the timing action occurs as the sinusoid passes through the value zero, the timing is not greatly affected by the amplitude of the sinusoid, and stability of the same order as that of the inductance and capacitance is obtained.

In commonly used exponential timing circuits, the timing action occurs as the variable (voltage or current) reaches a predetermined amplitude. The timing is therefore a function of the initial amplitude as well as the time constant of the exponential change. Stability of the same order as that of the passive circuit elements requires compensation for changes in tube characteristics and operating voltages. Stability is generally improved by using only the early and most rapidly changing part of the exponential wave. Timing in relaxation oscillators is generally done by exponential changes to predetermined amplitudes.

A rectangular wave sent through a delay line yields a timing wave in which the entire amplitude change occurs at the most useful time. The stability obtained is limited by the allowable volume and complexity of the line.

Repetition Rate. A conventional sine-wave oscillator followed by a relaxation or shaping circuit may be used to obtain synchronizing pulses having a stable repetition rate and short rise time. The sine wave may be converted to a square wave by several clipper stages as discussed in article 12. The square wave may then be differentiated to obtain a suitable trigger pulse.

Having a sinusoidal oscillator with good frequency stability, a phase shifter followed by shaping circuits may be used to obtain a second pulse with accurately controlled delay relative to an unshifted trigger pulse. This system has been used in radar equipment to measure range accurately.

Repetition rate may be determined by a free-running relaxation oscillator such as a multivibrator, blocking oscillator, or thyratron. The repetition rate is then usually more subject to drift than if an L-C oscillator is used, but a suitable trigger pulse and a large range of repetition rates are economically obtained. Figure 13 shows a relaxation oscillator

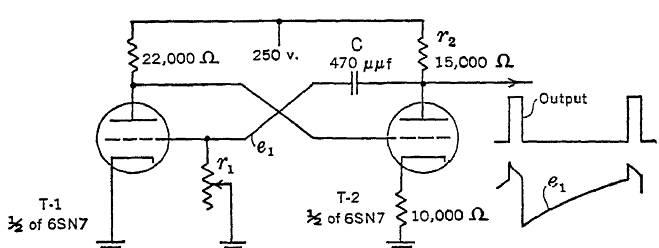

FIG. 13. Repetition Rate Determined by an Exponential Wave Form

providing trigger pulses of fixed duration as the repetition rate is changed. The pulse duration is determined by the exponential charging of capacitor C through r_2 and the low grid-to-cathode resistance of tube T-1. After each pulse the grid of tube T-1 is driven negative for a period determined by the exponential discharging of capacitor C through r_1 and the relatively small resistance of r_2 and tube T-2. The period between pulses is approximately proportional to the resistance r_1.

In some applications a delay line may be used to control repetition rate and simultaneously supply synchronizing pulses at desired times in each period. Thus, in Fig. 14, the blocking oscillator generates pulses which after traversing the delay line are applied to the trigger tube and initiate new pulses.

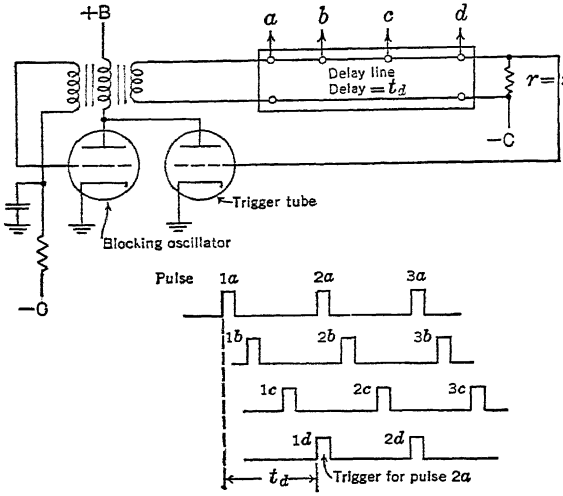

FIG. 14. Repetition Rate Determined by a Rectangular Wave Form

Duration. Pulses having a required duration may be generated by relaxation circuits or by pulse-forming lines and thyratrons, as discussed in article 15, "Pulse Modulation of an Oscillator." Alternatively, sinusoidal or other wave forms may be passed through pulse shaping circuits (see above) to produce pulses of the required duration.

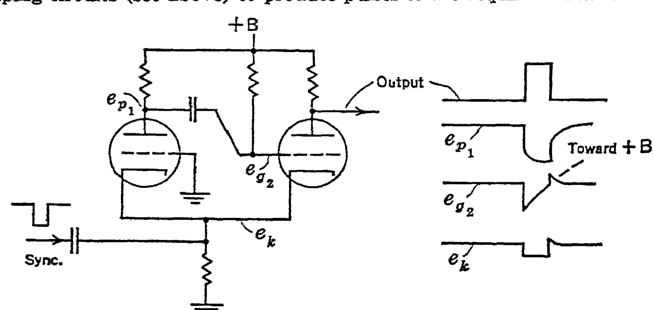

FIG. 15. Pulse Duration Determined by an Exponential Wave Form

A cathode-coupled one-pulse relaxation circuit is shown in Fig. 15 to illustrate control of pulse duration by exponential voltage change.

Blocking oscillators deliver maximum power during the pulse and therefore are adapted for high-power pulse equipment. Nominal control of pulse duration is obtained by means of grid capacitors and control of transformer inductance, in the circuit of Fig. 12. Precise duration and better pulse shape are obtained by means of a delay line as in Fig. 16. The transformer inductance is made large; the feedback, the line impedance, and the line terminating resistance are so chosen that the oscillator is shut off when the wave of grid

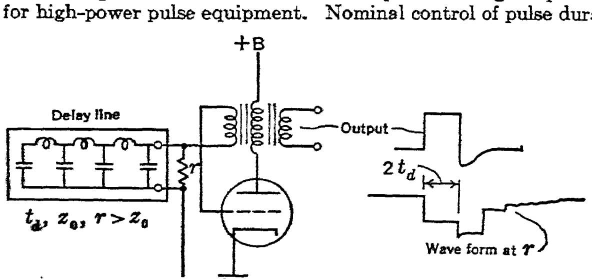

FIG. 16. Pulse Duration Determined by a Rectangular Wave Form

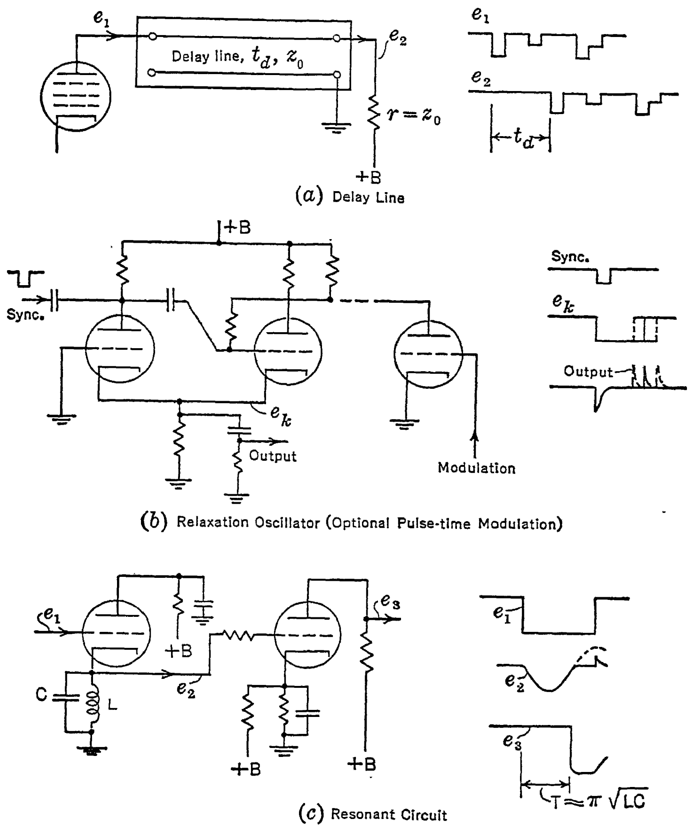
current reflected from the open end of the line reaches the terminating resistor. The pulse duration is then determined mainly by the round trip delay of the line and is little affected by variations in other circuit elements.

Delay. A complex wave may be delayed by passage through a delay line while maintaining substantially the same wave form. If it is only required that a delayed pulse be produced, the initiating pulse may trigger a relaxation oscillator, and the trailing edge of the relaxation pulse may be used after differentiation as the delayed pulse. The delay of the trailing edge of the relaxation pulse may be varied in accordance with a desired



(*a*) Delay Line

(*b*) Relaxation Oscillator (Optional Pulse-time Modulation)

(*c*) Resonant Circuit

Fig. 17. Circuits for Delaying Pulses

modulation for obtaining pulse-time modulation in a communication system. Special cathode-ray tubes have been developed to facilitate time modulation of the many time-sharing pulse channels in pulse-time multiplex systems. In another method, a resonant circuit is keyed on or suddenly shocked, and a delayed pulse is produced after a fraction of a cycle of oscillation. Typical circuits using (*a*) the delay line, (*b*) the relaxation oscillator, and (*c*) the resonant circuit are shown in Fig. 17.

The delay line can accept pulses having random spacing such as might be encountered in the output of a receiver. The other circuits illustrated must pass through a complete delay and recovery cycle between pulses and therefore are best used with isolated pulses.

15. PULSE MODULATION OF AN OSCILLATOR

An oscillator may be made to operate in pulses by including in its grid circuit a capacitor which charges during the oscillation and blocks or stops the oscillation. This is one form of the blocking oscillator. Oscillations start again after the capacitor has discharged sufficiently. The pulse recurrence rate and the pulse duration are approximately controlled by the time constants in the circuit, but only with limited stability.

The recurrence rate of a blocking oscillator may be stabilized by the use of synchronizing circuits to start tube conduction sooner after each pulse than would otherwise happen. The pulse duration may be stabilized by making a time-delay network shut off the oscillator.

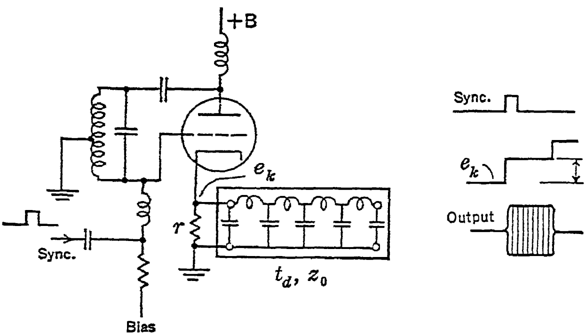


FIG. 18. Pulse-modulated Carrier-frequency Oscillator

The oscillator in Fig. 18 has provision for synchronization by a positive pulse applied to the grid. A delay line in the cathode circuit shuts off the oscillator after a time interval of twice the line delay. The discharging resistor r is usually many times as large as Z_0, the wave impedance of the line. At the start of the pulse the cathode current flows through an impedance approximately equal to Z_0, and develops a voltage wave E which travels through the line. The wave is reflected with the same polarity by the open far end and returns to increase the voltage at the cathode to approximately twice the initial voltage, stopping the oscillator.

Pulse modulation may also be accomplished by grid or plate modulation of an oscillator or amplifier. If high power is required, plate modulation of an oscillator is generally most economical. With plate modulation, the high voltage is impressed on the oscillator tube only during the pulses. The design of the oscillator tube is thereby made easier, or conversely the permissible maximum plate voltage on a given tube design may be increased far beyond the direct-voltage rating.

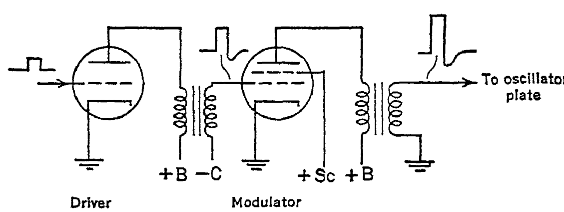

FIG. 19. Vacuum-tube Modulator

A vacuum-tube modulator is shown in Fig. 19. The modulator tube, cut off between pulses, is driven hard so that it passes high current through low impedance during the pulses. The modulator acts as a switch connecting the load to the B supply only during the pulses.

A thyratron pulse modulator is shown in Fig. 20. The artificial line is charged through a high resistance r_c between pulses. By the use of the line instead of a single capacitor, a

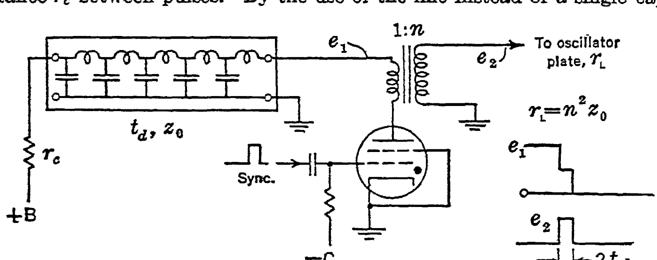

FIG. 20. Thyratron Modulator

rectangular pulse may be obtained rather than an exponentially decaying pulse. The thyratron discharges the line into the load and must deionize before the line can recharge. Deionization is expedited by making the thyratron resistance plus the transformed load resistance somewhat less than the line impedance so that the thyratron plate is driven slightly negative just after the pulse.

For high-voltage applications, the preferred form of artificial line is the "Guillemin line," shown in Fig. 29(*e*) below. Also, the thyratron may be replaced by a spark gap. Higher efficiency and faster charging of the line may be obtained by replacing the charging resistor r_c by an inductor. The line is then charged in a half-cycle of a charging oscillation, between pulses, to approximately twice the power supply voltage. A diode may be connected in series with the inductor to prevent discharge back into the power supply.

Pulse modulation imposes on an oscillator severe requirements of fast starting and stopping. The oscillator must ordinarily start from the background noise in the circuit and build up to maximum amplitude in a time interval which is much shorter than the pulse duration. Random variations in the noise amplitude cause random variations in starting time, termed "jitter."

To explain the starting and stopping time, the essential elements of the oscillator are indicated in Fig. 21. They are the resonator *CL* and the conductance *g*. During the starting time of a pulse, the net conductance is made negative by feedback; during the stopping time it is positive as determined by the damping of the circuit augmented by its useful load.

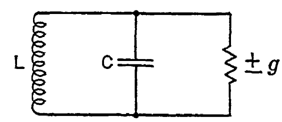

FIG. 21. Equivalent Circuit of an Oscillator

The starting or stopping time constant of oscillations is $2C/g$ The starting time, for the oscillations to build up by regeneration from the noise level, is of the order of 20 times the time constant determined by the negative conductance, and the jitter is somewhat less than this time constant. The stopping time is about equal to the stopping time constant, since the oscillation is merely damped from its peak value after the regeneration is cut off. These effects are shown in Fig. 8, p. 9-06.

16. MODULATING THE CHARACTERISTICS OF PULSES

Preceding sections of this chapter have indicated ways of forming pulses and controlling their characteristics. Coding of pulses for identification of the source or for transmission of information may be accomplished by mechanical switching or by electronic switching or modulation. Pulse duration may be changed by connecting or disconnecting sections in a delay line used to control a blocking oscillator. Similarly, the constants of a shaping circuit or relaxation circuit may be switched.

The circuit shown in Fig. 17(*b*) permits electronic modulation of pulse width such as might be used in a communication system. Differentiation of the output pulse, as shown in the figure, yields a pulse having electronically modulated phase relative to a base or marker pulse. Pulse phase or time may also be modulated at an audio rate by addition of audio voltage to linear sawtooth timing pulses as shown in Fig. 22. No plate current

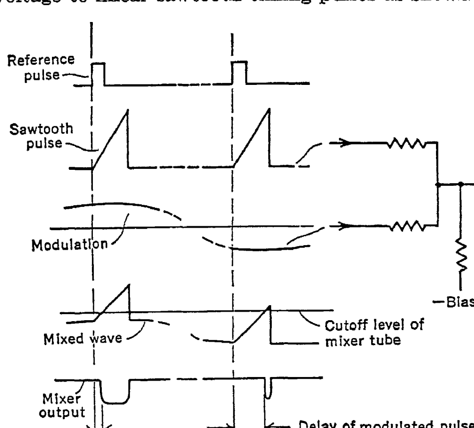

FIG. 22. Pulse-time Modulator

flows until the sum of the audio, the sawtooth, and the bias voltages exceeds the cutoff voltage of the mixer tube. The timing of the leading edge of the resulting plate-current pulse varies in direct proportion to the instantaneous value of the audio voltage. The mixer output pulse may be differentiated and shaped to obtain the desired wave form for pulse modulation of a carrier wave.

A group of pulses may be obtained by shaping a sine wave which has the proper periodicity, to obtain trigger pulses for a relaxation circuit. The sine wave is initiated and ended by a gate pulse long enough to permit generation of the required number of pulses. Figure 23 shows one such arrangement. Triode A is conducting normally. A negative

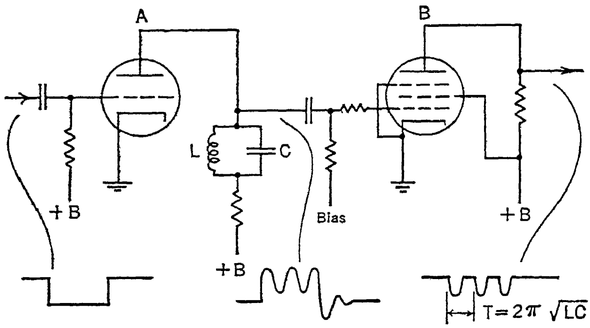

FIG. 23. Multiple-pulse Generator

gate pulse cuts off the triode, developing a positive gate and a free oscillation to drive the grid of the pentode B. At the end of the gate pulse the oscillations are quickly damped by the plate resistance of the triode. The number of pulses may be changed by switching the gate pulse duration.

Figure 24 shows the elements of a two-pulse generator using a delay line. A modification of this arrangement in which the pulse spacing would correspond to altitude has been proposed for use in air navigation (Lanac). An initiating pulse passes through a delay

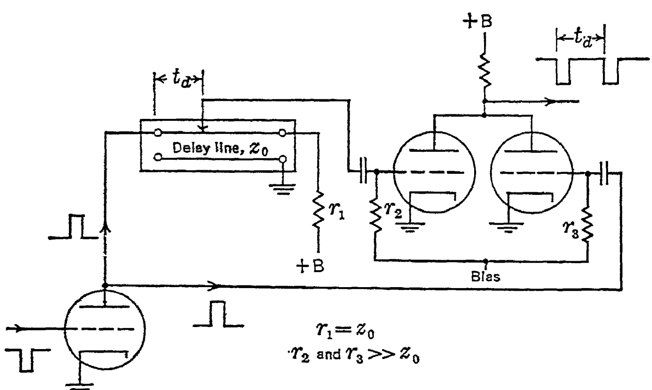

FIG. 24. Double-pulse Generator

line and is absorbed by the resistor terminating the line. The line is tapped to permit application of the pulse, after the required delay, to the grid of a tube. The direct and delayed pulses are mixed to produce a pair of pulses with variable spacing.

17. PULSE DETECTORS

Pulses are distinguished from sinusoidal and steady waves by rapid changes in amplitude, large ratio of peak to average value, small duty cycle, and wide frequency spectrum. The detection of pulses requires detecting means responsive to the special characteristics of pulses, usually to their time boundaries as distinguished from their peak amplitudes.

Bandwidth requirements have been discussed earlier in this section. Pulse amplifiers may include filters or coupling systems which favor pulses having certain characteristics, require more pulses in a group. The timing of two or more pulses in a group may be used for altitude coding in an air navigation system (Lanac) as mentioned previously.

Phase or time modulation of pulses in a communication system may be converted to audio signals by a corresponding type of detection. Phase modulation may be detected by providing reference pulses of uniform periodicity and using these to form gate pulses of suitable phase which the phase-modulated pulses overlap more or less in accordance with the modulation. If the gate and the phase-modulated pulses are applied to a coincidence mixer, plate current will flow during the interval of pulse overlap. The plate current, averaged over a few pulses, is then modulated in accordance with the phase modulation of the pulses. Special beam-deflection tubes have been developed for phase modulation and synchronous detection of many time-sharing channels in a pulsed multiplex system.

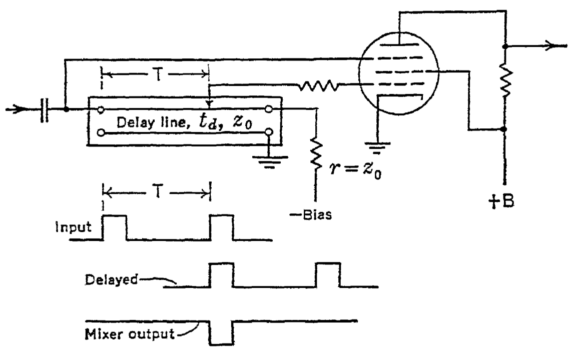

FIG. 27. Double-pulse Decoder

18. VACUUM TUBES

Most vacuum tubes, at the date of writing, have not been rated for pulse applications (see Section 4, especially pulse tubes such as magnetrons and thyratrons). However, many vacuum tubes have been used in pulse applications after rough estimation of their pulse capabilities from their ordinary ratings. The principal factors are peak and average cathode current, peak and average electrode voltages, electrode power dissipations, and tube life.

If a tube has class C amplifier ratings, the cathode current for long pulses may safely be 4 or 5 times the class C average-current rating. The average current should not exceed the class C average-current rating. For pulses a few microseconds in duration, peak currents of about 50 times the class C average-current rating may be taken from oxide-coated cathodes, with tube life commonly exceeding 500 hours. Pulse current densities of 10 to 20 amp per sq cm are used with specially processed oxide-coated cathodes. The cathodes must be heated to their operating temperature before large currents are permitted.

The ordinary peak-voltage ratings of tubes may often be safely exceeded in pulse applications. Insulation breakdown inside the tube, electrolysis of the glass, or poor plate-current cutoff characteristics may fix the permissible peak voltage. The peak plate voltage in class C applications is about twice the average plate voltage; this is usually a justification for permitting pulse peak voltages twice the rated average plate voltage. If the plate voltage is applied only during pulses, the sparkover voltage may set the limit at a much higher voltage.

Beam power tubes in pulse modulators are operated at high screen voltage in order to reduce the driving power required. The plate voltage is usually low during pulses of current flow, so that average plate power dissipation is low. Screen dissipation is high, however, and often limits average power. Permissible limits of plate and screen dissipation may be reduced as peak-voltage ratings are increased.

The space-charge effects which suppress secondary emission from the plate in beam tubes also tend to limit the flow of pulse current at low plate voltage. The usually desired properties of beam tubes are even more important for pulse amplifiers of very high power used as modulators. Secondary emission from the control grid is minimized to avoid loss of control caused by reverse grid current and to prevent parasitic oscillation.

A number of thyratrons specifically intended for pulse modulation are available. Miniature types deliver pulses of peak power of kilowatts; larger types deliver megawatts. Fast deionization is obtained in tubes filled with the lighter gases such as hydrogen and helium, slower deionization with argon and xenon. Cathode current densities are of the same order as in high-vacuum tubes but with much less voltage drop between plate and cathode. The internal voltage drop is high at the start of ionization, very rapidly decreasing as ionization reaches saturation. A maximum rate of rise of current is specified to limit the plate dissipation and the ion bombardment of the cathode at the start of the pulse. The rate of rise of current is usually limited by some inductance in series with the plate of the thyratron.

It is worthy of mention that, at the high currents used in pulse work, the transconductance of vacuum tubes is greater than usual, and transit time is reduced by the corresponding high voltages. The performance of a tube in a pulsed oscillator is therefore often better than its continuous-wave performance at high carrier frequencies subject to transit-time effects. In fact, some types will oscillate efficiently in high-power pulses at frequencies so high that continuous oscillation is impossible at their maximum d-c ratings.

19. PULSE TRANSFORMERS

The problem of designing a pulse transformer is generally similar to that of designing an audio-frequency transformer but for higher-frequency components with corresponding

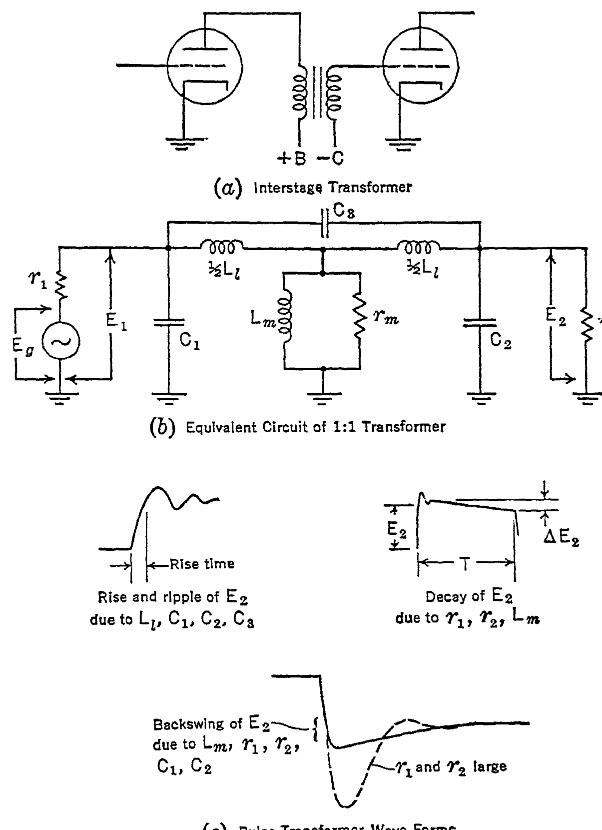

Fig. 28. Pulse Transformers

reduction in size. Maximum mutual inductance, minimum leakage inductance, and minimum incidental capacitance are desired. The ratio of maximum to minimum essential frequency components involved in faithfully transforming a single pulse wave form may be 100 to 1. If the pulse duration may vary by 10 to 1, the frequency ratio may be 1000 to 1. The requirements for high-power modulator transformers are usually much less severe in frequency ratio.

A rough estimate of transformer specifications may be obtained by analysis of the circuit of Fig. 28(a) and the equivalent circuit shown in Fig. 28(b). A turns ratio of 1 to 1 is assumed. The mutual inductance L_m may be neglected in estimating the rise time of the pulse. If r_1 and C_1 are small, the rise time is roughly $\sqrt{L_1C_2}$ or L_1/r_2, whichever is greater. The magnetizing current at the end of the pulse is

$$I_m = \frac{E_1T}{L_m} + \frac{E_1}{R_m} \tag{1}$$

if the pulse duration is T. The decrease in voltage during the pulse and the backswing at the trailing edge, both of which are caused by the magnetizing current, are roughly in the ratio

$$\frac{\Delta E_2}{E_2} = \frac{T}{L_m}\frac{r_1r_2}{r_1 + r_2} \tag{2}$$

if r_1 and r_2 are small and linear. If r_1 and r_2 become large on reversal of polarity, the backswing is determined by I_m, L_m, $C_1 + C_2$, C_3, and r_m. r_m represents the apparent shunt resistance of eddy currents and hysteresis in the core loss.

To reduce eddy currents or skin effect in the core, very thin laminations are used for pulse transformers. Permalloy and silicon-steel tapes from 0.0001 to 0.003 in. in thickness are wound into toroidal cores which are sliced for assembly with coils. Reduction of skin effect in the core permits greater ratios of mutual to leakage inductance by increasing the depth of penetration and the resulting effective permeability of the core volume. The available flux swing in the core may sometimes be increased by the use of reverse-magnetizing direct current. Because pulse wave forms are usually unidirectional, and the core has some retentivity, saturation may otherwise occur with a small flux swing per pulse. Some core materials especially suited for pulse applications are listed below.

Because of restrictions on leakage inductance, high-voltage pulse transformers are difficult to insulate. Impregnation with oil or polymerized resins to eliminate air spaces and moisture are effective in preventing corona and raising the breakdown voltage.

Table 1. Core Materials for Pulse Applications

Name and Manufacturer	*Description*
Hypersil Westinghouse Electric Corp.	Wound silicon-steel tape: grain-oriented 0.002 in' thick tape for high quality; plain 0.003 in. tape for less critical application.
Permalloy Bell Telephone Laboratories	Wound permalloy tape: from 0.0001 to 0.002 in. thick; several different alloys.
Silicon Nicalloy General Electric Co.	Conventional laminations: type B9W4A.
Sinimax and Monomax Allegheny Ludlum Steel Corp.	Conventional laminations: several different alloys (permalloys).

20. DELAY LINES *

A delay line is a network used for storing the energy of a pulse pattern and delivering out the same energy at a later time. (See Section 5; Networks, Lines, Transients.) The simplest form is a transmission line, in which case the delay is determined by the distance along the line at a velocity somewhat less than the velocity of light. While the transmission line or wave guide may give the best performance, it requires a length too great for most purposes, so more concentrated forms have been devised to save space.

Delay lines are used for two general purposes: one is the relative timing of different operations; the other is the delayed reproduction of a pulse pattern. The former may be tolerant of distortion in the delay process and can even be accomplished by other kinds of timing circuits such as relaxation oscillators. The delayed reproduction of a pulse pattern, however, places the most severe requirements on a delay network, especially against amplitude and phase distortion. For either purpose, precision of timing may be a requisite which involves directly the stability of the network and indirectly the fidelity of reproduction and the stability of associated circuits.

Figure 29 shows some typical concentrated delay networks. They rely on coils for concentrating the inductance and on dielectric for concentrating the capacitance. Further concentration of inductance may be obtained by iron-dust cores for the coils.

The continuous coil with capacitive loading is shown in Fig. 29(a). In a typical form, a coil of fine enameled wire is wound on a flexible core of insulation material having such small diameter that it can be coiled. The winding is wrapped with thin dielectric tape for capacitive loading, and the other conductor is provided by a braided sheath of fine

* This article by Harold A. Wheeler.

enameled wire. The sheath acts as a capacitive shield but not as an inductive shield, because the latter would destroy the desired inductance of the coiled inner conductor. The entire line is protected by a covering of insulation.

In a continuous coil, the mutual inductance along its length has the effect of decreasing the effective inductance at higher frequencies relative to that of lower frequencies, which causes phase distortion. In Fig. 30, the curved dotted line (*a*) shows this effect. Uniform delay, free of distortion, requires a straight phase curve illustrated by the solid line (*b*). It has been found possible to approximate this ideal by introducing substantial distributed capacitance in parallel with the series inductance, as is also shown in Fig. 29(*a*). This causes the effective inductance to increase with frequency and can be designed to compensate for the opposite effect of mutual inductance along the coil. Without such compensation, the effect may be reduced by using a coil diameter very small as compared with its length, which tends, however, to defeat the aim of concentration.

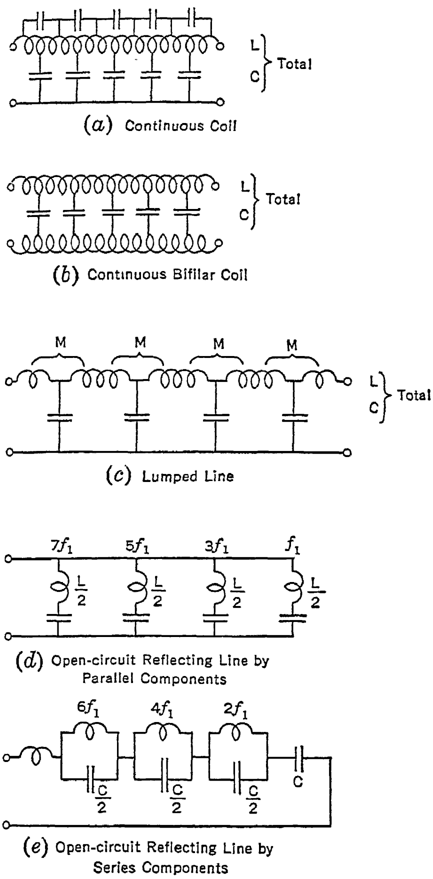

FIG. 29. Delay Lines

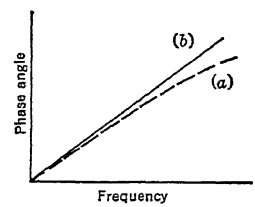

FIG. 30. Phase Distortion of Continuous Coil

The low-frequency delay (initial phase slope) of a delay line is

$$T = \sqrt{CL} \tag{3}$$

in terms of the total shunt capacitance C and total series inductance L (including mutual inductance). The corresponding wave impedance (characteristic impedance or image impedance) is

$$Z_0 = \sqrt{L/C} \tag{4}$$

Any of the following sets of units may be specified, the last (long used by Dr. Alan Hazeltine) being generally most convenient:

T	seconds	μs	μs
C	farads	μf	mμf
L	henrys	μh	mh
Z_0	ohms	ohms	kilohms

As an example, a rather long coiled line of 1 mμf and 1 mh has a delay of 1 μs and a wave impedance of 1 kilohm.

Another form of coiled line, shown in Fig. 29(*b*), is made of two coils wound in opposite screw-directions on the same core. One coil is wound in one direction on the core, then the other is wound on top in the opposite direction. The insulation may be only the enamel on the wires, or it may also include some thin layers of dielectric. This method gives the inductance of a two-layer coil with convenient capacitive loading. It is useful as a balanced four-terminal circuit or as a two-terminal reflecting line with far end on open circuit or short circuit.

The low-pass filter of Fig. 29(*c*) is a lumped delay line. Its useful bandwidth is somewhat less than its cutoff frequency and decreases further with more sections. The constant-k type (without mutual inductance) has concave phase distortion as shown in Fig. 31(a). By converting to an m-derived type, by the addition of mutual inductance M between adjacent inductors, it is possible to approach the ideal linear phase (b) to the approximation indicated by curve (c). For a line of many sections, the optimum value of the design parameter m is $\sqrt{3/2} = 1.22$. The number of sections required is

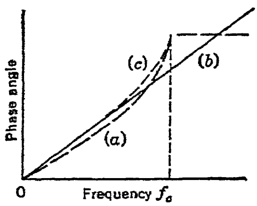

FIG. 31. Phase Distortion of Lumped Line

$$N = \frac{\pi}{m} f_c T \tag{5}$$

in terms of the cutoff frequency f_c (Mc) and the delay T (μs). As an example, a pulse 1 μs wide can be delayed 2 μs by a network of $f_c = 1$ Mc and $N = 5$ sections.

In a concentrated delay line with phase correction, especially if the delay is many times the permissible widening of the pulse, the attenuation increasing with frequency is likely to impose the practical limitation on the useful bandwidth. Therefore all losses must be minimized to secure the optimum design in limited space.

A reflecting line is often useful and has the advantage of a round trip which doubles the delay. The voltage polarity of reflection is direct or reverse, depending on whether the far end of the line is an open or short circuit. Ordinarily the near end is terminated with a resistance load matching the line impedance to preclude multiple reflection.

A reflecting line becomes a two-terminal network whose essential properties are expressed by the variation of impedance with frequency. An ideal delay line of uniform delay and no losses has a pure reactance as shown in Fig. 32 if the far end is on open circuit. The alternate zeros and poles are at odd and even multiples of the fundamental frequency:

$$f_1 = \frac{1}{4\sqrt{CL}} \tag{6}$$

At this frequency, the length is 1/4 wavelength in the line.

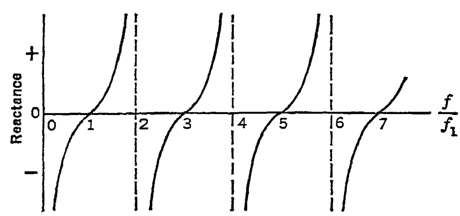

FIG. 32. Impedance of Open-circuit Reflecting Line

The impedance of a reflecting line can be duplicated over a limited frequency bandwidth by other two-terminal impedance networks which sometimes have advantages. Figure 29(d) presents the reactance pattern of Fig. 32 by a parallel connection of several series-tuned circuits having equal values of inductance but such values of capacitance as to resonate at odd multiples of the fundamental frequency. Figure 29(e) presents the same reactance pattern by a series connection of parallel-resonant circuits having equal values of capacitance and resonated at even multiples. This last network has a great advantage in pulse discharging functions (as proposed by E. A. Guillemin) because only the isolated capacitor C has to take the high-voltage charge preparatory to the discharge; the other capacitors can have much lower voltage ratings.

When a charged delay line is discharged into a matched load, the output is a pulse whose width is the round-trip delay $2T$, as shown in Fig. 33. The pulse starts suddenly by the discharge of energy near the terminals, but the trailing edge is sloping because the delayed energy is subject to the distortion in the line.

FIG. 33. Pulse Discharge of a Line into a Matched Load

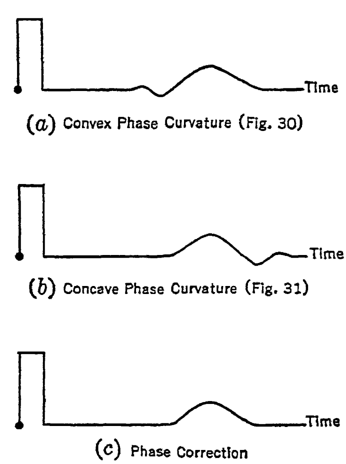

FIG. 34. Delay of a Pulse by a Reflecting Line on Open Circuit, Showing the Effects of Distortion

Figure 34 shows the distortion of a pulse subjected to round-trip delay in a reflecting line on open circuit. In every case the pulse is decreased in area by the attenuation and is widened by the amplitude distortion limiting the frequency bandwidth. The effects of phase distortion can be estimated by the method of paired echoes. The leading transient (*a*) and the trailing transient (*b*) are characteristic of convex and concave phase curvature, shown in Figs. 30 and 31. The former occurs in continuous coiled lines and the latter in lumped lines. In either case, phase correction (Fig. 34*c*) removes the transient oscillation, since the oscillation is caused by subnormal or abnormal delay of the higher-frequency components of energy in the pulse.

FIG. 35. Delay and Reversal of a Pulse by a Reflecting Line on Short Circuit

If the direct and reflected pulses have to be separated, a delay line on short circuit (or an equivalent two-terminal network) is used to secure the result shown in Fig. 35. Since the respective pulses are of opposite polarity, one or the other can be selected by a rectifier.

SECTION 10

TRANSMISSION CIRCUITS

TRANSMISSION CIRCUITS

WIRE TRANSMISSION LINES

By John D. Taylor

1. TYPES OF COMMUNICATION TRANSMISSION CIRCUITS

Wire communication circuits are classified in two groups, open (bare) wire and cable. Each group includes a number of different gages and types of wire, and the electrical characteristics of each gage and type are different. Both groups have their respective fields of use, and frequently these fields overlap and supplement each other. Open wire is generally economical where the circuit requirements are relatively small and cable costs would be prohibitive. Cable is desirable and economical where large groups of circuits and the higher-frequency types of services are involved, and where maximum protection from surface interferences is essential.

Cable is also employed for specific applications; for example, coaxial cable for television and radio transmission lines.

2. FREQUENCY SPECTRUM

Communication intelligence and signals (with the exception of those d-c signals used in telegraph, emergency, control, and other services) are usually transmitted between points in the form of a-c electrical energy or wave propagation of definite frequencies or frequency ranges. Because of the different devices for and methods of generating and transmitting these various a-c frequencies, and in order to avoid interference between the numerous circuits and services, frequency allocations have been determined for the various classes of communication and signal facilities.

Communication services may be classified, for the purpose of assigning suitable facilities, according to the frequency range within which they operate. Figure 1 is a chart of frequencies employed in power and communication services up to about 5 mc. (See Sect. 17, art. 8.)

3. ELECTRICAL CHARACTERISTICS

Primary constants of wire lines consist of resistance r in ohms, inductance L in henries, capacitance C in farads, and leakage conductance g in mhos. For convenience, L, C, or g may be expressed in smaller units, such as microfarads (millionths of a farad) for C. These constants vary differently for different wire materials, sizes, spacings, insulation, conductivity, temperature, and moisture conditions, as well as for different types of construction, as indicated in Table 1.

Secondary constants are values derived from primary constants; for communication purposes, they consist principally of (1) impedance z in ohms and phase angle, (2) propagation constant, composed of the attenuation and wave length constants, (3) wave length, (4) velocity of propagation, and (5) cut-off frequency. From the various constants, the electrical characteristics of the different wire lines have been determined, and these characteristics are useful in considering the suitability of such lines for communication purposes and in the engineering of the wire communication plant.

The secondary constants, expressed in terms of the primary constants, are as indicated in the following equations. These equations apply to uniform lines of infinite length or terminated in their characteristic impedances.

CHARACTERISTIC IMPEDANCE, $Z_0 \angle \theta$. A wire transmission line has both series impedance, z, and shunt admittance, y. For a line of uniformly distributed primary constants and of infinite length $z = r + j\omega L$ and $y = g + j\omega C$, where ω (angular velocity) $= 2\pi f$ radians [1 radian $= (360/2\pi)°$].

$$Z_0 = \sqrt{\frac{z}{y}} = \sqrt[4]{\frac{r^2 + \omega^2 L^2}{g^2 + \omega^2 C^2}} \quad \text{ohms} \tag{1}$$

and

$$\angle \theta = \frac{1}{2}\left(\tan^{-1}\frac{\omega L}{r} - \tan^{-1}\frac{\omega C}{g}\right)$$

Table 1. Characteristics of Representative Types of Wire Telephone Lines at 1000 Cycles (1)

Type of Line	Gage of Wire, mils	Spacing of Wires, in.	Type of Loading *	Distributed (2) Constants per Loop Mile				Propagation Constant				Line Impedance				Wave-length, miles	Velocity, thousands of miles per second	(5) Cut-off Frequency, cycles	Attenuation, db per mile
				r, ohms (68° F for o.w., 55° F for ca.)	L, henries	(3) C μf	(4) g μmhos	Polar: Magnitude	Polar: Angle, degrees +	Rectangular: α nepers	Rectangular: β radians	Polar: Magnitude	Polar: Angle, degrees −	Rectangular: r, ohms	Rectangular: x, ohms −

* The type of loading is designated as follows: First a letter indicating the spacing of coils: H = 6000 feet; next the number of millihenries per coil; then S or P for side or phantom. See Section 17, art. 16.

Notes: (1) All values are dry weather, calculated and approximate. Values actually vary from cable to cable and pair to pair in the same cable.
(2) Assumed distributed for loaded cable.
(3) Assumes 40-wire o.w. line.
(4) DP in. for 12-in. and CS in. for 8-in. spacing.
(5) Exceeds open-wire system requirements.

For standard non-loaded telephone cable lines, L and g are relatively small, so that for approximate computations these constants may be neglected and

$$Z_0 \doteq \sqrt{\frac{r}{\omega C}} \angle 45^\circ \quad \text{ohms} \tag{2}$$

For lumped loaded cable lines (the usual method of loading such lines), the midsection characteristic impedance Z_0 of an infinite loaded line may be determined from a pi network, converted to a T network, which is electrically equivalent to the combined lumped and distributed constants of a complete loading section of the line. The a (series) and

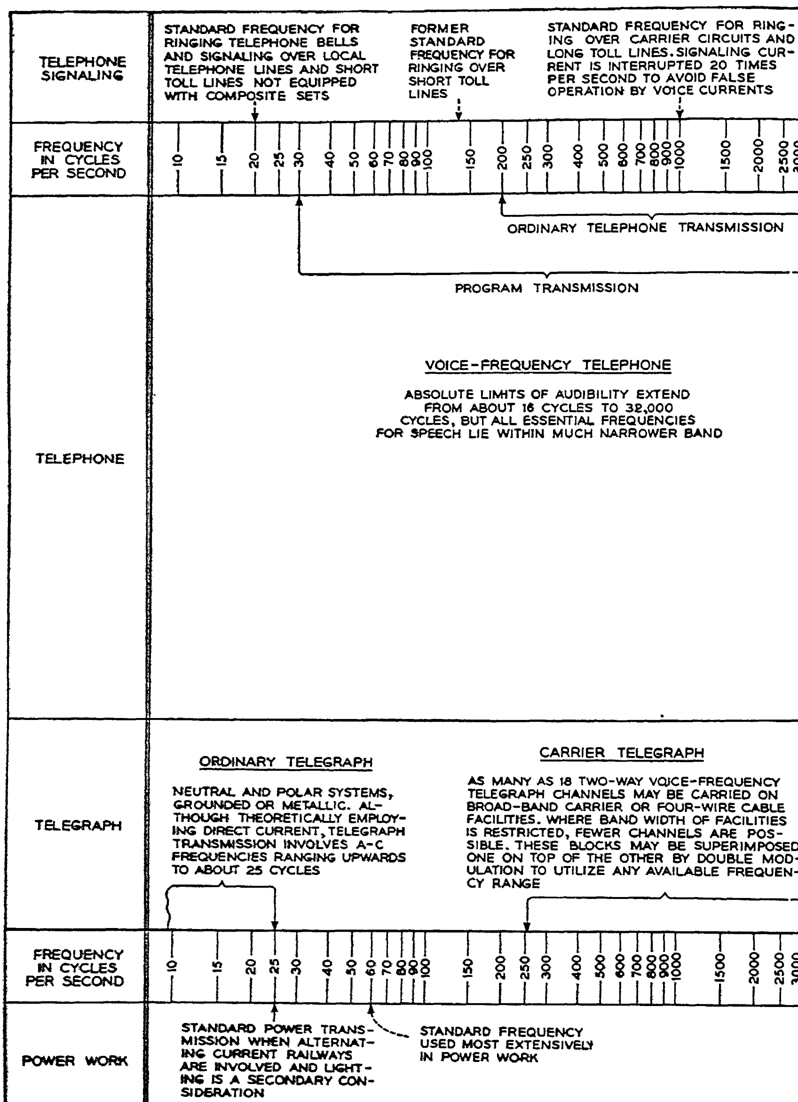

FIG. 1. Operating Frequencies for Power and

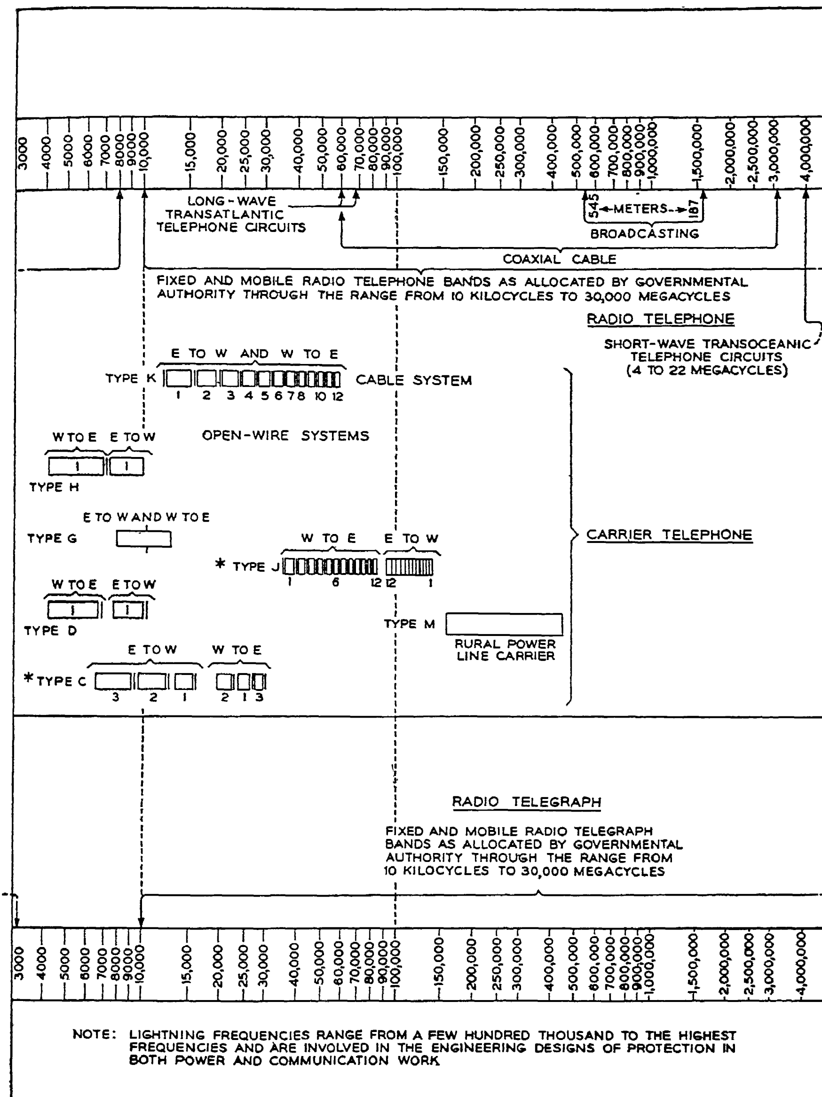
b (shunt) values of the T network having thus been determined,

$$Z_0 = \sqrt{ab + \frac{a^2}{4}} \quad \text{ohms} \tag{3}$$

For uniform or lumped loaded cable lines at voice frequencies ωL is large with respect to r and

$$Z_0 \doteq \sqrt{\frac{L}{C}} \angle 0° \quad \text{ohms} \tag{4}$$



* THESE REPRESENT THE FREQUENCY ALLOCATIONS FOR ONE SYSTEM OF THIS TYPE; OTHERS ARE DISPLACED SLIGHTLY, OR EMPLOY OTHER SIDEBAND

Communication Services (Courtesy Bell System)

For non-loaded open wire lines at radio frequencies

$$Z_0 \doteq 276 \log_{10} \frac{2D}{d} \quad \text{ohms} \tag{5}$$

where D is the distance between the centers of the wires and d is the diameter of the wires.

For coaxial (concentric tube) cable lines at carrier and higher frequencies

$$Z_0 \doteq 138 \log_{10} \frac{b}{a} \quad \text{ohms} \tag{6}$$

where a is the outer radius of the inner conductor and b is the inner radius of the outer conductor.

PROPAGATION CONSTANT. The propagation constant, γ, is a function of the series impedance, z, and the admittance, y, in the vector relation

$$\gamma = \sqrt{zy} = \sqrt{(r + j\omega L)(g + j\omega C)} \tag{7}$$

Also, γ is composed of an attenuation constant α and a wave length constant β in the relation

$$\gamma = \alpha + j\beta = \gamma \cos\theta + j\gamma \sin\theta \tag{8}$$

where

$$\alpha = \sqrt{1/2\sqrt{(r^2 + \omega^2L^2)(g^2 + \omega^2C^2)} + 1/2\,(gr - \omega^2LC)} \tag{8a}$$

$$\beta = \sqrt{1/2\sqrt{(r^2 + \omega^2L^2)(g^2 + \omega^2C^2)} - 1/2\,(gr - \omega^2LC)} \tag{8b}$$

Equation (8a) gives α in nepers (1 neper = 8.686 db), and eq. (8b) gives β in radians (1 radian = 57.296°). It is usually more convenient to calculate α and β from eqs. (7) and (8) than from eqs. (8a) and (8b).

From the above discussion it is seen that the propagation constant represents both the dying-away and phase-change effects of the voltages and currents, as they progress along the line.

If γ is given for 1 mile, then the total attenuation and phase change effects for l miles is $l\gamma$. The ratio of the current I_2 at the receiving end to the current I_1 at the sending end of a uniform line, l miles long and properly terminated, is

$$\frac{I_2}{I_1} = \varepsilon^{-l\gamma} = \varepsilon^{-l(\alpha+j\beta)} = \varepsilon^{-l\alpha}/\overline{l\beta} \tag{9}$$

Thus, the magnitude of $I_2 = I_1\varepsilon^{-l\alpha}$ and the two currents differ in phase by the angle $l\beta$, which is expressed in radians.

From Eq. (9)

$$2.303 \log_{10} \frac{I_2}{I_1} = -l\alpha$$

and the magnitude of the propagated current I_2, in terms of the sending current I_1, at any point along a uniform transmission line, is

$$\frac{I_2}{I_1} = \frac{1}{\log_{10}^{-1} \dfrac{l\alpha}{2.303}} \tag{10}$$

Also, if P_2 is the received power and E_1 and I_1 are the sending end voltage and current, respectively, with phase angle θ, then

$$P_2 = E_1 I_1 \varepsilon^{-2l\alpha} \cos\theta \tag{11}$$

showing that the power is attenuated in accordance with the square of the current ratio.

If the constants of the transmission line are such that $r/L = g/C$ or $rC = Lg$, then the line attenuation and velocity of propagation do not change appreciably with frequency and the line is said to be *distortionless*, since

$$\alpha \doteq \sqrt{rg} \text{ and } W \doteq \frac{1}{\sqrt{LC}} \tag{12}$$

For standard non-loaded telephone cables, L and g are considered negligible; hence from eqs. (8)

$$\alpha \doteq \beta \doteq \sqrt{\frac{\omega r C}{2}} \quad \text{nepers (for } \alpha) \quad \text{and} \quad \text{radians (for } \beta) \tag{13}$$

For uniformly or lumped loaded cable lines (up to about mid-frequency range) where r and g are small compared to ωL and ωC respectively, an approximate expression for α is

$$\alpha \doteq \frac{r}{2}\sqrt{\frac{C}{L}} + \frac{g}{2}\sqrt{\frac{L}{C}} \doteq \sqrt{CL}\left(\frac{r}{2L} + \frac{g}{2C}\right) \quad \text{nepers} \tag{14}$$

In this equation, $r/2L$ and $g/2C$ are the damping constants of the series and shunt constants, respectively, of the line.

If g is assumed to be zero, eq. (14) becomes

$$\alpha \doteq \frac{r}{2}\sqrt{\frac{C}{L}} \doteq \sqrt{\frac{r}{2L} \cdot \frac{rC}{2}} \quad \text{nepers} \tag{15}$$

Equation (15) also applies for open-wire lines in the r-f range.

Thus, it is seen from eqs. (13) and (15) that, for values of $(r/2L) < \omega$, α is decreased by increasing L, i.e., by loading the cable line, although the full advantage is not realized, because, in loading the line, r is increased slightly by the resistance of the loading coils.

For coaxial (concentric tube) cable lines in the r-f range

$$\alpha \doteq \frac{r}{2Z_0} \quad \text{nepers} \tag{16}$$

and, where both conductors are of the same material and the line dimensions are available,

$$\alpha \doteq \frac{\sqrt{\rho\mu f}(1/a + 1/b)}{276 \log_{10}(b/a)} \cdot 10^{-9} \quad \text{neper per unit length} \tag{17}$$

where ρ = resistivity of conductors in emu (about 1730 emu for pure copper).
μ = magnetic permeability of the insulation.
f = frequency in cycles per second.
a = outer radius of the inner conductor.
b = inner radius of the outer conductor.

WAVE LENGTH. The phase of the voltage and current for a uniform line is continually changing in a modified sine-wave pattern, as progression takes place along the line. A complete phase change of 2π radians (360°) will occur in the length of line traversed by the voltage and current during the time they pass through 1 cycle. Thus, the wavelength λ for a particular line may be equated as

$$\lambda = \frac{2\pi}{\beta} \quad \text{miles} \tag{18}$$

β being the phase change in radians per mile.

VELOCITY OF PROPAGATION. Since a wave length is the length traversed by the voltage and current during 1 cycle, the velocity of propagation W may be equated as

$$W = \lambda f \quad \text{miles per second} \tag{19}$$

f being the frequency in cycles per second.

For loaded cable lines, the inductance and capacitance of the line have a direct bearing on the wave length constant, wave length, and velocity of propagation. Since r and g are usually negligible for such lines, eq. (8b) for β becomes

$$\beta \doteq \omega\sqrt{LC} \doteq 2\pi f\sqrt{LC} \tag{20}$$

Since $\lambda = 2\pi/\beta$,

$$W = \lambda f = \frac{2\pi f}{\beta} \doteq \frac{1}{\sqrt{LC}} \quad \text{miles per second} \tag{21}$$

Note: If L and C are expressed as the values for one load section, then β and λ are in loads and W is in loads per second.

CUTOFF FREQUENCY. For non-loaded lines (cable or open wire), the cutoff frequency is usually high enough for all practical purposes for the service for which these facilities will be used, but for loaded cable lines the cutoff frequency is an important factor and may be expressed as

$$f_c = \frac{1}{\pi\sqrt{LC}} \tag{22}$$

where L is the inductance of the loading coil in henries and C is the capacitance of the loading section in farads for any particular line.

Thus, the periodic lumped loaded line transmits all frequencies up to a critical or cutoff frequency. However, in the actual line there are some deviations from the ideal loading and some resistance in the line and loading coils, resulting in the attenuation of the transmitted frequency range to some degree.

4. EQUIVALENT NETWORKS

Equivalent networks for a length of uniform line, transmitting alternating currents, may be constructed in the T or pi (π) form.

For the T network, a, the value of each of the two series arms, and b, the value of the shunt arm, may be obtained from the equations

$$a = Z_0 \tanh \frac{l\gamma}{2} \tag{23a}$$

$$b = \frac{Z_0}{\sinh l\gamma} \tag{23b}$$

where Z_0, l, and γ are the characteristic impedance, length of line in miles, and the propagation constant per mile.

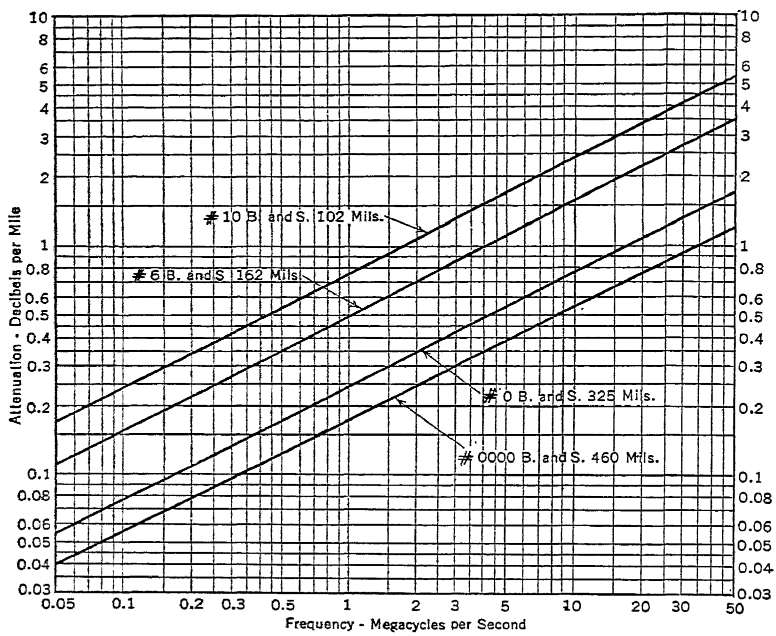


FIG. 2. Calculated Attenuation vs. Frequency Characteristics, 600 ohm, Two-wire Lines, Solid Copper Conductors; Leakage and Radiation Neglected

For the pi network, r, the value of each of the two shunt arms, and s, the value of the series arm, may be obtained from the equations

$$r = Z_0 \coth \frac{l\gamma}{2} \tag{24a}$$

$$s = Z_0 \sinh l\gamma \tag{24b}$$

where Z_0, l, and γ have the same meaning as for the T network.

Figure 2 shows the calculated attenuation-frequency characteristics of 600-ohm, two-wire, solid copper lines, in which leakage conductance and radiation are assumed to be negligible. Calculations are based on the equation

$$\alpha \doteq 8.686 \frac{\sqrt{1830f}}{aZ_0} \cdot 10^{-6} \quad \text{decibel per mile} \tag{25}$$

where a = radii of the various conductors in miles, f = megacycles per second, and Z_0 = characteristic impedances of the various lines. The effect on current distribution of the return wire (important only when the ratio of separation to wire diameter is less than 20 to 1) is neglected in the equation.

Figure 3 shows the calculated attenuation-frequency characteristics of copper concentric tube lines having optimum ratios of conductor radii. Leakage is neglected. Calculations are based on eq. (17). Assuming both conductors to be of the same material, α will be

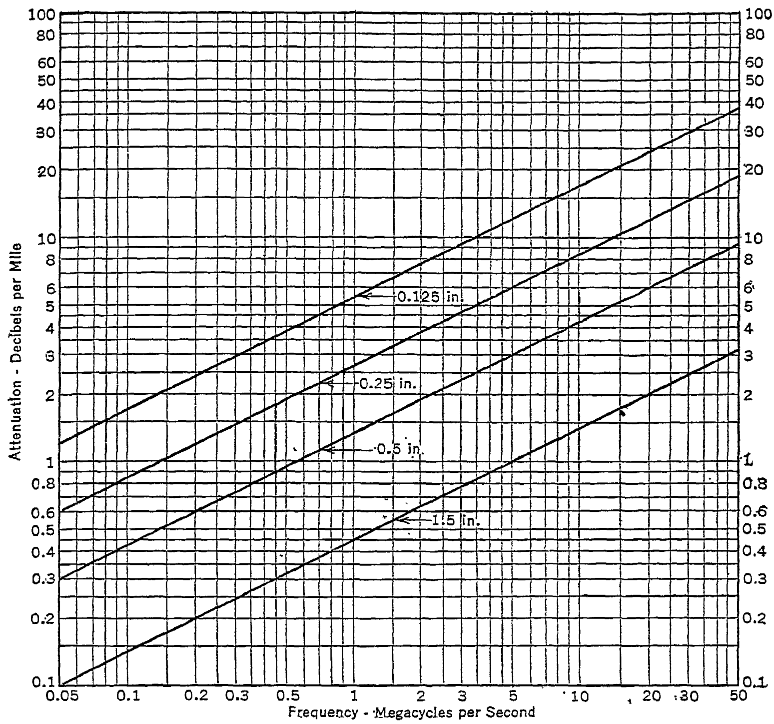

FIG. 3. Calculated Attenuation vs. Frequency Characteristics, Copper Concentric Tube Lines. Optimum ratio of conductor radii. Leakage neglected. Dimension indicated is inner radius of outer conductor.

a minimum when the ratio $b/a = 3.6$. With $\rho = 1730$ and α a minimum, eq. (17) can be reduced to

$$\alpha \doteq \frac{0.686\sqrt{f}}{b} \quad \text{decibels per mile} \tag{26}$$

where f is in megacycles per second and b is the inner radius of the outer conductor in inches.

WAVE GUIDES—THEORY

By S. A. Schelkunoff

Definition. A wave guide is a structure consisting of either conductors or dielectrics, or both, in which the boundaries between different media are cylindrical (surfaces made up by a translation of a straight line; circular cross-section is not essential). A *metal wave guide* is a wave guide containing at least one conductor. A *dielectric wave guide* is a wave guide consisting of dielectrics only.

5. MODES OF TRANSMISSION

Three types of waves are possible in straight metal wave guides filled with a homogeneous dielectric: transverse electromagnetic or TEM waves, transverse electric or TE waves, and transverse magnetic or TM waves. In TEM waves the electric and magnetic vectors are perpendicular to the direction of the guide; in TE waves the electric vector is so disposed; and in TM waves the magnetic vector is perpendicular to the guide. TEM waves are possible only if the guide consists of two or more separate conductors; there are no restrictions on the existence of the other types. If the dielectric is non-homogeneous, then in general the waves are of *hybrid type*, with all components of E and H vectors present.

Each wave guide permits an infinite number of transmission modes. Besides the abovementioned general characteristics, each mode is distinguished by a transverse field pattern consistent with the structure of the guide. Theoretically, at least, it is possible to excite an arbitrary field pattern over a given cross-section of the guide; but, in general, this pattern will not be maintained along the guide. The self-maintaining patterns are the ones that define the various modes of transmission. In general, these patterns depend on the frequency as well as the structure of the wave guide; but, if the dielectric is homogeneous, then the patterns are independent of the frequency and are given solely by the geometry of the metal boundaries. Each self-maintaining pattern is either attenuated or is traveling with a phase velocity peculiar to it. (See Propagation Constants, article 6.) An arbitrary pattern excited over a given cross-section breaks up into self-maintaining patterns. The field at various distances from the source is the result of interference between the self-maintaining patterns arriving with different amplitudes and phases.

In wave guides with rectangular, circular, and elliptic boundaries, the various TE and TM modes are designated by a double subscript, TE_{mn} and TM_{mn}, where m and n are integers appearing in the mathematical functions describing transverse field patterns. For each shape of the guide, indices m and n reflect certain physical characteristics of the wave; but the same indices for different shapes correspond to waves with different characteristics, and waves with similar characteristics may have different indices. This happens because a gradual deformation of a circular boundary into a rectangular affects different modes differently.

In a wave guide of arbitrary shape the various modes are designated by a single subscript which denotes the position of the "cutoff frequency" on the frequency scale. The *dominant wave* is the wave with the lowest cutoff frequency.

6. PROPAGATION CONSTANTS OF IDEAL WAVE GUIDES

For an ideal non-dissipative wave guide with a homogeneous dielectric the propagation constant γ_g along the guide for a given transmission mode is

$$\gamma_g = \omega_c\sqrt{\mu\varepsilon}\sqrt{1 - \left(\frac{\omega}{\omega_c}\right)^2} \qquad \omega = 2\pi f \tag{1}$$

where the *cutoff frequency* f_c is determined by the permeability μ and dielectric constant ε and by the geometry of the boundaries. For $f < f_c$, γ is real and the wave is attenuated even though there is no dissipation of energy. For $f > f_c$ the above equation becomes

$$\gamma_g = i\omega\sqrt{\mu\varepsilon}\sqrt{1 - \left(\frac{\omega_c}{\omega}\right)^2}$$

and the propagation constant is imaginary. The wave becomes *active* in transmitting energy to large distances since under the assumed ideal conditions the amplitude of the wave does not diminish. These characteristics are the characteristics of a high-pass filter.

For wave guides with a non-homogeneous dielectric there is no simple general expression for the propagation constant.

PHASE VELOCITY. Above the cutoff the phase velocity along the guide is

$$v_g = \frac{v}{\sqrt{1 - (\omega_c/\omega)^2}} \qquad v = \frac{1}{\sqrt{\mu\varepsilon}} = \frac{c}{\sqrt{\varepsilon_r}} \tag{2}$$

where v is the intrinsic velocity of the dielectric (velocity of light in the dielectric), c is the intrinsic velocity of vacuum, and ε_r is the dielectric constant relative to vacuum. In hollow wave guides the phase velocity is always higher than the velocity of light in free space; this is in keeping with the high-pass characteristics of wave guides.

GROUP VELOCITY. The group velocity or the velocity of a "wave packet" is

$$v_{\text{group}} = v\sqrt{1 - \left(\frac{\omega_c}{\omega}\right)^2} \tag{3}$$

The product of the group and phase velocities equals the square of the intrinsic velocity.

WAVELENGTH IN THE GUIDE. The wavelength λ_g in the guide (the distance from crest to crest of the wave) is

$$\lambda_g = \frac{v_g}{f} = \frac{(v/f)}{\sqrt{1-(f_c/f)^2}} = \frac{\lambda_v}{\sqrt{\varepsilon_r[1-(f_c/f)]^2}} \tag{4}$$

where λ_v is the free-space wavelength corresponding to the given frequency f and ε_r is the dielectric constant relative to vacuum.

7. RECTANGULAR WAVE GUIDES

FIELDS. In a metal wave guide the effect of the conductivity of the walls on the field distribution is negligible. The following expressions are for perfectly conducting walls, assuming that the coordinate system is disposed as in Fig. 1. The time factor $\exp j\omega t$ is omitted.

$\mathrm{TE}_{m,n}$ wave (if traveling in the positive z direction):

$$E_x = A\frac{n\pi}{b}\cos\frac{m\pi x}{a}\sin\frac{n\pi y}{b}e^{-\gamma z} \qquad E_y = -A\frac{m\pi}{a}\sin\frac{m\pi x}{a}\cos\frac{n\pi y}{b}e^{-\gamma z}$$

$$H_x = -\frac{E_y}{K_z^{TE}} \qquad H_y = \frac{E_x}{K_z^{TE}} \qquad H_z = A\frac{\chi_{mn}^2}{j\omega\mu}\cos\frac{m\pi x}{a}\cos\frac{n\pi y}{b}e^{-\gamma z} \tag{5}$$

$$K_z = \frac{j\omega\mu}{\gamma} \qquad \gamma = \sqrt{j\omega\mu(g+j\omega\varepsilon)+\chi_{mn}^2} \qquad \chi_{mn} = \sqrt{\frac{m^2\pi^2}{a^2}+\frac{n^2\pi^2}{b^2}}$$

where m, n are integers, not equal to zero simultaneously. The quantities g, μ, and ε are respectively the conductivity, the permeability, and the dielectric constant of the dielectric in the guide. Figure 2 shows electric lines for some TE waves; they are also the lines of constant H_z. The transverse H component is perpendicular to the E vector. The density of lines is proportional to the transverse field components. The pattern of the $\mathrm{TE}_{1,0}$ wave in Fig. 2(a) is the building block for patterns of the $\mathrm{TE}_{m,0}$ waves as illustrated in Fig. 2(c); m is the number of such blocks in the pattern of the $\mathrm{TE}_{m,0}$ wave. In the $\mathrm{TE}_{0,n}$ wave the lines are parallel to the horizontal faces of the guide. The pattern of the $\mathrm{TE}_{1,1}$ wave in Fig. 2(c) is the building block for the pattern of the $\mathrm{TE}_{m,n}$ wave when m and n are different from zero; m is the number of such blocks in the x direction (the horizontal direction), and n is the number of blocks in the y direction.

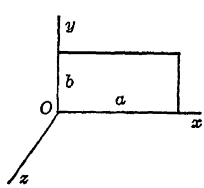

FIG. 1

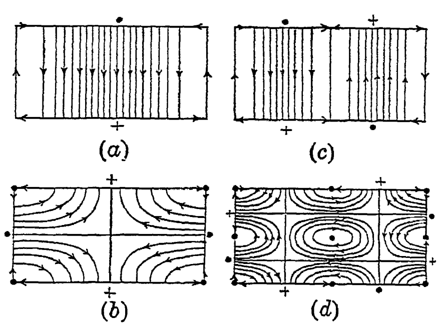

FIG. 2. Electric Lines in Rectangular Guides; (a) $\mathrm{TE}_{1,0}$ Wave; (b) $\mathrm{TE}_{1,1}$ Wave; (c) $\mathrm{TE}_{2,0}$ Wave; (d) $\mathrm{TE}_{2,2}$ Wave

$\mathrm{TM}_{m,n}$ wave (if traveling in the positive z direction):

$$H_x = A\frac{n\pi}{b}\sin\frac{m\pi x}{a}\cos\frac{n\pi y}{b}e^{-\gamma z} \qquad H_y = -A\frac{m\pi}{a}\cos\frac{m\pi x}{a}\sin\frac{n\pi y}{b}e^{-\gamma z}$$

$$E_x = K_z^{TM}H_y \qquad E_y = -K_z^{TM}H_x \qquad E_z = A\frac{\chi_{mn}^2}{g+j\omega\varepsilon}\sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b}e^{-\gamma z} \tag{6}$$

$$K_z^{TM} = \frac{\gamma}{g+j\omega\varepsilon} \qquad \gamma = \sqrt{j\omega\mu(g+j\omega\varepsilon)+\chi_{mn}^2} \qquad \chi_{mn} = \sqrt{\frac{m^2\pi^2}{a^2}+\frac{n^2\pi^2}{b^2}}$$

where m, n are integers not equal to zero. Figure 3 shows magnetic lines for some TM waves; they are also the lines of constant E_z. The transverse E component is perpendicular to the H vector. The density of lines is proportional to the transverse field components.

The pattern of the $TM_{1,1}$ wave in Fig. 3(*a*) is the building block for the pattern of the $TM_{m,n}$ wave; m is the number of such blocks in the x direction, and n is the corresponding number in the y direction.

CUTOFF FREQUENCIES. The cutoff frequencies for the various modes of transmission are the frequencies at which the propagation constant vanishes; at these frequencies the propagation constant changes from a real to an imaginary value; these frequencies separate the pass band of frequencies from the stop band. In this sense the cutoff frequencies are defined only for non-dissipative wave guides; the cutoff frequencies of slightly dissipative wave guides are usually defined by neglecting dissipation. In general, the cutoff frequency may be defined as the frequency at which the phase of the propagation constant is 45°; but when the dissipation is really large the concept of "cutoff" loses its practical value.

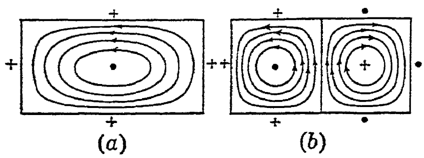

FIG. 3. Magnetic Lines in Rectangular Guides; (*a*) $TM_{1,1}$ Wave; (*b*) $TM_{2,1}$ Wave

For rectangular wave guides the cutoff frequencies and corresponding wavelengths (in vacuum) are

$$f_{mn} = \frac{c}{2\sqrt{\varepsilon_r}}\sqrt{\left(\frac{m}{a}\right)^2 + \left(\frac{n}{b}\right)^2} \qquad \lambda_{mn} = \frac{2\sqrt{\varepsilon_r}}{\sqrt{(m/a)^2 + (n/b)^2}} \tag{7}$$

where c is the velocity of light in vacuum.

The same formulas hold of TE and TM waves. For the dominant wave

$$\lambda_{1,0} = 2a\sqrt{\varepsilon_r} \qquad f_{1,0} = \frac{c}{2a\sqrt{\varepsilon_r}} \tag{8}$$

where a is the longer dimension of the cross-section of the guide.

ATTENUATION IN THE PASS BAND. In a previous section the exact expression is given for the propagation constant γ when the walls of the guide are perfect conductors. To allow for the imperfect conductivity of the walls the following correction term should be added to γ

$$\Delta\gamma = \alpha_m(1 + j) \tag{9}$$

where α_m is the attenuation in nepers per meter due to absorption of energy by the walls. For TE_{mn} wave

$$\alpha_m = \frac{\mathcal{R}\sqrt{\varepsilon_r}}{60\pi b}\left[\frac{p(pm^2 + n^2)}{p^2m^2 + n^2}\sqrt{1 - \nu_{mn}^2} + \frac{(1 + p)\nu_{mn}^2}{\sqrt{1 - \nu_{mn}^2}}\right] \qquad m \neq 0,\ n \neq 0$$

$$\alpha_m = \frac{\mathcal{R}\sqrt{\varepsilon_r}}{120\pi}\left(\frac{1}{b} + \frac{2}{a}\nu_{m,0}^2\right)(1 - \nu_{m,0}^2)^{-1/2} \qquad m \neq 0,\ n = 0 \tag{10}$$

$$\alpha_m = \frac{\mathcal{R}\sqrt{\varepsilon_r}}{120\pi}\left(\frac{1}{a} + \frac{2}{b}\nu_{0,n}^2\right)(1 - \nu_{0,n}^2)^{-1/2} \qquad m = 0,\ n \neq 0$$

where $p = b/a$, $\nu_{mn} = f_{mn}/f$, and $\mathcal{R}$ is the *surface resistance* of the walls, and

$$\mathcal{R} = \sqrt{\frac{\pi\mu f}{g_m}} = \frac{2\pi\sqrt{30\mu_r}}{\sqrt{g_m\lambda_v}} = \frac{34.4\sqrt{\mu_r}}{\sqrt{g_m\lambda_v}} \tag{11}$$

In this equation, μ_r is the permeability of the walls relative to vacuum, g_m is the conductivity, and λ_v is the wavelength in vacuum for the given frequency f. For pure copper, $g = 5.80 \times 10^7$ mhos per meter and

$$\mathcal{R} = 2.61 \times 10^{-7}\sqrt{f} = 8.25 \times 10^{-7}\sqrt{\frac{f}{10}} = \frac{0.00452}{\sqrt{\lambda_v}} = \frac{0.0143}{\sqrt{10\lambda_v}} \tag{12}$$

For the TM_{mn} wave

$$\alpha_m = \frac{\mathcal{R}\sqrt{\varepsilon_r}(m^2b^3 + n^2a^3)}{60\pi ab(m^2b^2 + n^2a^2)}(1 - \nu_{mn}^2)^{-1/2} \tag{13}$$

The above formulas for α_m break down in the immediate vicinity of the cutoff; the attenuation does not go to infinity—it is merely large compared to the attenuation elsewhere in the pass band (see a later section on the attenuation near the cutoff).

8. CIRCULAR WAVE GUIDES

FIELDS. For the $\mathrm{TE}_{n,m}$ wave the cylindrical components of the field vectors are

$$E_\rho = A\,\frac{n}{\rho}\,J_n\left(\frac{k_{n,m}\rho}{a}\right)\sin n\varphi\, e^{-\gamma z} \qquad E_\varphi = A\,\frac{k_{n,m}}{a}\,J_n'\left(\frac{k_{n,m}\rho}{a}\right)\cos n\varphi\, e^{-\gamma z}$$

$$H_\rho = -\frac{E_\varphi}{K_z^{TE}} \qquad H_\varphi = \frac{E_\rho}{K_z^{TE}} \qquad H_z = A\,\frac{k_{n,m}^2}{j\omega\mu a^2}\,J_n\left(\frac{k_{n,m}\rho}{a}\right)\cos n\varphi\, e^{-\gamma z} \tag{14}$$

$$K_z^{TE} = \frac{j\omega\mu}{\gamma} \qquad \gamma = \sqrt{j\omega\mu(g + j\omega\varepsilon) + \frac{k_{n,m}^2}{a^2}}$$

where $k_{n,m}$ is the mth non-vanishing zero of the first derivative of the Bessel function $J_n'(k)$, and a is the inner radius of the guide. Some k's are given below:

$k_{0,1} = 3.83$	$k_{0,2} = 7.02$	$k_{0,3} = 10.17$
$k_{1,1} = 1.84$	$k_{1,2} = 5.33$	$k_{1,3} = 8.54$
$k_{2,1} = 3.05$	$k_{2,2} = 6.71$	$k_{2,3} = 9.97$
$k_{3,1} = 4.20$	$k_{3,2} = 8.02$	$k_{3,3} = 11.35$

Figure 4 shows electric lines for some TE waves. The electric lines of $\mathrm{TE}_{0,m}$ waves are circles; for this reason $\mathrm{TE}_{0,m}$ waves are called *circular electric waves.*

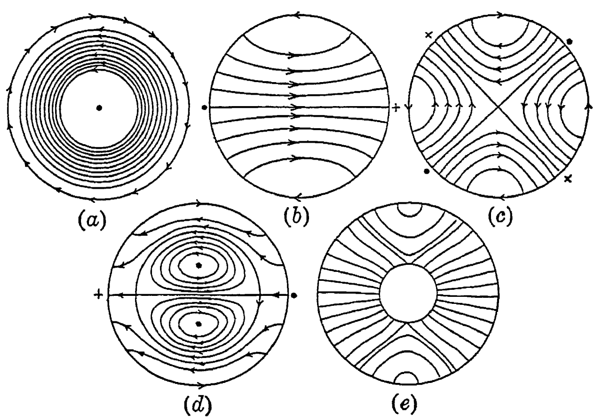

FIG. 4. Electric Lines in Circular Guides; (a) $\mathrm{TE}_{0,1}$ Wave; (b) $\mathrm{TE}_{1,1}$ Wave; (c) $\mathrm{TE}_{2,1}$ Wave; (d) $\mathrm{TE}_{1,2}$ Wave; (e) $\mathrm{TE}_{1,1}$ Wave Between Coaxial Cylinders

For the $\mathrm{TM}_{n,m}$ wave the field is

$$H_\rho = A\,\frac{n}{\rho}\,J_n\left(\frac{k_{nm}\rho}{a}\right)\sin n\varphi\, e^{-\gamma z} \qquad H_\varphi = A\,\frac{k_{nm}}{a}\,J_n'\left(\frac{k_{nm}\rho}{a}\right)\cos n\varphi\, e^{-\gamma z} \tag{15}$$

$$E_\rho = K_z^{TM} H_\varphi \qquad E_\varphi = -K_z^{TM} H_\rho \qquad E_z = -A\,\frac{k_{nm}^2}{(g + j\omega\varepsilon)a^2}\,J_n\left(\frac{k_{nm}\rho}{a}\right)\cos n\varphi\, e^{-\gamma z}$$

$$K_z^{TM} = \frac{\gamma}{g + j\omega\varepsilon} \qquad \gamma = \sqrt{j\omega\mu(g + j\omega\varepsilon) + \frac{k_{nm}^2}{a^2}}$$

where k_{nm} is the mth non-vanishing zero of the Bessel function $J_n(k)$. Some k's are given below:

$k_{0,1} = 2.40$	$k_{0,2} = 5.52$	$k_{0,3} = 8.65$
$k_{1,1} = 3.83$	$k_{1,2} = 7.02$	$k_{1,3} = 10.17$
$k_{2,1} = 5.14$	$k_{2,2} = 8.42$	$k_{2,3} = 11.62$
$k_{3,1} = 6.38$	$k_{3,2} = 9.76$	$k_{3,3} = 13.02$

Figure 5 shows magnetic lines of some TM waves. The magnetic lines of $\mathrm{TM}_{0,m}$ waves are circles; for this reason $\mathrm{TM}_{0,m}$ waves are called *circular magnetic waves.*

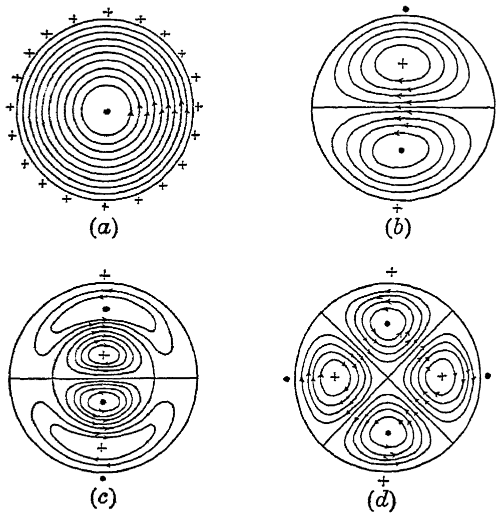

FIG. 5. Magnetic Lines in Circular Guides; (a) $TM_{0,1}$ Wave; (b) $TM_{1,1}$ Wave; (c) $TM_{1,2}$ Wave; (d) $TM_{2,1}$ Wave

CUTOFF FREQUENCIES. The cutoff frequencies and corresponding wavelengths (in vacuum) are

$$f_{nm} = \frac{ck_{nm}}{2\pi a\sqrt{\varepsilon_r}} \qquad \lambda_{nm} = \frac{2\pi a\sqrt{\varepsilon_r}}{k_{nm}} \tag{16}$$

where c is the velocity light in vacuum and k_{nm} is the quantity defined in the preceding section. For the dominant wave ($TE_{1,1}$)

$$\lambda_{1,1} = 1.7d\sqrt{\varepsilon_r} \tag{17}$$

where d is the inner diameter of the guide.

ATTENUATION IN THE PASS BAND. The propagation constant γ given in a previous section is for the case of ideal non-absorbing walls. To allow for absorption by these walls, γ should be augmented by

$$\Delta\gamma = \alpha_m(1 + j) \tag{18}$$

where α_m is the attenuation in nepers per meter caused by the absorbing walls. For TE waves

$$\alpha_m = \frac{\mathcal{R}\sqrt{\varepsilon_r}}{120\pi a}\left(\frac{n^2}{k_{nm}^2 - n^2} + \nu_{nm}^2\right)(1 - \nu_{nm}^2)^{-\frac{1}{2}} \tag{18a}$$

where $\nu_{nm} = f_{nm}/f$. The surface resistance $\mathcal{R}$ is given in the corresponding section on rectangular wave guides.

For circular electric waves $n = 0$ and

$$\alpha_m = \frac{\mathcal{R}\sqrt{\varepsilon_r}}{120\pi a}\nu_{0,m}^2(1 - \nu_{0,m}^2)^{-\frac{1}{2}} \tag{18b}$$

If the dielectric is non-dissipative, the attenuation of circular electric waves steadily decreases with increasing frequency

For dominant waves ($TE_{1,1}$)

$$\alpha_m = \frac{\mathcal{R}\sqrt{\varepsilon_r}}{a}[3.76(1 - \nu_{1,1}^2)^{-\frac{1}{2}} - 2.65(1 - \nu_{1,1}^2)^{\frac{1}{2}}]10^{-3} \quad \text{neper/meter}$$

For TM waves

$$\alpha_m = \frac{\mathcal{R}\sqrt{\varepsilon_r}}{120\pi a}(1 - \nu_{nm}^2)^{-\frac{1}{2}}$$

9. WAVE GUIDES OF ARBITRARY CROSS-SECTION

CUTOFF FREQUENCIES. For wave guides of arbitrary cross-section the cutoff wavelength (in vacuum) and the cutoff frequency are given by

$$\lambda_c = 2\pi\sqrt{\varepsilon_r}\sqrt{\frac{\iint T^2\,dS}{\iint |\text{grad } T|^2\,dS}} \qquad f_c = \frac{c}{\lambda_c} \tag{19}$$

where c is the velocity of light in vacuum, and T is proportional either to E_z or to H_z, depending on the type of the wave. This formula is exact; but generally it is not feasible to obtain T exactly. However, first-order errors in T lead to second-order errors in λ_c, and the formula is extremely useful, especially for estimating the cutoff frequency of the dominant wave; only a reasonable guess is needed for T (see the next section).

WAVE GUIDES WITH CROSS-SECTIONS OF THE TYPE SHOWN IN FIG. 6(*a*). For dominant waves in wave guides of the shape shown in Fig. 6(*a*) electric lines run across in the manner indicated in the figure. Such wave guides are essentially pairs of parallel strips, shunted on both sides with cylinders, Fig. 6(*b*). Longitudinal magnetic

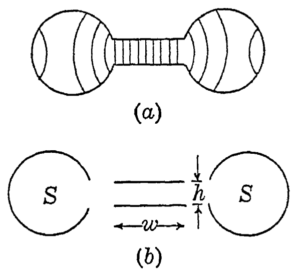

FIG. 6

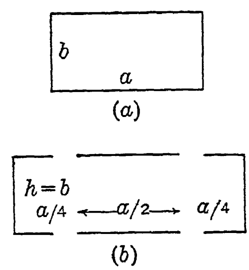

FIG. 7

lines run largely inside the cylinders, in opposite directions. On account of the increased capacitance in the middle, the cutoff frequency of such a wave guide is lower than that of a rectangular wave guide. To make an estimate of the frequency we let $T = H_z = +1$ in one cylinder and $T = -1$ in the other. Between the parallel strips we assume that the longitudinal magnetic flux varies linearly from $+1$ to -1; that is, we let $T = 1 - (2x/w)$, where w is the width of the strips.

The gradient of T is zero inside the cylinders and $(-2/w)$ between the strips. Substituting in the formula contained in the preceding section, we obtain

$$\lambda_1 \simeq \pi\sqrt{\varepsilon_r}\sqrt{\frac{2w}{h}\left(S + \frac{1}{6}wh\right)} \tag{20}$$

where h is the distance between the strips and S is the cross-sectional area of each cylinder. In the above form, the formula applies even when the cylinders are not circular. The width w should be comparable to one-half of the total width.

If this formula is applied to a rectangular wave guide whose cross-section is broken up as in Fig. 7, we find $\lambda_1 \simeq 1.81a\sqrt{\varepsilon_r}$ instead of the exact value $\lambda_1 = 2a\sqrt{\varepsilon_r}$. The error is about 10 per cent. The error diminishes as h decreases relatively to other dimensions.

10. SPECIAL CHARACTERISTICS OF WAVE GUIDES

CONDUCTION CURRENT IN THE WALLS OF A WAVE GUIDE. The conduction current in a metal wall of a wave guide is equal to the tangential magnetic intensity and is perpendicular to it. The direction is that in which a right-handed screw will advance when the H vector (which is supposed to be attached to the handle) is turned through 90° to make it coincident with the normal looking into the wall.

In the case of dominant waves in a rectangular wave guide the current in the walls parallel to the E vector is strictly transverse. In the other walls the longitudinal current is sinusoidally distributed, with the highest density in the middle; the transverse current is zero in the middle and maximum at the edges. In these walls, the transverse current flows in opposite directions from the middle. As the frequency increases, this current diminishes.

ATTENUATION IN THE VICINITY OF THE CUTOFF FREQUENCY. The following expression for the propagation constant is valid for all frequencies

$$\gamma = \sqrt{\gamma_0^2 + j\omega\mu g + 2\alpha_m\gamma_0(1 + j)} \tag{21}$$

where γ_0 is the propagation constant calculated on the assumption $g = \alpha_m = 0$. Whereas α_m is infinite at the cutoff, $\alpha_m\gamma_0$ is finite. For frequencies not too near the cutoff this formula is unnecessarily complicated, and it is recommended only for the immediate vicinity of the cutoff.

CHARACTERISTIC IMPEDANCES AND POWER TRANSFER. The ratio $K_z = E_t/H_t$ of the transverse components of the E and H vectors is called the *wave impedance*. The average power W transferred per unit area of the cross-section of the wave guide is

$$W = K_z H_{t,\text{eff}}^2 \tag{22}$$

where $H_{t,\text{eff}}$ is the effective value of H_t (the factor $1/2$ should be included if the amplitude of H_t is being used).

For the dominant wave the total power transfer P is given by

$$P = K_{P,V}V_{\text{eff}}^2 = K_{P,I}I_{\text{eff}}^2 = K_{V,I}V_{\text{eff}}I_{\text{eff}} \tag{23}$$

where V_{eff} is the effective value of the maximum transverse voltage, I_{eff} is the effective longitudinal current, and the K's are the characteristic impedances. For rectangular wave guides

$$K_{P,V} = \frac{754b}{a\sqrt{1 - \nu_{1,0}^2}} \qquad K_{P,I} = \frac{465b}{a\sqrt{1 - \nu_{1,0}^2}} \qquad K_{V,I} = \sqrt{K_{P,V}K_{P,I}} \tag{23a}$$

For circular wave guides

$$K_{P,V} = \frac{764}{\sqrt{1 - \nu_{1,1}^2}} \qquad K_{P,I} = \frac{354}{\sqrt{1 - \nu_{1,1}^2}} \qquad K_{V,I} = \sqrt{K_{P,V}K_{P,I}} \tag{23b}$$

For wave guides of the shape shown in Fig. 6, approximate formulas are

$$K_{P,V} \simeq K_{P,I} \simeq K_{V,I} \simeq \frac{377h}{w\sqrt{1 - \nu^2}} \tag{23c}$$

In these formulas ν denotes the ratio of the cutoff frequency for the dominant wave to the operating frequency.

The above expressions may be used without any reservation in power calculations. The following section should be consulted before any attempt is made to calculate reflections and standing waves.

11. WAVE-GUIDE DISCONTINUITIES

Any local change in the shape of a wave guide or any obstruction represents a *wave-guide discontinuity*. Local fields are likely to be associated with such discontinuities. A capacitor or a coil shunted across a low-frequency transmission line are examples of discontinuities. The local fields store energy during one half of the cycle and release it during the other; they act as virtual generators, operating on power borrowed from the traveling wave. If the operating frequency is higher than the cutoff frequency of the dominant wave but lower than the cutoff frequency for any other wave, there is no possibility for the energy to be sent back to its source or to the load in any mode except the dominant. In these circumstances the effect of the local field made up of higher-order waves may be represented by a reactive transducer which in its turn may be expressed as a T or pi network. The branch reactances of these equivalent networks may be computed in terms of the reflection and transmission coefficients if the latter are measured or obtained directly from a solution of an appropriate electromagnetic boundary value problem. In some special cases the equivalent network reduces to a series or shunt reactance.

If two wave guides of different dimensions are joined together, the junction introduces a reactive discontinuity of the above-mentioned type as well as a discontinuity in a characteristic impedance to the dominant wave. The reflection coefficient will be determined not merely by the impedance mismatch but by the reactive discontinuity as well. This is a general statement, and it applies to ordinary low-frequency transmission lines, for which, however, the series branches of the reactive discontinuity are so small, and the shunt branches so large, that their effect is negligible. In wave guides, on the other hand, the effect is ordinarily not negligible.

Some discontinuities are introduced inadvertently, as in joining two wave guides; others are introduced deliberately as circuit elements. Simplest circuit elements are transverse diaphragms or irises, Fig. 8(*a*), (*b*), (*c*), and transverse strips or wires, Fig. 8(*d*). If the irises and wires are thin, they are substantially shunt reactances. If the edges of the iris are perpendicular to the E vector, as in Fig. 8(*a*), the iris is capacitive; if the edges are parallel to the E vector, as in Fig. 8(*b*), the iris is inductive; in the case shown in Fig. 8(*c*), the iris is a parallel combination of an inductance and capacitance and may be designed to be an antiresonant circuit. Thin transverse wires introduce a shunt inductance nearly independent of the frequency. As the radius increases, the series branches of the equivalent transducer become important.

FIG. 8

WAVE-GUIDE COMPONENTS

By George L. Ragan

12. WAVE-GUIDE CHARACTERISTICS

The form of wave guide most commonly used is a metal tube of rectangular cross-section whose width a is about twice its height b. Within a twofold frequency range, only the dominant (TE_{10}) mode is actively propagated, and the orientation of the fields within the tube is unique. That is, the electric field is perpendicular to the broader walls of the wave guide. By contrast, the frequency range within which the dominant (TE_{11}) mode in round wave guide is propagated to the exclusion of all others is only 1.31 to 1, and the orientation of the fields within the tube is not uniquely determined by the wave-guide geometry as it is in the case of rectangular wave guide. Consequently, bends and irregularities in round tubing cause changes in field orientation and even introduce elliptical polarization effects. It is because of this difficulty that round wave guide is little used as a transmission line. However, round wave guide is frequently used in short sections for rotary joints. In this application, the symmetrical TM_{01} mode is used.

Expressions for calculating cutoff wavelength, attenuation in copper wave guide, and power transmitted in common wave-guide modes appear in Table 1.

Table 1. Wave-guide Expressions *

Wave-guide Shape	Mode	λ_c	α/α_1†	P/P_1‡
Rectangular..........	TE_{10}	$2a$	$4.16\left[\frac{a}{2b} + \left(\frac{\lambda}{\lambda_c}\right)^2\right]$	$6.63ab$
Round..............	TE_{11}	$1.706d$	$3.55\left[0.420 + \left(\frac{\lambda}{\lambda_c}\right)^2\right]$	$4.98d^2$
Round..............	TM_{01}	$1.306d$	2.72	$2.83d^2\left(\frac{\lambda_c}{\lambda}\right)^2$ if $\lambda > 0.657d$

* Tables and figures in articles 12–19 are reproduced by permission from G. L. Ragan, *Microwave Transmission Circuits*, Vol. 9, Rad. Lab. Series, McGraw-Hill Book Co., 1948.

† α = attenuation for copper wave guide, decibels per meter.

$$\alpha_1 = \frac{10^{-4}(\lambda/\lambda_c)}{\lambda^{3/2}\sqrt{1-(\lambda/\lambda_c)^2}}$$

‡ $P_1 = 10^{-4}\,E_{\max}{}^2\sqrt{1-\left(\frac{\lambda}{\lambda_c}\right)^2}.$

The notation used in this article is as follows:

a = larger inside dimension of rectangular wave guide, in meters.
b = smaller inside dimension of rectangular wave guide, in meters.
d = inside diameter of round wave guide, in meters.
λ = free-space wavelength, in meters.
λ_c = cutoff wavelength for the mode, in meters.
α = attenuation in decibels per meter.
P = power transmitted, in watts.
E = electric field intensity, in volts per meter.

In Table 2, numerical values for a few representative wave guides are given. The figure E_{max} = 30,000 volts/cm is based on experimental work on air at atmospheric pressure (M.I.T. *Radiation Laboratory Series*, McGraw-Hill Book Co., Vol. 9, Chapter 4).

13. FLEXIBLE WAVE GUIDES AND COUPLING UNITS

Flexible wave guide is used similarly to flexible coaxial cable. Applications include connections to shock-mounted units; connections to pieces of equipment which must be moved about; temporary or emergency replacement lines; and as patch connections, particularly in test equipment.

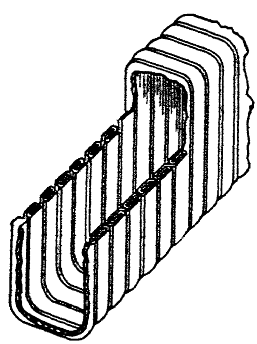

Fig. 1. Wound Metal-hose Wave Guide (Courtesy McGraw-Hill Book Co.)

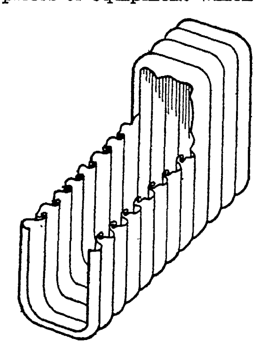

Fig. 2. Titeflex Wave Guide (Courtesy McGraw-Hill Book Co.)

Two types of construction which have proved to be especially useful are illustrated in Figs. 1 and 2. Figure 1 shows the "metal-hose" type manufactured by the American Metal Hose branch of the American Brass Co., Waterbury, Conn. This type is made of fairly heavy metal wound in the interlocking manner indicated. Flexibility is afforded by sliding of the interlocked contacting surfaces. The "Titeflex" type shown in Fig. 2 is manufactured by Titeflex, Inc., Newark, N. J. Titeflex is made of thin metal wound as shown and soft-soldered. Flexibility is afforded by flexure of the thin metal convolutions. It has been found that a molded-on rubber jacket affords needed protection to both types and in addition improves the performance of the metal-hose type by causing lower contact resistance. A complete rubber-covered section is shown in Fig. 3. Such wave guides may be bent on radii equal to about 20 times the respective nominal dimensions of the wave guide.

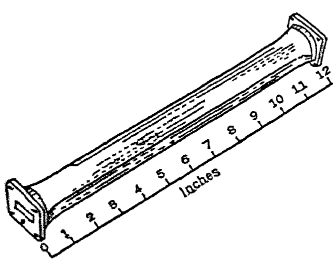

Fig. 3. Rubber-covered Flexible Waveguide Assembly (Courtesy McGraw-Hill Book Co.)

Several other types of flexible wave guide have been found useful, especially in short lengths, as flexible coupling units. These include: (*a*) Corrugated wave guide; essentially a thin-walled metal bellows of rectangular cross-section (American Metal Hose). The depth of convolutions must be a small fraction of a wavelength. (*b*) Spun bellows assembly; a soft-soldered assembly of thin-walled units each of which includes a circular bellows section the depth of whose convolution is effectively one-half wavelength (American Metal Hose).

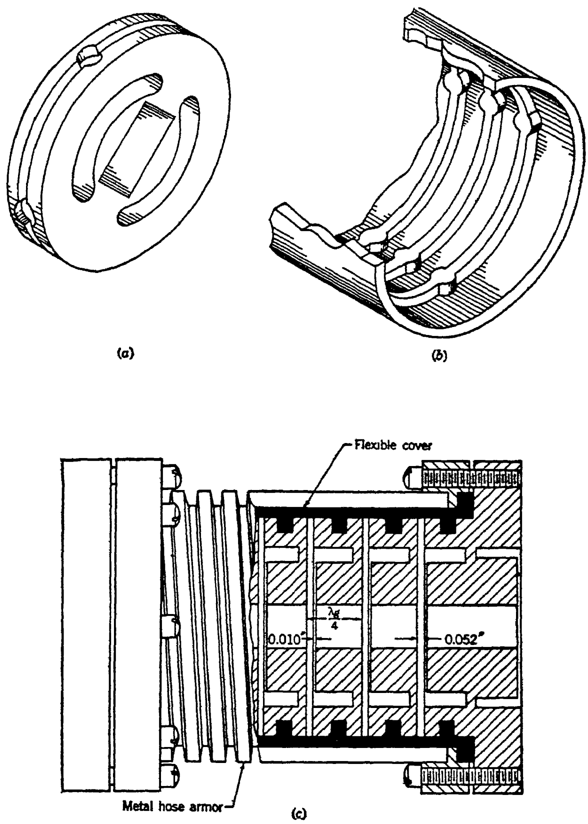

FIG. 4. Typical Vertebral Assembly; (*a*) is a Single Choke Disk; (*b*) is the Flexible Cover; (*c*) is the Assembly (Courtesy McGraw-Hill Book Co.)

(*c*) Cook bellows assembly (Cook Electric Co., Chicago, Ill.); a somewhat more rugged and broader-band bellows similar in principle to (*b*).

A coupling unit providing a maximum flexibility in longitudinal, transverse, and angular displacements is the so-called vertebral type illustrated in Fig. 4. This unit is based on the choke-flange or capacity-type wave-guide connector described in article 14 below. Power leakage from the open space between adjacent sections is minimized by the action of the choke grooves, and fairly large displacements may be tolerated without causing serious impedance mismatch.

14. WAVE-GUIDE CONNECTORS

Two sections of wave guide are usually joined by couplings of either contact type, Fig. 5, or choke-flange type, Fig. 6. The contact type has some advantages and provides excellent results if certain precautions in design and use are observed. The choke-flange type, however, is found to be more reliable for general use.

The design of contact couplings must be such that good contact is secured at all points around the periphery of the butt-joined wave guides. Particular care must be exercised to avoid the formation of cavities by permitting the contact to be made at points on the bolting flanges before the wave-guide ends are forced into good contact. The contact surfaces must be carefully machined and must be kept free of dirt, corrosion, and mechanical deformations.

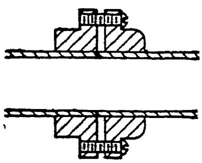

FIG. 5. Contact Coupling (Courtesy McGraw-Hill Book Co.)

When these precautions are observed, a junction is obtained which is practically perfect in all respects. This type of coupling is exceedingly valuable in certain laboratory design work where the required care in use can be taken. Likelihood of deterioration of the quality of the contacts in use under field conditions, however, presents a serious obstacle to their general utility. One contact-type coupling which has given satisfactory service for use with 1 1/2 in. by 3 in. wave guide is that designated by the Army-Navy Cable Coordinating Committee as UG-65/U and UG-66/U.

The choke-flange type coupling of Fig. 6, in which quality of contact is unimportant, affords a connector admirably suited to use under adverse conditions. In addition, such a coupling scheme is very useful in rotary joints. Parts (*b*) and (*c*) of Fig. 6 are designed principally for such use. The wave-guide ends are slightly separated, and currents interrupted by the gap *A* excite a folded section of line which surrounds the gap. This section of line is terminated in a short circuit (closed end), and its length is effectively one-half wavelength. Hence it presents at its input end essentially zero impedance to the flow of currents interrupted by the gap *A*. The contact between flanges occurs at the point *B*, which is at the midpoint of the half-wavelength line, and hence at a point of essentially zero current. It is for this reason that the quality of the contact between flanges is unimportant.

Naturally, there is only one specific wavelength for which the conditions outlined above exist, and at this wavelength only is the connector perfectly matched (i.e., reflectionless). In the design of such connectors, one must be guided by the principles discussed below if a low degree of frequency sensitivity is to be achieved. Since the same principles are involved in the choke-type coupling scheme commonly used in most rotary joints (see article 17 below), they will be discussed in some detail.

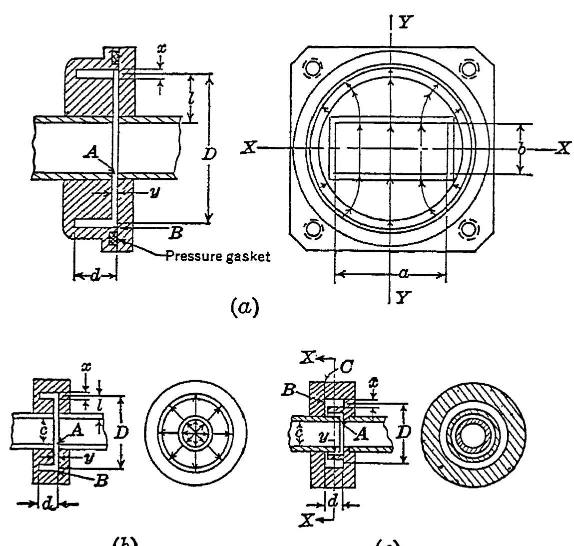

FIG. 6. Choke-flange Couplings; (*a*) Rectangular Wave Guide; (*b*) and (*c*) Circular Wave Guide (Courtesy McGraw-Hill Book Co.)

In considering the action of the choke-flange coupling, it is convenient to consider separately two sections, each effectively one-quarter wavelength long at the design frequency: (*a*) the radial section from *A* to *B*, and (*b*) the circular groove of depth *d*. The circular groove is terminated in zero impedance and presents at *B*, an effective quarter wavelength away, a high impedance which, in series with the contact resistance at *B*, terminates the radial section of line. This high-impedance termination of the radial line is transformed to a low impedance at *A*, an effective quarter wavelength away. The design problem resolves itself into that of providing, at frequencies in the neighborhood of the design frequency, a maximum impedance at *B* and a minimum impedance at *A*. It is easily argued that these objectives are realized (*a*) by maximizing the characteristic impedance of the groove section by making the groove width x as large as is practical, and (*b*) by minimizing the characteristic impedance of the radial section by making the gap y as small as is practical.

For example, let us compare the voltage standing wave ratio (*VSWR*) introduced to $\lambda = 9$ cm by two chokes, both perfectly matched at 10.7 cm, differing only in regard at the values of x and y. For one design, $x = 0.150$ in., $y = 0.104$ in., $VSWR = 1.13$. For the other design, $x = 0.250$ in., $y = 0.050$ in., and $VSWR = 1.03$.

Design details and performance figures for a number of choke-flange units are given in Table 3.

15. BENDS, TWISTS, AND ANGLES

If rectangular wave guide is bent or twisted gradually enough, i.e., in a length representing several wavelengths, the reflections set up in the wave guide are negligibly small. Alternatively, it may be bent or twisted rather abruptly without introducing serious reflections if the mean length of bend or twist is a multiple of half the guide wavelength. Care must always be exercised to avoid the introduction of bumps or ripples in the wave-guide walls or of excessive distortions of the cross-sectional dimensions. The achievement of this end is materially assisted by filling the wave guide with a low-melting-point alloy such as Woods metal or Cerrobend before working it, and melting it out afterwards.

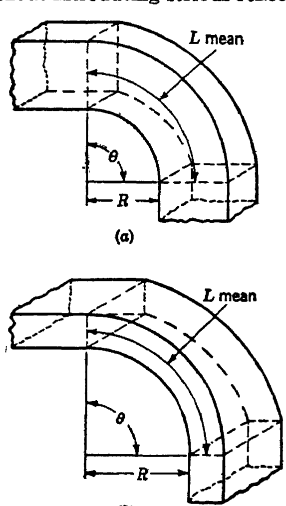

Fig. 7. Wave-guide Bends; (*a*) H Bend; (*b*) E bend (Courtesy McGraw-Hill Book Co.)

Figure 7 illustrates two types of bend, designated as *H*-plane and *E*-plane bends, depending on whether the bending radius vector lies in the plane of the magnetic field lines (*H*) or electric field lines (*E*). Incidentally, these bends are sometimes conveniently referred to as "hard bends" (*H*) or "easy bends" (*E*) for obvious mechanical reasons. The performance data for some bends and twists are given in Table 4.

It is sometimes preferable, in order to achieve minimum space factor, to substitute fabricated corners for bends. Two types of well-matched corner are illustrated in Fig. 8. The double-mitered type is usually to be preferred (*a*) because the dimensional tolerances are larger, and (*b*) because this type can carry more power, since it has less acute corners and a less restricted cross-section. Both types may be designed for any desired angle, not being restricted to the 90° type drawn.

It is found experimentally that the mean separation L between miters in the double-mitered *E*-plane corner is a quarter guide wavelength for best match. This is easily understood as providing a cancellation of mismatches by reason of quarter-wave spacing between identical reflections. In double-mitered *H*-plane corners, however, the spacing deviates slightly from the expected quarter-wave value. This is presumably because of the disturbance due to a greater

excitation of local fields. Figure 9 gives the spacing found experimentally to give well-matched double-mitered H-plane corners of 90° total angle. Her λ_0/λ_c is the ratio of design free-space wavelength to the cutoff wavelength. The band width (for $VSWR$ below 1.06) is found to range from about 20 per cent (occurring for λ_0/λ_c of about 0.6) to about 8 per cent (for λ_0/λ_c of about 0.85).

16. IMPEDANCE MATCHING AND IMPEDANCE TRANSFORMERS

In designing a specific wave-guide component, certain parameters are varied in an attempt to arrive at a design which performs its specified function and at the same time introduces into the wave guide the minimum impedance discontinuity, i.e., the minimum of reflection of the incident r-f wave. It is frequently impossible to achieve the desired degree of freedom from reflected waves without sacrificing quality of performance in some other respect. When such an occasion arises, it is necessary to compensate for this im-

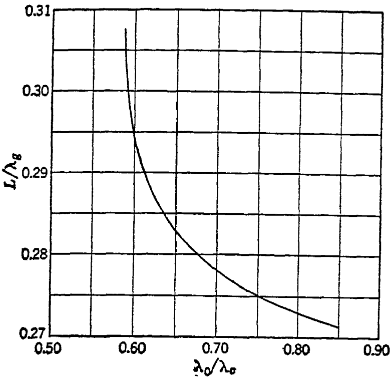

FIG. 9 Design Curve for Double-mitered H-plane Corners (Courtesy McGraw-Hill Book Co.)

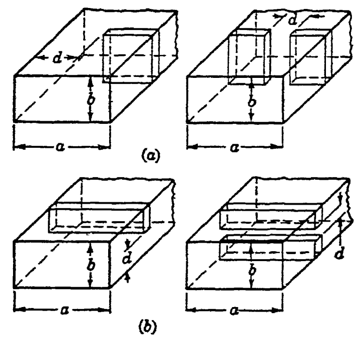

FIG. 10. Wave-guide Impedance-matching Diaphragms; (a) Inductive Types; (b) Capacitive Types (Courtesy McGraw-Hill Book Co.)

pedance discontinuity by introducing into the wave guide an impedance-matching transformer.

Impedance transformers may be classified into two general categories, fixed and variable. The fixed type is inserted at the time of fabrication according to instructions given by the designer, whereas the variable type may be altered by the user of the equipment to achieve the desired performance. Though the variable type may give superior performance when adjusted with the required skill and care, it is capable of doing more harm than good if improperly adjusted. The variable type is, therefore, to be avoided whenever possible.

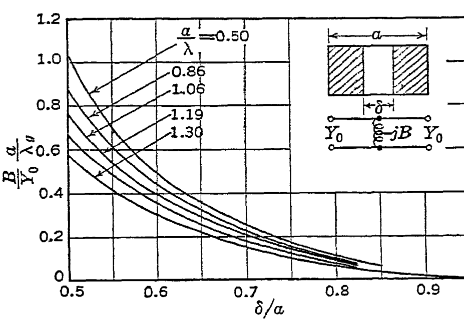

FIG. 11. Design Curves for Symmetrical Inductive Diaphragms (Courtesy McGraw-Hill Book Co.)

The fixed-type impedance transformer usually consists of one or more thin metal strips soldered into the wave guide in one of the forms shown in Fig. 10. The most widely used is the symmetrical inductive diaphragm shown in the upper right figure. The equivalent circuit and design data for this type are given in Fig. 11. The asymmetrical inductive diaphragm, design data for which are given in Fig. 12, is used somewhat less, as the local field distortions set up by it are more extensive. The capacitive types are little used because of the restriction of the permissible power level imposed by the high electrical fields occurring across the gap formed.

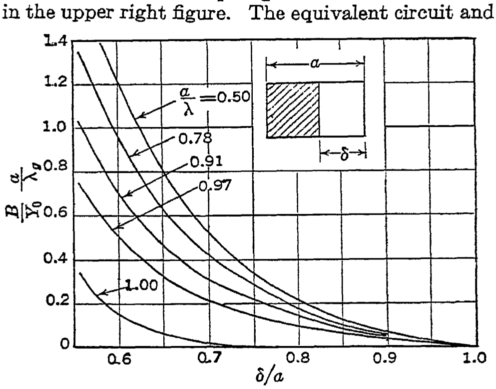

FIG. 12. Design Curves for Asymmetrical Inductive Diaphragms (Courtesy McGraw-Hill Book Co.)

The curves of Figs. 11 and 12 are for infinitely thin metal strips. A rough compensation for increased thickness may be made by assuming a strip to extend into the open space by an amount equal to half the thickness of the strip.

The normalized susceptance B/Y_0 required to correct for a measured voltage-standing-wave ratio r may be determined by the relation

$$\frac{B}{Y_0} = \frac{r-1}{\sqrt{r}} \tag{1}$$

The distance d, from the determined position of a minimum in the voltage-standing-wave pattern, toward the load (for inductive diaphragms) or toward the source (for capacitive diaphragms) may be determined from the relation

$$\frac{d}{\lambda_g} = \frac{90° - \tan^{-1}(1/2\, B/Y_0)}{720°} \tag{2}$$

Alternatively, both B/Y_0 and d may be read from a transmission line chart or admittance diagram.

Several other types of fixed-impedance transformer have seen limited use. One of these is the quarter-wave transformer of ordinary transmission lines. A wave-guide section of the desired lower characteristic impedance is formed by soldering a plate of suitable thickness to one of the two broad walls of the guide. This plate is the full wave-guide width and a quarter guide wavelength long. Since guide width a is not changed, characteristic impedance is proportional to unfilled wave-guide height b.

Another scheme utilizes capacitive "buttons" soldered in place, or dents formed by a suitable rounded tool. Either button or dent forms a projection from the broad wall of the guide which acts essentially as a shunting capacitive element.

Variable-impedance transformers or "tuners" have appeared in numerous forms. They have usually either two or three adjustable elements appropriately spaced along the guide. Among the forms which the adjustable elements have assumed are: (*a*) "Stubs," or branching sections of wave guide perpendicular to the main wave guide and containing adjustable short-circuiting plungers. The stub line may branch from either the broad wall (E-plane stub) or narrow wall (H-plane stub) of the guide. (*b*) Screws, inserted through threaded holes in the broad wall. (*c*) "Slugs," obstacles of either dielectric or metallic materials, designed to alter the characteristic impedance of the guide in the section into which they are inserted (usually a quarter guide wavelength long). These slugs are ordinarily inserted through a narrow longitudinal slot in one of the broad wave-guide walls.

Stubs may introduce either inductive or capacitive susceptance. Three stubs spaced at quarter-wavelength intervals can, in theory, transform any load impedance into any desired input impedance. In practice, if one is interested in matching out or introducing a *VSWR* of 2 or less, two stubs spaced an odd number of eighth wavelengths apart are adequate and have the advantage of easier adjustment.

Small-diameter screws inserted into the wave guide introduce a capacitive susceptance only. This limitation makes the attainment of a proper adjustment much more difficult than that for stubs. As the screw diameter is increased to a size comparable to the wave-guide dimensions, it achieves an inductive effect when retracted, just as does a stub, which it begins to resemble. This opens up the possibility of a screw-type tuner which is relatively easily adjusted. As for stub tuners, an odd number of eighth wavelengths proves to be a good spacing.

A single screw of small diameter, mounted on a sliding sleeve fitted closely around the wave guide, and projecting through a longitudinal slot in the wave guide, constitutes a very useful tuning device. By adjusting both insertion length and position along the slot, any tuning requirement is easily met.

"Slug" tuners may be similar in action to the single screw tuner just described. Or they may consist of two identical slugs whose overall reflection is varied by varying the spacing between them, and the phase of this overall reflection is varied by sliding the two slugs, as a single unit, along the guide.

A simple form of variable-impedance transformer is the phase shifter or "line stretcher" type. This type does not alter the magnitude of the wave reflected by an impedance discontinuity but merely alters its phase. Such a device is very useful in promoting stability of magnetron oscillators in long lines.

One common form is made simply by cutting longitudinal slots in both broad walls of the wave guide and squeezing the section thus formed to alter the wave-guide width. As width changes, guide wavelength and hence total phase length of the section change.

17. TRANSITION UNITS

Whenever it is desired to couple two different wave guides together, either in the same or different modes, some type of transition unit is needed. Similarly, a transition between coaxial lines and wave guides is frequently needed. One very important need for transition units is in connection with rotary joints, where the dominant wave-guide mode cannot be used (see article 18).

A number of types of transitions between coaxial lines and wave guides are illustrated in Fig. 13. Types (*e*) and (*f*) are especially suited for low-power work; types (*g*), (*d*), and (*c*) are recommended for intermediate powers; and types (*h*) and (*i*) are especially suitable for high powers.

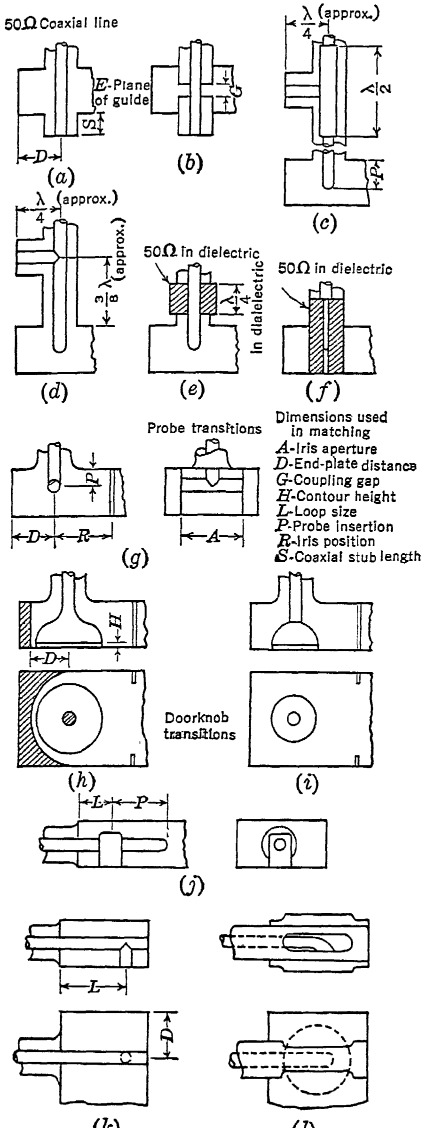

FIG. 13. Transitions from Coaxial Line to Wave Guide (Courtesy McGraw-Hill Book Co.)

A simple transformer designed to couple from 1 by 1/2 in. wave guide to 1 1/4 by 5/8 in. wave guide is shown in Fig. 14. Such a transformer section may be calculated by making

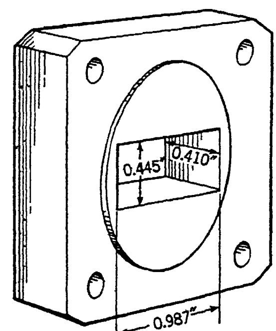

FIG. 14. Quarter-wavelength Transformer between 1 x 1/2 inch to 1 1/4 x 5/8 inch Wave Guides (Courtesy McGraw-Hill Book Co.)

the intermediate section a quarter wavelength long (in terms of its own λ_g), and choosing its dimensions so as to give a characteristic impedance equal to the geometric mean of those of the joined wave guides. For this calculation, the characteristic impedance may be taken as

$$Z_0 = \sqrt{\frac{\mu}{\varepsilon}}\,\frac{\lambda_g}{\lambda_0}\,\frac{b}{a} \tag{3}$$

If one prefers, two rectangular wave guides could be joined by a relatively long tapered

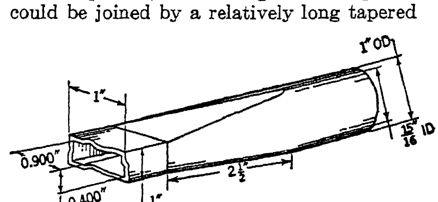

FIG. 15. Taper from Rectangular to Round Wave Guide (Courtesy McGraw-Hill Book Co.)

section. Such a taper is commonly used between rectangular and round wave guides, as illustrated in Fig. 15. If space does not permit such a taper between rectangular and round guides, a transformer section such as that shown in Fig. 16 may be used.

Transitions between the TE_{10} mode in rectangular wave guide and the TM_{01} mode in round wave guide are particularly useful in rotary joints. Three such transition units are shown in Figs. 17, 18, and 19. Varying degrees of complexity are illustrated. In Fig. 17, the parameters were adjusted so that satisfactory impedance match and TM_{01} mode purity are obtained without the matching diaphragms or mode-filter ring shown in the other designs. The design of Fig. 18 is especially recommended for high-power work, as no sharp corners are present to cause breakdown.

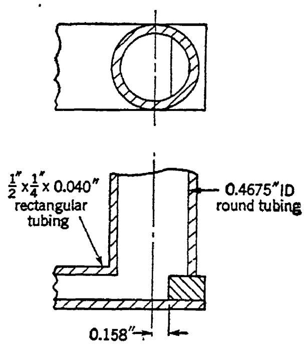

FIG. 17. Transition from Rectangular TE_{10} to Round TM_{01} Mode for 1.25 cm Wavelength (Courtesy McGraw-Hill Book Co.)

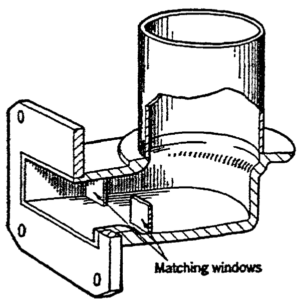

FIG. 18. TM_{01} Transition for High-power Use (Courtesy McGraw-Hill Book Co.)

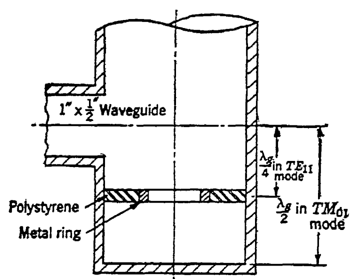

FIG. 19. TM_{01} Transition with Combination Stub and Resonant Ring Filter (Courtesy McGraw-Hill Book Co.)

18. MOTIONAL JOINTS

This classification includes rotary joints, oscillating joints, hinge or "knuckle" joints, and universal joints. Rotary joints, exemplified by Figs. 20, 21, and 22, permit continued rotation about an axis; oscillating joints permit limited rotary oscillations about an axis.

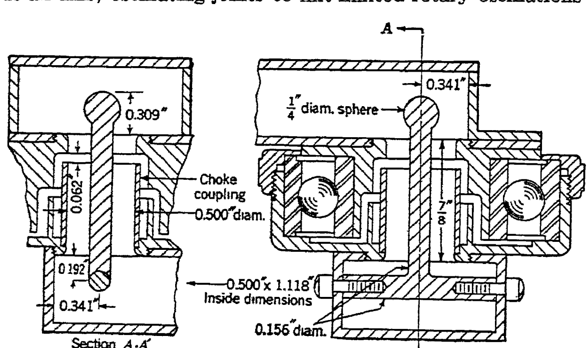

FIG. 20. Rotary Joint, Combining Coaxial Line and Wave Guide, for Use at 3-cm Wavelength (Courtesy McGraw-Hill Book Co.)

Hinge or knuckle joints, Fig. 23, permit angular displacements of one wave guide with respect to another, the axis of the hinging being perpendicular to the wave-guide axis. Universal joints, Fig. 24, permit the motion provided by gimbals.

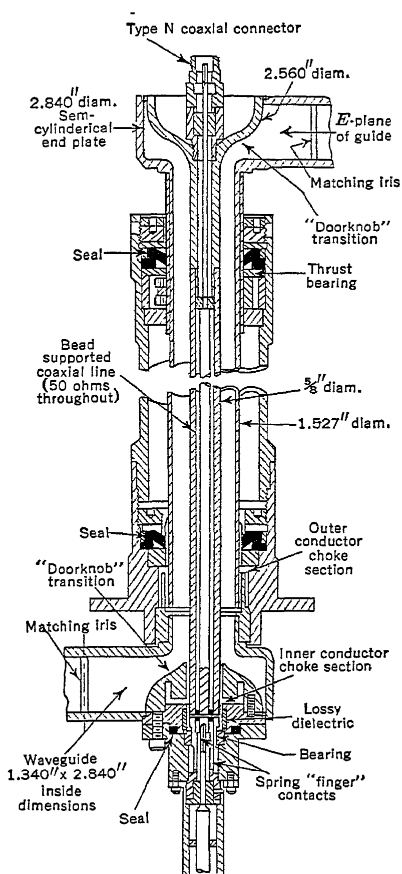

FIG. 21. Rotary Joint for 10-cm Wavelength (Courtesy McGraw-Hill Book Co.)

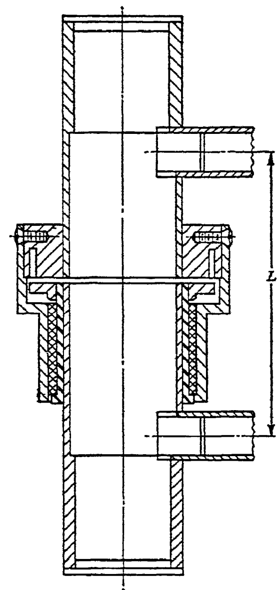

FIG. 22. Rotary Joint Using TM_{01} Mode in Round Wave Guide (Courtesy McGraw-Hill Book Co.)

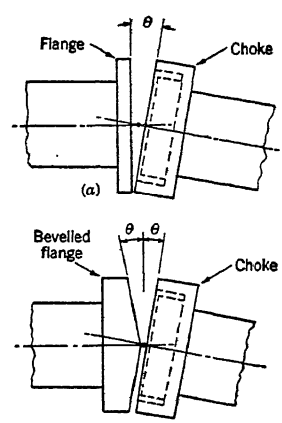

FIG. 23. Hinge or Knuckle Joints (Courtesy McGraw-Hill Book Co.)

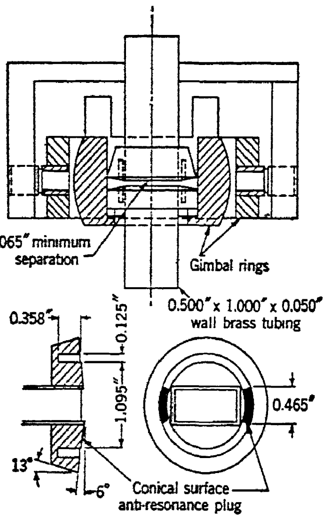
Any transition unit from the dominant wave-guide mode to a coaxial line or to a round wave guide excited in a circularly symmetrical mode may serve as the basis for a rotary joint. In Figs. 20 and 21, the actual rotation is accomplished in coaxial line. Gaps in the coaxial line conductors are bridged by "choke couplings" similar to those described in article 14. A convenient feature of the high-power rotary joint of Fig. 21 is the inclusion, within the center conductor of the main joint, of a second coaxial rotary joint for an auxiliary transmission line.

An important consideration in the design of rotary joints using the TM_{01} mode is concerned with the choice of a length L, Fig. 22, which avoids troublesome resonance effects. Such resonances are associated with the dominant mode fields which inevitably exist, despite efforts to avoid their excitation, in the round wave-guide section.

Any rotary joint may, obviously, be used as an oscillating joint merely by restricting its rotational amplitude. A simpler design, however, may be arrived at by applying the principles of the vertebral assembly of chokes and flanges described in article 13.



Two constructions of H-plane hinge joints are illustrated in Fig. 23. Again, the choke and flange connector is used as a basis of the design. Similar hinge joints of E-plane type are in use.

The universal type joint of Fig. 24 is essentially a double hinging obtained by means of gimbals and suitable modifications of the choke-flange principle. In this design, two chokes are opposed, rather than choke and flange, in order to permit greater freedom of motion without leakage of power from the openings around the joint. The antiresonance plugs, shown darkened, prevent trouble from resonances which are found to occur whenever two chokes are opposed. The same resonance trouble is found when wave guides are joined by opposing two chokes.

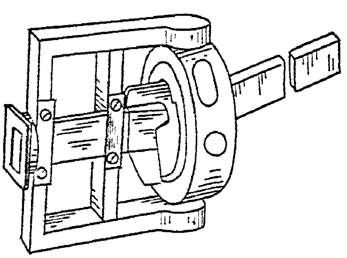


FIG. 24. Universal Joint (Courtesy McGraw-Hill Book Co.)

19. OTHER COMPONENTS

The foregoing discussion is, of course, far from exhaustive. Space has permitted the inclusion of only a few designs representative of the types discussed. In addition, several types of component have not been treated, even cursorily, because of space limitations.

Among the more important omissions are the so-called T-R or duplexing components which permit the transmission of r-f power and the reception of r-f signals on the same wave-guide and antenna assembly. Still other circuits, which are conspicuously omitted, are the so-called mixer circuits in which received signals are mixed in suitable crystals or tubes with a local oscillator signal to generate the i-f signals supplied to the receiver.

Those interested in pursuing these omitted items will find them described in the appropriate volume of the M.I.T. *Radiation Laboratory Series* listed in the bibliography.

TRANSMISSION IN SPACE

By J. C. Schelleng

20. WAVE PROPAGATION AND GENERAL VIEW OF THE RADIO SPECTRUM

Radio propagation is a special instance of the propagation of electromagnetic waves. As electromagnetic waves have so much in common with light, an understanding of radio propagation begins with an understanding of optics. Radio propagation provides examples of most optical phenomena: interference, reflection, simple refraction and double refraction, diffraction, etc. Many of the standard formulas of optics can be carried over without change into the radio field. Although it is beyond the scope of this article to discuss these fundamental considerations, a few general principles will be mentioned.

RADIATION AND TRANSMISSION IN FREE SPACE. Radiation of electromagnetic waves take place whenever an electrical charge is accelerated. The wave which is set up is transverse, its electrical field at any point being a vector perpendicular to the direction of transmission, lying in the plane specified by the direction of propagation and the direction of acceleration of charge, and measured in units of potential per unit of length in the direction of the field, e.g., microvolts per meter. When the space surrounding the source is free of material, the electrical field is propagated outward with the velocity of light, and at sufficiently great distances it is proportional to that component of the acceleration which is parallel to the electric field at the point in space under consideration (Fig. 1). These statements are true whether the acceleration is sinusoidal or not. In radio communication, the accelerated charges are the electrons in the conductors of the antenna. For engineering purposes it is more convenient to use formulas involving quantities other than acceleration and charge. Thus, in free space, the electric field intensity, E, from a short electric dipole is

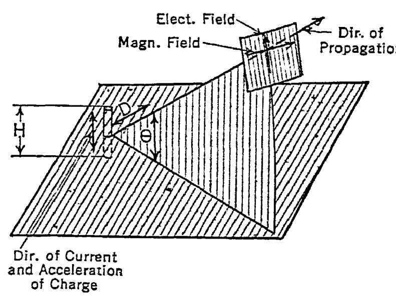

FIG. 1. Vector Relations in Radiation

$$\mathcal{E} = 60\pi \frac{hI}{\lambda d} \cos\theta \tag{1}$$

h, d, and λ are the effective height, distance from doublet to measuring point and wavelength, all in the same unit of length (e.g., meters); $\mathcal{E}$ is in volts per unit length (e.g., per meter), and I is in amperes; see article 28, pp. 5–52. A convenient form for either electric or magnetic dipole is

$$\mathcal{E} = \frac{\sqrt{45P}}{d} \cos\theta \tag{2}$$

in which P is the radiated power in watts, and $\mathcal{E}$ and d are in the same units as for eq. (1). The field varies inversely with the distance. For an especially useful formula for the ratio of power picked up by a receiving antenna to that radiated from a distant transmitter, the conditions being those of free-space transmission, the reader is referred to Section 6, article 28, eq. (11).

GROUND WAVE AND SKY WAVE. Two general modes of wave propagation are useful in radio communication: the *ground wave*, which passes *along* the surface of the earth; and the *sky wave*, which, traveling at an angle with the surface, passes through the lower atmosphere, is reflected from the upper atmosphere, and is enabled in this way to return to the earth at a distant point. The ground wave is used over short distances; the sky wave, or ionospheric wave, is required for the longer spans. Intermediate ranges may involve either or both, depending on the frequency used, the time of day, and other circumstances.

The reciprocity theorem of Lord Rayleigh, originally derived and widely used for electric-circuit analysis, has been shown by Carson and others to be true in cases involving radiation (*B.S.T.J.*, April 1930, and earlier papers). It results from one form of this theorem that with certain limitations the efficiency of radio transmission in opposite directions is the same, provided that the usual measures have been taken to match the generator and load to the antennas, and that the path is free of elements which fail to act reciprocally by themselves. A one-way amplifier is an obvious example of such an element. Another example, less obvious, actually occurs in the upper atmosphere itself, namely, the ions which tend to spiral about the earth's magnetic field in one direction but not in the other, thus producing a non-reciprocal element. As a result, strict reciprocity can be expected where the ground wave is concerned, but it becomes doubtful with the sky wave, and it

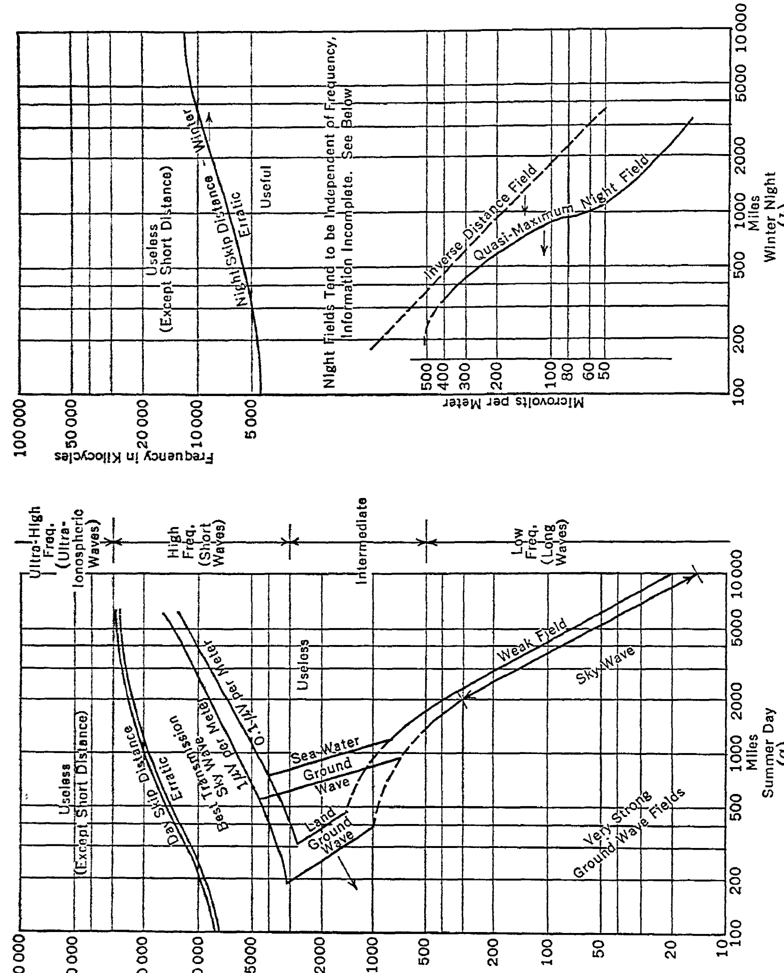

FIG. 2. General View of the Frequency-distance Relations throughout the Radio Spectrum (Vertical antennas, 1 Kw radiated)

almost certainly fails where rotation of the plane of polarization (indicating a magnetic effect) is observed. Even in the last case, the *averages* of field (as opposed to instantaneous values) usually appear to be reciprocal, and this possibly is always true at the higher frequencies.

POLARIZATION. For frequencies below 2000 kc vertical antennas are almost universally used. This is primarily because it is usually desirable to radiate with maximum efficiency in a nearly horizontal direction, which is relatively easy with vertical antennas but is impossible with horizontal antennas unless they are several wavelengths above the ground. Hence, to keep antenna dimensions within reasonable limits, horizontal electric fields are not used except for short waves.

GENERAL VIEW OF THE SPECTRUM. With respect to frequency, daylight propagation falls into natural divisions. These may be listed as follows: (1) low frequency, long distances; (2) intermediate frequency, short and intermediate distances; (3) high frequency, all distances; (4) ultra-ionospheric frequency, short distances. Here we arbitrarily describe a short distance as one from zero to 100 miles, an intermediate distance as one from 100 to 1000 miles, and a long distance as one greater than 1000 miles. Likewise, we usually think of a low frequency as one less than perhaps 500 kc. Physically, the characteristic that distinguishes a low frequency from a high frequency (3000 to 30,000 kc) is the low resistivity of the reflecting layer for the low frequencies. In fact, the ionosphere resembles a fair metallic reflector for waves of low frequencies. The wave of high frequency, on the other hand, sees in the layers of the upper atmosphere something like a reflecting plane of dielectric; the type of reflection which is most common is similar in many ways to the familiar optical phenomenon of total internal reflection. The intermediate frequencies form a transition range (500 to 3000 kc), which includes much ground-wave transmission over short and intermediate distances. Frequencies commonly designated as "ultra-high," but which are better called "ultra-ionospheric" because they are not reflected by the ionosphere, are those greater than about 30,000 kc. At night the differences between ionospheric waves of different frequencies are much less marked than by day. Waves having frequencies in excess of 1000 megacycles, more or less, are frequently called microwaves. See also Section 1, article 24.

Figure 2 gives a typical overall view of the whole radio spectrum for distances from 100 to 10,000 miles and for vertical antennas. Lines are drawn indicating the distance at which a radiated power of 1 kw would produce certain specified field strengths, e.g., 1 μv per meter. Diagram *a* represents transmission conditions on a summer day; diagram *b*, those on a winter night. On winter days, the sky wave becomes generally stronger than on summer days. As a general rule, for a given distance the highest frequency that can be received by day (the skip frequency) is greater in winter than in summer; and the lowest (absorption limit) is lower in winter than in summer. At night lower frequencies are required in winter than in summer. Transmission in the high-frequency range is markedly affected by the changes accompanying the cycle of solar activity (e.g., sunspots); since the actual phenomena are too variable to be represented by so simple a chart as Fig. 2, the comprehensive data and predictions issued by the National Bureau of Standards (Central Radio Propagation Laboratory) may be consulted to advantage in cases of actual use.

21. THE GROUND WAVE

FREE-SPACE TRANSMISSION. Historically the propagation of the ground wave has been studied by examining idealized situations. The simplest of these is the field set up in free space by a simple doublet antenna. Equations (1) and (2) give the appropriate solution and apply accurately provided that the earth is known to be without effect and the air to be a uniform and lossless dielectric. These assumptions are not true in general.

PROPAGATION OVER PERFECTLY CONDUCTING PLANE EARTH. Some situations are taken care of by assuming the earth to be a homogeneous plane and then applying the standard principles of optics. This is particularly simple if the earth in effect has *infinite conductivity*. The solution is then merely the combination of a direct wave with a reflected wave virtually coming from the "image" of the antenna in the earth plane. With low antennas and infinite earth conductivity we are led to a simple and important relation pointed out at an early date by M. Abraham. For distances short enough not to violate the assumptions as to the effective flatness of the earth and negligible attenuation, a short vertical grounded antenna of effective height h produces a field strength $\mathcal{E}_0$ in the region about it equal to

$$\mathcal{E}_0 = 120\pi \frac{hI}{d\lambda} \cos\theta \tag{3}$$

units as in (1). The formula corresponding to (2) is

$$\mathcal{E}_0 = \frac{\sqrt{90P}}{d} \cos\theta \tag{4}$$

The doubling of the numerical factor in passing from (1) to (3) merely expresses the fact that the field may be regarded as the sum of one field received directly and another by reflection from the image. Note, however, that (2) and (4) being expressed in terms of power instead of current have factors in the ratio of 1 to $\sqrt{2}$. Formulas (1) to (4) apply for distances greater than a few wavelengths. When the distance is of the order of 1 wavelength or less, the term due to *acceleration* of charge is supplemented by terms due to *velocity* and *position* (*proximity*) of charge, but for most practical purposes these may be neglected for distances greater than 1 wavelength. Except in the immediate vicinity of the antenna, the velocity of phase propagation is $2.998 \cdot 10^{10}$ cm per sec, the velocity of light in air.

PROPAGATION ALONG A PERFECTLY CONDUCTING SPHERICAL EARTH. A next step beyond that represented by (4) is the propagation of a field from a vertical grounded antenna, located at the surface of a perfectly conducting earth which is spherical rather than plane. Watson's solution [*Proc. Roy. Soc.* (A) Vol. 95, 83, 546 (1919)] is in the form of a series in which all but one term may be neglected at the greater distances. This term is as follows:

$$\varepsilon = 0.1136\varepsilon_0 \frac{d^{1/2}}{\lambda^{1/6}} \varepsilon^{-0.00376d/\lambda^{1/3}} \tag{5}$$

where ε_0 is the inverse distance field as given by (3) or (4), and d and λ are in kilometers, d being measured along the surface. This formula holds when $d/\lambda^{1/3} > 160$. For smaller distances, (3) or (4) applies. In (5), atmospheric refraction has been neglected.

The following simple empirical formula based on Watson's results and on calculations of other terms in his series carried out by C. R. Burrows can be used for distances less than about 5000 km:

$$\varepsilon = \varepsilon_0(1 + 2z)^{1/2}\varepsilon^{-z} \tag{6}$$

where $z = 0.0035\ d/\lambda^{1/3}$ and d and λ are in kilometers. All these diffraction calculations assume that the density of the lower atmosphere is independent of height; atmospheric refraction is neglected. When the deviation of refractive index from that at ground level is a simple linear function of height, refraction has the same effect as increasing the size of the earth to a virtual radius which for average conditions is about $^4/_3$ the actual radius. With refraction we have $z = 0.0029d/\lambda^{1/3}$. It is not obvious which of these values should be used. Although the refraction effect is important at sea level, it must become small at heights of several miles. Perhaps the effect can be neglected at low frequencies. At higher frequencies experiments clearly show that it should be taken into account.

TRANSMISSION ALONG AN IMPERFECTLY CONDUCTING PLANE EARTH. At distances shorter than those which give appreciable attenuation due to the shadow of the bulge of the earth, strong attenuation due to energy dissipation in the ground is found in many cases of importance in practice. Since the shadow effect is then unimportant, the solution of wave propagation over a plane of finite conductivity becomes applicable. The basic solution of this problem, due to A. Sommerfeld [*Ann. der Physik,* (4) Vol. 28, 665 (1909)], has been extended by various investigators. Owing to finite earth conductivity the wave ceases to have the simple form contemplated in connection with eq. (3) for infinite conductivity, the inverse-distance attenuation of which represents a spherically expanding wave. The field strength at the surface decreases in intensity more rapidly than the inverse of distance, owing to the absorption of energy by the currents set up in the imperfectly conducting earth. For the lower frequencies, an approximation due to van der Pol [*Jahrbuch der Drahtloson,* Vol. 37, No. 4, 152 (1931)] is useful. This is:

$$\varepsilon = \varepsilon_0 \cdot \frac{(2 + 0.3\rho)}{(2 + \rho + 0.6\rho^2)} \tag{7}$$

where ε_0 is the inverse-distance field given by (3) or (4) and

$$\rho = \frac{\pi \cdot 10^{-15}}{6} \cdot \frac{d}{\sigma\lambda^2}$$

σ is the conductivity in emu units and varies from 1 to 4×10^{-11} for sea water to 10^{-15} for very broken land; d and λ are expressed in kilometers; ρ is the "numerical distance" of Sommerfeld. Note that according to (7) the field varies inversely as the first power of distance near the transmitter and inversely as the square of the distance for $\rho \gg 20$. Also note that, since λ and σ enter only as the product $\sigma\lambda^2$, the field strength remains unaltered when the wavelength is decreased by a factor, provided that the conductivity is simultaneously increased by the square of that factor. Equation (7) holds only so long as the dielectric currents in the earth remain negligible compared with the conduction currents. This is insured if the frequency in kilocycles is very low compared with $1.8 \times 10^{-18}\ \sigma/K$, K being the dielectric constant of the ground. Numerically, the frequency should be considerably lower, for sea water, than 10^6 kc; for land, than 10^4 kc; and for fresh water, than 250 kc, the figure depending on the ground constants, which differ from place to place and to some extent with temperature.

An interesting characteristic of waves traveling along an imperfect conductor, first discussed by J. Zenneck [*Ann. der Physik,* (4) Vol. 23, 846 (1907)], is that parallel to the surface there is a longitudinal component of electric field, that is, one extending in the direction of propagation. Its amplitude and phase depend on the resistivity and dielectric constant of the ground, the phenomenon being very different over fresh water, sea water, moist ground, and dry ground. Its amplitude is zero for perfect conductivity and increases as the conductivity decreases. The phase of this component in general differs from that of the vertical component so that in the vertical plane the wave exhibits elliptical polarization. By Poynting's theorem the existence of this component is a necessary accompaniment of energy loss in the ground. The phenomenon is of importance in the design of wave antennas, which depend for their effectiveness entirely on this horizontal component. [See "Wireless Waves at the Earth's Surface" by G. W. O. Howe, *Wireless Engineer*, Vol. 17, 385 (September 1940).]

IMPERFECTLY CONDUCTING SPHERE. A still closer approximation to actual conditions is afforded by the assumptions that geometrically the earth is a perfect sphere (i.e., that local irregularities may be ignored) and that electrically over any given path it has uniform conductivity and specific inductive capacity. As to refraction in the atmosphere, the assumption made above in connection with a perfectly conducting sphere is repeated. Though these assumptions still describe a somewhat idealized picture, they nevertheless represent a large step in the direction of realism, a difficult and important mathematical task which has been successfully accomplished by the combined labors of several investigators, including Balth van der Pol. Excellent summaries, including bibliographies, have been given by C. R. Burrows and M. C. Gray [*Proc. I.R.E.*, Vol. 29, No. 1, 16 (January 1941)] and by K. A. Norton [*Proc. I.R.E.*, Vol. 29, No. 12, 623 (December 1941)]. Figures 3, 4, and 5 are based on the paper of Burrows and Gray.

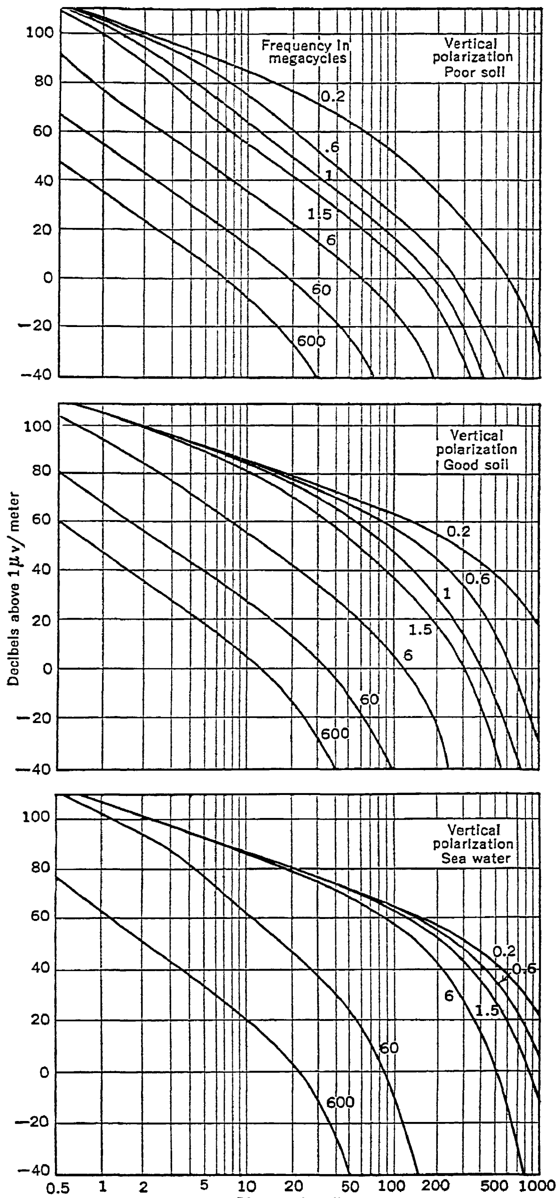

FIG. 3. Field Along Imperfectly Conducting Spherical Earth, with 4/3 Earth-radius. Short vertical antenna at ground level, measurement at ground level, for sea-water $\sigma = 4 \times 10^{-11}$ emu, $\epsilon = 80$; good soil $\sigma = 2 \times 10^{-13}$ emu, $\epsilon = 30$; poor soil $\sigma = 10^{-14}$ emu, $\epsilon = 4$, 1 kw radiated (Courtesy *Proc. I.R.E.*)

Figure 3 gives theoretical field strengths between two points on the surface of the earth when vertical polarization is used. "Standard refraction" conditions ($^4/_3$ earth radius) are assumed to occur over a sufficient depth of atmosphere to produce bending at all frequencies, a postulate frequently made which might, however, properly be questioned with reference to the lower frequencies shown, since with them transmission to the longer distances involves at intermediate points regions which are far above the earth's surface and at which the rate of decrease of refractive index with height is no longer comparable with that at the surface. The legend of the figure gives the soil constants assumed in the calculation. Important features of the curve are the "inverse-distance" tendency at the upper left corners as in the approximation of eq. (4), the rapid drop due to failing diffraction at the lower right as suggested by eq. (5), and the inverse square of distance in between as indicated by eq. (7) (for $\rho \gg 20$). A useful series of calculations along these general lines (K. A. Norton) is included in "Standards of Good Engineering Practice Concerning Standard Broadcast Stations," issued by the Federal Communications Commission, for sale by the Superintendent of Documents, Washington 25, D. C. This document also gives comprehensive information of the ground conductivities pertinent in this frequency range in the form of a United States map.

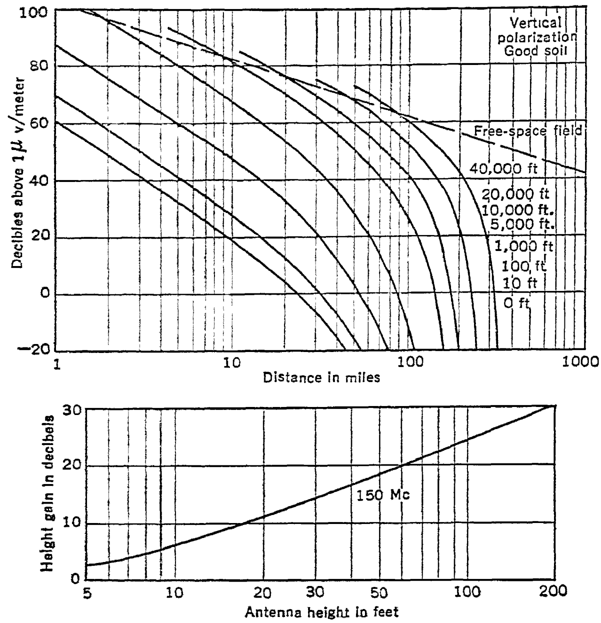

FIG. 4. Fields at 150 Mc as a Function of Height of Transmitter and Receiver, Good Soil (Courtesy *Proc. I.R.E.*)

Figure 4 illustrates propagation from one point on or near the ground to another at heights from zero to 40,000 ft above it for the special case of 150 megacycles. If the transmitting antenna (vertical polarization) is on the ground, the upper graph gives the calculated field directly. The lower graph gives the correction to be added if the antenna is elevated not more than 200 ft. The increase which accompanies the elevation of the receiver, and the inevitable failure of diffraction at greater distances, are striking features of the graph.

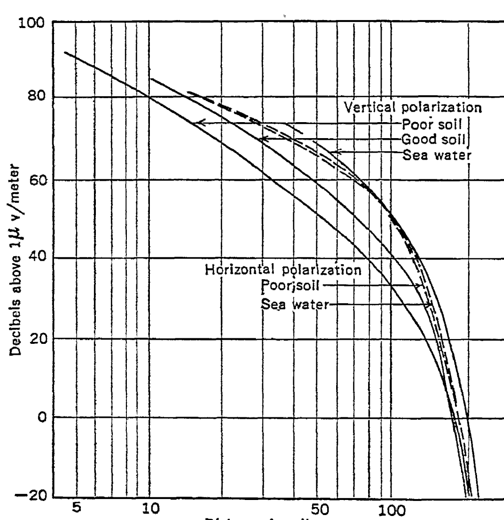

FIG. 5. Fields at 150 Mc and 10,000 Ft. as a Function of Ground and Polarization (Courtesy *Proc. I.R.E.*)

Figure 5 exemplifies for fixed antenna heights and fixed frequency how the field depends on the underlying ground and on the polarization. Note the insensitiveness of horizontal polarization to ground constants.

ULTRA-IONOSPHERIC RANGE. This is the range of frequencies higher than those capable of reflection by the ionized upper atmosphere. The dividing frequency is not at all sharp or constant but is of the order of 30 megacycles. Ultra-ionospheric waves whose length is short enough for the practical application of quasi-optical techniques such as the use of parabolic reflectors and lenses have been called "microwaves," and here an equally hazy division might be placed somewhere near 1000 megacycles.

Although the absence of reflection of ultra-ionospheric waves might hypothetically be accounted for by their penetration into a region where they are dissipated by absorption before being freed by reflection, three experiments now indicate actual passage through the ionosphere into interstellar space. In chronological order these are the detection of galactic noise by K. Jansky (and the subsequent mapping of the Milky Way by Grote Reber), the measurement of thermal radiation from the sun by G. C. Southworth [*J. Franklin Inst.*, Vol. 239, No. 4, 285 (April 1945)], and the dramatic "detection and ranging" of the moon by radar reported by DeWitt et al. [J. Mofenson, "Radar Echoes from the Moon," *Electronics*, Vol. 19, No. 4, 92–98 (April 1946)]. These experiments strongly suggest inadequacy of ionization as the reason for absence of reflections.

Qualitatively propagation in this range strikingly resembles the familiar phenomena of light. Radio "vision" tends to be limited to the optical line of sight, though *diffraction* actually extends coverage considerably beyond obstructions, such as hills or the bulge of the earth, except for extremely high radio frequencies. The earth (land or water) for many purposes may be regarded as an example of Lloyd's mirror, the ground-located receiver tending to be in the first dark fringe produced by *reflection*. *Refraction* tends to make the distant station "visible," just as it reveals the sun a few minutes before sunrise, and it produces variations and anomalies which correspond to the twinkling of stars and to the mirage. The comparison might be extended to other phenomena.

The effect of regular reflection is most pronounced in the meter range, though even in the centimeter range cleared land or water may make a good "mirror" for glancing incidence. In such cases reflection may be calculated as to amplitude and phase by means of standard optical formulas provided that an equivalent conductivity and dielectric constant are known. [P. O. Pederson, *The Propagation of Radio Waves*, Copenhagen, 1927; C. B. Feldman, "The Optical Behavior of the Ground for Short Radio Waves," *Proc. I.R.E.*, Vol. 21, No. 6, 764 (June 1933); Barfield, *J. I.E.E.*, Vol. 75, No. 452, 214 (1934); R. L. Smith-Rose, *J. I.E.E.*, Vol. 75, No. 452, 221 (1934).] As has already been implied, though reflection has a favorable effect with long waves of vertical polarization, causing the factor of 2 which differentiates eq. (3) from (1), in this range it is commonly unfavorable owing to the phase of the reflection coefficient caused by the predominance of dielectric currents in the ground at these ultra-high frequencies. The effect of reflection need not be unfavorable, however, if one or both of the terminals is located at a sufficient altitude. At high enough altitudes a regular succession of maxima and minima is encountered, whose position and amplitudes may be calculated from the amplitude and phase of reflection.

In the microwave range caution is necessary in applying the concept of reflection. Here one may not always regard the earth as the smooth and abrupt boundary between materials described simply by their conductivities and specific inductive capacities. Reflection is not always specular but is very likely to be diffuse, as the success of radar mapping proves. One should not ignore even here, however, the strong tendency toward specular reflection that glancing incidence imparts to the scattering from a rough surface.

Simple plane-wave reflection theory leads to a useful relationship which has been observed to hold with fair consistency in the range from 3 to 10 meters and even in the microwave region if the warning in the last paragraph does not apply. Over level land or over fresh water with vertical or horizontal antennas, and over sea water with horizontal antennas, the received field is:

$$\mathcal{E} = 12\pi\sqrt{5}\,\frac{\sqrt{P}}{d^2}\,\frac{H_1H_2}{\lambda} \quad \text{volts per meter} \tag{8}$$

the radiated power P being in watts, and d, H_1, H_2, and λ in meters. H_1 and H_2 are altitudes above the general reflecting area, be it ocean, valley floor, or plain. This equation is obtained by multiplying the free-space field of eq. (2) by $4\pi H_1H_2/\lambda d$, a procedure justified if $H_1H_2/\lambda d$ is less than 0.1 provided that the reflecting coefficient of the ground is near unity for the grazing incidence involved. The usefulness of eq. (8) is not limited to transmission over plane earth, as assumed in its derivation, but roughly applies also over spherical earth for transmission below the line of slight when 3 meters $< \lambda <$ 10 meters, 3 meters $< H <$ 25 meters, 1 km $< d <$ 50 km. In this extended range (8) is to be regarded as an empirical formula whose range of validity has not yet been determined. When terminals are located on hills, with a level valley between, this formula needs a correction factor due to ground reflections local to the terminals.

An interesting extension of eq. (8), valid within the same limitations, is obtained analogously to eq. (13) in the section on radio antennas. If G_T and G_R are the power gains of the antennas (in terms of an "isotropic radiator"), and P_T and P_R the powers transmitted and received, it can be shown that

$$\frac{P_R}{P_T} = G_T G_R \left(\frac{H_1 H_2}{d^2}\right)^2 \tag{8a}$$

Note that power received is independent of frequency. If the antennas are short doublets, $G = 1.5$. (K. Bullington, *Proc. I.R.E.*, 1947.)

With vertical antennas over sea water, but otherwise with conditions specified above, an approximate inverse-square-of-distance variation has been found up to 30 or 40 km, with the important difference that propagation became poorer as the frequency was raised. This is in accord with simple optical theory, due account being taken of the electrical constants of sea water. Equation (8) therefore does not apply here, though it does for horizontal antennas over sea water.

Since diffraction extends the range beyond obstacles it is a favorable factor. Ignoring diffraction and refraction we could at most transmit only to points above the line of sight. The range would then be limited to $D = 3500(\sqrt{H_1} + \sqrt{H_2})$, all distances being in meters. Within this range eq. (8) is applicable unless the antennas are too high, with qualifications already mentioned. Note that line of sight does not at all guarantee the free-space field strength.

It is possible to make instructive calculations of the fields behind obstructions, such as hills, by application of the standard mathematical theory of diffraction. Thus, the behavior of a knife edge in the familiar optical example becomes a guide in radio transmission past obstacles. In a radio problem, in order to obtain a reasonable estimate of this kind, the effect of ground reflection at the transmitter and at the receiver needs to be taken into account.

If the index of refraction of air is calculated as a function of height from average meteorological conditions [Humphreys, *Physics of the Air*, McGraw-Hill (1940), p. 80], the gradual decrease of index leads to a "standard" or "normal" condition which can be taken into account in a simple manner. Such calculations and theoretical considerations indicate that, if the topographic cross-section of the path is plotted as though the earth had a radius $^4/_3$ times its actual radius, the solution of the corresponding problem assuming a uniform refractive index is also the solution for the actual problem including the effect of refraction. We have already had occasion to use this method above in the "spherical earth" problem. In dealing with microwaves, however, this simplication will be misleading if the possibility of many other distributions of refractive index is forgotten.

In connection with the foregoing topics, reference may be made to articles in *Proc. I.R.E.*, Vol. 21, No. 3 (March 1933), by Jones (p. 349); Trevor and Carter (p. 387); Schelleng, Burrows, and Ferrell (p. 427); and Englund, Crawford, and Mumford (p. 464); also Englund, Crawford, and Mumford, *B.S.T.J.*, Vol. 14, No. 3, 369 (July 1935).

At shorter wavelengths refractive variations within a small range of height may become important because the wave in traveling between two points occupies only a small fraction of a kilometer (that is, the necessary Fresnel zones are now included in a small transverse area). It results, for example, that such waves may be trapped beneath a level of minimum refractive index and may travel unusually long distances, and that under other conditions they may unexpectedly fail over short ones.

Refraction theory as applied to extremely short waves has led to the use of a *modified refractive index* of the air, M, as a function of height, h. If the actual index as ordinarily used is $n(h)$ and the radius of the earth is a, the definition $M \cdot 10^{-6} = n(h) - 1 + h/a$ leads to the same solution with an assumed flat earth that the actual index leads to with curved earth, the scale factor 10^{-6} being used for numerical convenience.

Just as short waves are "bent down" by the ionosphere because its refractive index decreases with height—that is, the phase velocity increases with height—so in the troposphere a decrease in modified index will tend to confine microwaves beneath it. Indeed, if meteorological conditions are such as to give a maximum index at a certain level with progressively smaller values above and below, one would on ray theory expect the ray in its horizontal passage to undergo consecutive upward and downward bendings about the level of maximum index (minimum velocity). Similarly the wave might be confined between an index which decreases with height and the reflecting floor of the ocean (or perhaps of land). Such phenomena do occur, and their importance is that they may lead to abnormally high or abnormally low fields. The reason for the strong fields is that cylindrical rather than spherical expansion causes a slower decrease with distance, i.e., increased range horizontally. The phenomena resulting are likely to be complicated and variable, though on the other hand such "anomalies" may be so consistent as to be the normal condition. ["9 cm and 3 cm Propagation in Low Ocean Ducts" by M. Katzin, R. W. Bauchman, and Wm. Binnian, Dept. of Com., Office of the Publication Board, Report PB 13747 (1945); "Wave Theoretical Interpretation of Propagation in Low Level Ocean Ducts" by C. L. Pekeris, Dept. of Com., Office of the Publication Board, Report PB 20228.] Another way of looking at these ducts is to use wave guide concepts: in fact, a duct is a wave guide with many modes of propagation which are excited to different extents depending on the elevation of the transmitter with reference to that of the duct. The second article cited discusses the subject from that point of view. For a summary of the war work dealing with the various aspects of this problem see *Radio Wave Propagation, Consolidated Summary Technical Report of the Committee on Propagation*, by Burrows and Attwood, Academic Press, New York.

With wavelengths longer than 10 cm the absorption of energy from the wave due to the atmosphere itself is not important for practical purposes, but with shorter waves at least three known mechanisms may have to be considered. *Water in the liquid* or *solid* phase (e.g., rainfall) is one of these that can become very serious at wavelengths of a centimeter or two. The loss depends on the total water per unit volume and on the size of drop or particle and is due to scattering. Although this is harmful to radio transmission, the phenomenon is being utilized by meteorologists in the detection and location of storm areas by means of radar. In the *vapor phase, water* has its longest wave resonance at 1.3 cm, so that near this wavelength high absorption is to be expected and is found for high humidities. *Oxygen* has its first resonance absorption at 0.5 cm.

Directional properties of tropospheric waves have been studied at a wavelength 3.25 cm by W. M. Sharpless, and at 1.25 cm by A. B. Crawford and W. M. Sharpless, *Proc. I.R.E.*, Vol. 34, No. 11, 837–848. Deviations in azimuth were found to be at most of the order of 0.1°. Although in elevation the deviations were several times as great as this, they were never large. Fading about the free-space field strength was observed, and at times the field exceeded this by a factor of 4 (12 db). At times there were multiple waves coming in from slightly different directions, the variations of which produced fading.

22. THE SKY WAVE

THE IONOSPHERE. Whereas for most radio services up to a few hundred miles transmission depends on the direct ground wave, for all long distances successful transmission depends on the existence of a "ceiling" in the upper atmosphere which, by returning to the earth the outgoing waves, lays down a useful signal at distant points where the ground wave is negligible. Even the longest waves used in radio communication depend on such "sky waves" for distances beyond a thousand miles or two. In this section we shall describe present views of this ceiling, the common name for which is the "ionosphere," formerly called the "Kennelly-Heaviside layer." The first suggestion that an electrically conducting region exists in the upper atmosphere was made by Balfour Stewart to explain variations in the magnetic field of the earth. Kennelly and Heaviside were the first to see the necessity of such a region for explaining radio transmission phenomena.

At sea level, the atmosphere is scarcely conducting at all, but as the elevation is increased the conductivity increases owing to an increase in the number of ions in unit volume. This ionic density increases both because the major sources of ionization are outside the earth and because, at the lower pressures encountered, the ions last longer before recombination neutralizes them electrically. Heavy ions (e.g., ionized molecules) have much less effect on radio waves than electrons. Electrons are known to exist in sufficient quantity in the upper atmosphere to produce most of the effect observed, but the radio effects of heavy ions have not as yet been definitely identified. The number and distribution of these ions depend on various factors, including altitude, geographical and geomagnetic latitude, local time, time of year, and solar activity (e.g., sunspots). The variation with altitude is very important. It has been found that the increase with altitude is not at all uniform and simple, but that there are regions where the density attains, or tends to attain, maximum values. Although methods thus far devised are not suited for studying those levels above the maxima where the density may actually decrease with height, it is probable that one or more of such decreases actually occur. These levels of maximum (or tendencies thereto), frequently called "layers," are illustrated in Fig. 6. The maximum occurring somewhat above 100 km is known as the E layer, and those above 160 km as the F layers, names which will perhaps be superseded when the mechanism of their production is explained. It is fairly definitely known that ultraviolet light from the sun is an important source of ionization, particularly in the E region and in one region of the F layer. This leads to the large differences between the day and night behavior of radio waves, in particular to phenomena occurring at sunrise and sunset.

Another cause of ionization is particles from the sun, which most authorities regard as the radiation by which solar disturbances communicate the major disturbing effects to the earth. These are in particular thought to be the cause of the absorbing "clouds" which seem to form in polar regions beneath the E layer and hinder short-wave transmission during magnetic storms. The distribution of ionization changes with time, and Fig. 6 is to be regarded merely as typical. Tendencies toward maxima come and go, and both the E and F regions seem to be composites of two or more layers. The E layer is the most consistent and is the most important one in the broadcast band (1500 kc and lower) and at lower frequencies. For these lower frequencies, the waves do not ordinarily penetrate higher than the E layer. For the lowest frequencies it is not known whether reflection occurs at the E layer or at some lower level, there being some evidence that the height is 80 or 90 km. The F region is of most importance for the short waves, particularly over longer distances, but the E region also contributes components to the signal, which is usually very complex.

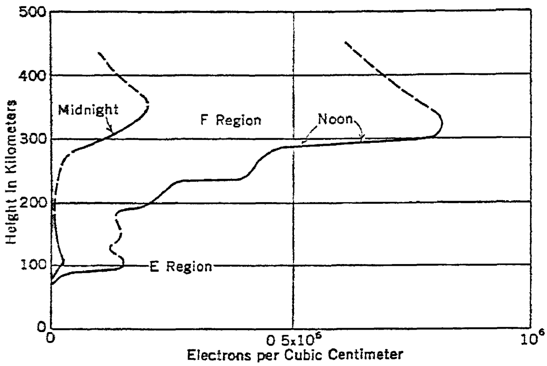

FIG. 6. Concentration of Electrons in the Upper Atmosphere. The D region is the ionosphere below 90 km, the F region is the part above 160 km, and the E region is the part between these limits.

The most fruitful method of studying these regions has been the pulse or echo method of Breit and Tuve [*Phys. Rev.*, (II) Vol. 28, 554 (1926)], in which a very short-wave train of a given frequency is radiated upwards and the times required for various reflections to be returned are obtained with an oscillograph, preferably of the cathode-ray type. These times may be converted into virtual heights of the reflecting layer by assuming the pulse to travel with the velocity of light. This method of "radio detection and ranging" is in fact one of the forerunners of radar. Actually, the pulse travels with a slower group velocity than this while in the ionized region, but as a result of making measurements at several frequencies it is often found that the virtual height within limits is nearly independent of frequency, and for such frequencies the actual cannot be very different from the virtual height. Transmission through the ionized region is complicated by the earth's magnetic field, which makes of it a doubly refracting medium in which the wave is broken into two components of different polarization traveling with different velocities. It is this characteristic which has led to the identification of the electron as the active ion. The magnetic field leads to complications in practical communication by causing rotations in the plane of polarization, leading to one type of fading (see later section on fading) and to errors in direction finding with loop aerials.

It is natural to suppose that the electrical characteristics of the ionized region are linear, so that different disturbances may be superposed without interaction. Evidence has been found, however, that this is not invariably true [B. D. H. Tellegen, *Nature*, p. 840 (June 10, 1933)]. If two broadcasting stations of high power operate on entirely different wavelengths and are separated by some hundred kilometers, modulation originally impressed on one has been found under certain conditions to have been transferred to the wave of the second. This indicates that the ionosphere does not have strictly linear characteristics. It is called the Luxemburg effect.

(London)*, Vol. 7 (September 1932); Kirby, Berkner, and Stuart, *Proc. I.R.E.*, Vol. 22, No. 4, 481 (April 1934); Schafer and Goodall, *Nature*, June 3 and Sept. 30, 1933; Dellinger, *Trans. A.I.E.E.*, *Supplement*, Vol. 58, 803 (1939); Darrow, *Bell Sys. Tech. J.*, Vol. 19, No. 3, 455 (July 1940).

SKY-WAVE PROPAGATION. It is the general belief that waves which travel long distances do so by means of multiple reflections, although the suggestion has been made that short waves (e.g., frequencies above 3000 kc) do so in a single step. Thus, in Fig. 7 a wave is conceived to travel from A to B by three reflections from the E region (3), or by two from the F region (2). The single-step path is represented by curve 1. If at each ionospheric reflection double refraction due to the earth's magnetic field were to occur, for the two-reflection wave not one but four (2^2) components might be found, and for the three-reflection mechanism, eight. Whether the complexity is thus explained or not, it is a fact that the received wave is frequently very complicated. As Fig. 7 suggests, there is wide diversity among components in their angles of elevation. In general, however, for all these paths, the received energy arrives with a downward component of velocity. This is of great importance in practice, since the mode of transmission places important directional requirements on the antennas at the two terminals. In the horizontal plane, radio waves as a general thing travel along the great circle defined by the locations of the terminals. Consequently, the waves on arrival are usually directed approximately along

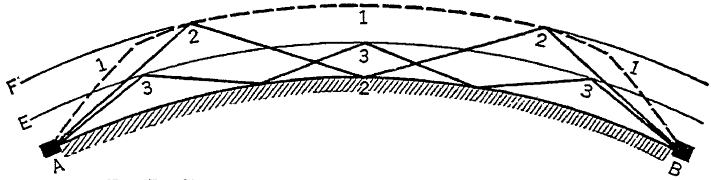

FIG. 7. Sky-wave Propagation according to the Ray Theory

the true bearing of the transmitter, regardless of frequency range. Small variations and differences exist in azimuth, with occasional large ones. See Friis, Feldman, and Sharpless, *Proc. I.R.E.*, Vol. 22, No. 1, 47 (January 1934); Friis and Feldman, *Proc. I.R.E.*, Vol. 25, No. 7, 841 (July 1937).

LOW FREQUENCIES (LONG WAVES). Among the chief characteristics here are: (1) at a given frequency, the diurnal variation of the field and the difference between day and night attenuation; (2) by day, the greater attenuation at the higher frequencies; (3) by night, the relatively low attenuation and the relative independence of attenuation on frequency; (4) seasonal variations; (5) propagation substantially along the great-circle path and the departure and arrival in a substantially horizontal direction; and (6) the practical absence of fading.

Typical diurnal variations of field strength from American transatlantic long-wave stations as received in England are shown in Fig. 8, which is reproduced from Espenschied, Anderson, and Bailey, *Proc. I.R.E.*, Vol. 14, No. 1, 7 (February 1926). The times when the path is entirely in daylight, entirely in darkness, and partially in each are shown by the shading in the strip at the bottom.

Both seasonal variations and diurnal variations are brought about by the changing position of the path relative to the hemisphere illuminated by the sun. In the summer, the duration of the daylight transmission phenomena is naturally longer than in the winter on account of the longer days. It is this change in the lengths of the day and night periods which is the most striking feature of the seasonal variation, rather than any change in the strength of signal. When the entire path is illuminated by the sun, or when the entire path is in darkness, the characteristic day or night phenomena are observed. When the path is half illuminated, half darkened, a characteristic minimum may be found in the diurnal curve. This is illustrated in Fig. 8, which shows a pronounced minimum occurring near sunset in the 57,000-cycle curve.

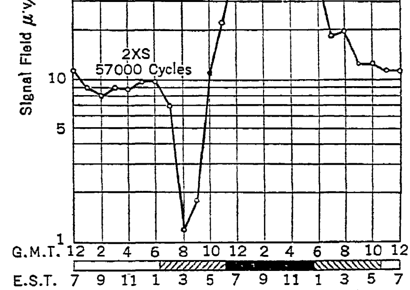

FIG. 8. Diurnal Characteristics of Low Frequencies in Transatlantic Propagation

It is evident that the field to be obtained at any time cannot be predicted by any simple formula, but if precision is not required it is possible to determine its order of magnitude for the night and for the day condition. Very roughly, the midnight field in long-distance transmission has an average of the order one-fifth the inverse-distance value. By day, the fields are more consistent and the average values are indicated by the Austin-Cohen formula,

$$\varepsilon = \varepsilon_0 \sqrt{\frac{\theta}{\sin\theta}}\, \varepsilon^{-46 \times 10^{-6} D f^{0.6}} \tag{9}$$

where ε_0 is given by (3) or (4), θ in radians is the angle subtended at the center of earth by the path, D is in kilometers, and f is in kilocycles and is less than 1000 kc. These constants were suggested by Austin in 1926 [*Proc. I.R.E.*, Vol. 14, No. 3, 377 (June 1926)] in order to make the formula more nearly universal for daytime transmission than the original formula, in which the exponent was $-87 \times 10^{-6}Df^{0.5}$ A convenient form is

$$\varepsilon = 3 \times 10^5 \frac{\sqrt{P}}{D} \cdot \sqrt{\frac{\theta}{\sin\theta}} \cdot \varepsilon^{-46 \times 10^{-6}Df^{0.6}} \tag{10}$$

in which P is radiated power in kilowatts and E is in microvolts per meter. The difficulty of expressing transmission data in this simple and usable form is brought out by the fact that in one part of the frequency range covered, namely from 17 to 60 kc, data received in transatlantic transmission are better represented when the exponential factor is modified to $\varepsilon^{-4 \times 10^{-6}Df^{1.25}}$ [Espenschied, Anderson, and Bailey, *Proc. I.R.E.*, Vol. 14, No. 1, 7 (February 1926)].

Effects accompanying magnetic storms, and secular variation, are discussed under "Solar Disturbances" in article 23.

INTERMEDIATE FREQUENCY. As indicated in Fig. 2, the daytime field of the sky wave in this range, broadly speaking, is attenuated beyond the possibility of usefulness. Apparently enough ultraviolet light from the sun penetrates to levels of the order of 100 km to maintain an absorbing stratum of ionization in spite of relatively rapid recombination. Near sunset, however, this cloud disappears, permitting a considerable reflection to distant points on the ground during the night. There is still absorption, and it is variable as Fig. 9 shows, but propagation to long distances is ordinarily possible. (See Standards of Good Engineering Practice, loc. cit., from which Fig. 9 is reproduced.) Note that this figure is reasonably consistent with the value one-fifth of inverse-distance field mentioned in the preceding section for low frequencies.

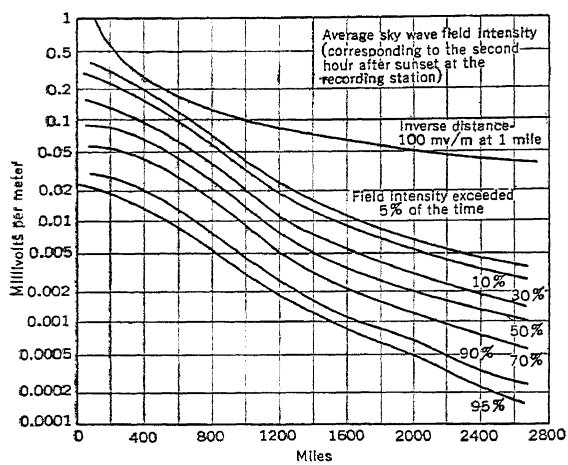

FIG. 9. Night-time Field Strengths from 250 to 2700 Miles (F.C.C. Data)

To a first approximation night-time transmission in this range is independent of frequency.

HIGH FREQUENCIES (SHORT WAVES). In contrast with the low-frequency range discussed above, there is a range of frequencies above approximately 3000 kc in which daylight sky wave transmission improves with increasing frequency, though this trend is subsequently reversed. This short-wave range is limited at the high-frequency end by the inadequacy of electrons per unit volume of the ionosphere. The limiting frequency in the daytime is not very different from 30,000 kc (10 meters). Both limits are variable, and the figures given are somewhat arbitrary. Among the chief characteristics of transmission in this range are: (1) the diurnal variation of field strength and the prominence of day-to-day fluctuations; (2) the greater distances of transmission obtained with the higher frequencies, especially by day; (3) the "skip" effect, or the existence of a region about the transmitter in which the direct wave is absent owing to attenuation of the ground wave, and the sky wave, if present at all, is weak and erratic owing to electron limitation; (4) habitual fading, sometimes of extreme rapidity, and the common occurrence of selective fading; (5) the necessity in most cases for more than one frequency for 24-hour service; (6) the great reduction of field strength in northern and southern latitudes concomitant with magnetic storms and, by contrast, the absence of a pronounced effect in equatorial regions, and other phenomena having a solar origin; (7) a secular variation following the 11-year sunspot cycle; (8) great-circle transmission and a wide variety of angles in the vertical plane.

Diurnal Variation. Typical diurnal variations are shown in Fig. 10, which depicts the changes occurring in a 24-hour interval over a path between Deal, N. J., and New Southgate, England, the radiated power being 1 kw. The curves bring out the advantages of the higher frequencies by day and of the lower by night. A typical curve on an intermediate frequency also is shown (10.55 mc). Day-to-day variations are more pronounced on such intermediate frequencies than for either higher or lower frequencies. On some days the intermediate frequency transmission may resemble the lower frequencies, on others the higher.

Variation with Distance. For a given distance, the transmission conditions depend on the geographical latitude of the stations and to some extent on the geomagnetic latitudes, the difference in longitude, the time of the day, the time of the year, and the time in the solar cycle. Figure 2 will serve as an approximate indication of the frequencies suitable for various distances for day and for night. The curves were based largely on data obtained during the years 1926 to 1930, a period which included a sunspot maximum. In general, the frequency required is higher the lower the latitude, the nearer the time to noon at the midpoint of the path, and the nearer to the secular sunspot maximum. In the winter the maximum usable (MUF) frequency for midday is greater than in summer, but the lowest usable high frequency (LUHF) is lower. In a diurnal curve, the characteristic day and night conditions are obtained for a longer period the more uniform the conditions along the path. Thus, a north-south path has a more abrupt change from day to night conditions than an east-west path, and the transition condition is of shorter duration. This transition period is relatively difficult because no single frequency can be best adapted to both the day and night portions of the path. Hence, long east-west paths tend to be more difficult than north-south paths. Usually, a day frequency gives a weaker field by day than a night frequency does by night. The variation of best frequency with secular magnetic change is exemplified by transatlantic paths such as that from New York to London. During the sunspot maximum of 1930, the best daytime frequency was about 18,000 kc, whereas, during the minimum which followed, the best was under 15,000 kc. (See later discussion under "Maximum and Minimum Usable High Frequencies.")

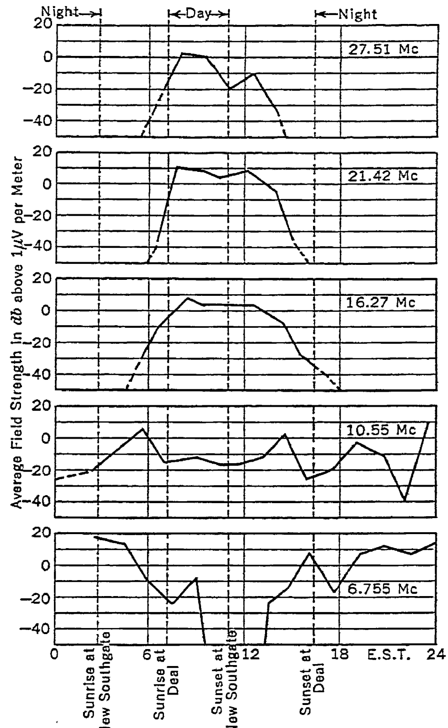

FIG. 10. Diurnal Characteristics of High Frequencies in Transatlantic Propagation

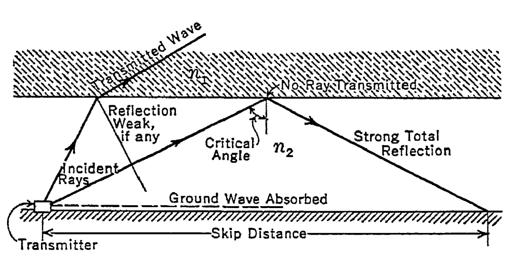

FIG. 11. The Skip Distance as a Phenomenon of Total Reflection

The Skip Effect. This effect is in many ways analogous to the phenomenon of total reflection in optics. A light wave (Fig. 11) passing from one medium of dielectric constant n_2 into another of smaller dielectric constant n_1 is subject to reflection at all angles if the change in dielectric constant is abrupt, and to *total* reflection for angles of incidence greater than $\Psi = \sin^{-1} n_1/n_2$. In radio, the type of reflection resembling total reflection is believed to be the more important, since the change in dielectric constant is gradual. For large angles of incidence (incident ray approaching the horizontal) the wave may be reflected to a great distance, but for angles less than the critical angle Ψ (closer approach to the vertical) the wave may pass through without substantial reflection. Although the radio problem is more complex than that of the optical illustration owing to the gradualness of the change in refractive index brought about by the gradual change in ionic density, in both cases the strong wave of total reflection is absent at the smaller angles of incidence. Since the index, n_2, of air at sea level is unity, waves incident at the ionosphere at an angle less than $\sin^{-1} n_1$ pass through. n_1 is to be taken as the index of the ionized region at the altitude of maximum ionic density (minimum refractive index), and, since it is a function of frequency, time, and other factors, the skip distance is a function of the same factors. Figure 2 shows approximate values of skip distances, obtained experimentally, for day and night conditions as a function of frequency. [Taylor and Hulburt, *Phys. Rev.*, Vol. 27, 189 (February 1926).]

Directions of Departure and Arrival. For a single wave component, this direction can be expressed by two angles. One is that in the horizontal plane and can be given either in terms of true north or as deviations from the great circle containing the transmitter. The other is the angle in the vertical plane and is usually given as the angle between the ray and the horizontal plane.

In the horizontal plane, the direction of arrival does not ordinarily deviate markedly from the great circle, deviations greater than a few degrees being unusual.

In the vertical plane, the angle with the horizontal may be anywhere in the range from 0° to 90°, depending on conditions in the ionosphere, distance between stations, and frequency. In general, as constructions such as that of Fig. 7 would indicate, the angle for short paths is high. For long distances, the angles tend to be small. Thus, in transatlantic communication, angles from 10° to 20° are common. Angles as low as 8° and as high as 38° have been measured. The average seems to be not far from 15°. On the other hand, signals received near New York from Buenos Aires commonly arrive at vertical angles less than 5°. In the case of the transatlantic paths, a great deal of attention has been given to these questions by Friis, Feldman, and Sharpless, *Proc. I.R.E.*, Vol. 22, No. 1, 47 (January 1934), and by Feldman, *Proc. I.R.E.*, Vol. 27, No. 10, 635 (October 1939). They found that the directions of individual wave components do not change rapidly or capriciously; that the components which arrive at the higher angles arrive later than those at the lower, qualitatively as might be expected from Fig. 7. In the vertical plane, angular spreads between lowest and highest component have been found at times to be smaller than 1° and at other times as large as 20°.

Polarization. In sky-wave transmission of high frequencies the composite polarization of the received wave is on the average independent of that transmitted. The direction of the electric field changes in a random manner with a rapidity which is connected with that of fading.

Echoes of Long Delay. Among the more unusual echoes of long delay, two types are of particular interest. Under certain conditions, "round-the-world echoes" can be observed. These are waves having a delay of about $^1/_7$ second, which travel all the way along a path which probably is not very different from the great circle separating the day and the night hemispheres. They are not usually observed but are prevalent at certain times of the year for a given pair of stations.

A second type of echo exhibits delays as great as 30 seconds. This extraordinary retardation may be due to extremely low group velocities in the ionosphere or to waves which travel long distances outside the ionosphere before they return. They are as rare as they are mysterious.

Maximum and Minimum Usable High Frequencies. Several years ago the National Bureau of Standards began a systematic study and publication of the month-to-month variations in the ionosphere at Washington, D. C., with predictions of transmission conditions to be expected. During the war this work was developed comprehensively. From the point of view of operation, it is important to know for a given time and path the *maximum usable frequency* (MUF) permitted by the skip phenomenon and the *lowest usable high frequency* (LUHF) permitted by ionospheric absorption. Predictions on a worldwide basis are available. (See publications of the Central Radio Propagation Laboratory, National Bureau of Standards, Washington 25, D. C.)

23. OBSTACLES TO TRANSMISSION

ATMOSPHERIC INTERFERENCE. "Atmospherics" or "static" are electric waves of natural origin which often mar radio reception or make it impossible. The sounds produced vary from the crackling of extremely short impulses called "clicks," such as may be produced by local lightning flashes, to the steady background roar called "grinders." Hisslike atmospherics have also been observed. The principal characteristics of atmospherics may be listed as follows:

1. They are more intense in summer than in winter, regardless of radio frequency. In the northern hemisphere they reach their maximum in July or August. This leads to more difficult transmission at that time.

2. They have a diurnal variation in intensity. For frequencies below about 10,000 kc the night-time intensity is greater than the daytime. The difference is greatest at about 1000 kc in the vicinity of New York City, being perhaps 50 db, and is very small at 15 kc. For the octave above 10,000 kc atmospherics are strongest in the daytime (see Fig. 12).

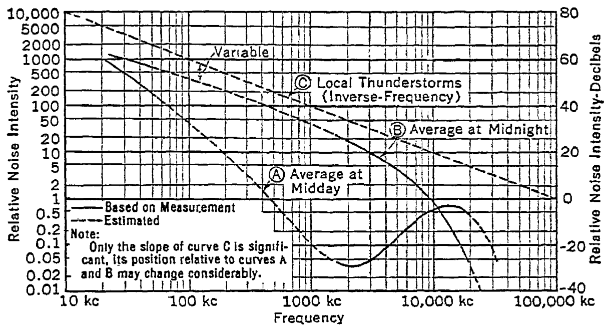

FIG. 12. Atmospheric Noise as a Function of Frequency in the Vicinity of New York City

The diurnal variation has a definite relation to the diurnal variation in the transmission characteristics of the frequency used. [C. N. Anderson, *Proc. I.R.E.*, Vol. 21, No. 10, 1462 (October 1933).]

3. The law of variation of amplitude of atmospherics with frequency cannot be simply stated and is in fact not definitely known. Some evidence favors an inverse first, and some an inverse second power. Figure 12 gives one estimate of the frequency distribution [R. K. Potter, *Proc. I.R.E.*, Vol. 20, No. 9, 1514 (September 1932)]. The figure is for reception in the northeastern part of the United States; elsewhere the intensity and its distribution with frequency would probably be somewhat different. By day the amplitude apparently follows approximately the inverse square of the frequency up to 1000 kc. At higher frequencies an increase having a maximum at about 15,000 kc sets in, but at this frequency noise originating in the receiver is likely to be more important. The night curve seems to follow the inverse first power up to about 10,000 kc. The advantage of low frequencies due to better transmission is evidently reduced by the greater amount of atmospheric disturbance encountered. Likewise, for the low frequencies, the advantage due to the fact that the fields at night are stronger than day fields is similarly reduced by the fact that atmospherics are then stronger.

4. Atmospherics are predominantly of tropical origin. Exceptions are those on intermediate frequencies (500 to 3000 kc) during the day, and atmospherics on all ultra-ionospheric waves. These are of comparatively local origin. On the low frequencies, less atmospheric interference is found the farther the receiver is removed from the tropics. For example, they are less in Maine than near New York. [Austin, *Proc. I.R.E.*, June 1926, p. 373; Espenschied, Anderson and Bailey, *Proc. I.R.E.*, Vol. 14, No. 1, 7 (February 1926).]

5. They are said to be stronger on land than over the ocean. [Austin, *Proc. I.R.E.*, Vol. 14, No. 1, 133 (February 1926).]

6. Atmospherics arrive at a receiver from all directions, but usually certain general directions predominate and over a small period of time the directivity may be comparatively sharp. This is important in reception, since directional discrimination in the receiving antenna can be used to reduce the interference without reducing the desired signal; this is not possible if the desired signal arrives from the same direction as the atmospherics. When there is a variable null direction in the antenna polar diagram, the improvement obtainable is very considerable unless the disturbances arrive through a wide range of angles. [Espenschied, Anderson, and Bailey, *Proc. I.R.E.*, Vol. 14, No. 1, 7 (February 1926).]

This directional characteristic is due to the existence of broad centers of origin which seem to coincide with thunderstorm centers, most of which are over land. Among those of greatest importance to reception in the United States are Ecuador, Brazil, and Central Africa in the winter, and Mexico and Central America and the waters between there and

Florida, Florida, and New Mexico in the summer. The sources actually causing interference will depend on the distance range of the frequency used. Thus, frequencies of the order of 1000 kc will have only local static by day, and ultra-ionospheric waves will never be troubled by distant sources. At night, all services using the sky wave may be exposed to distant sources. The very low frequencies are exposed to distant sources at all times. (See papers by Dean and by Harper, *Proc. I.R.E.*, July 1929, pp. 1185 and 1214.)

7. Atmospherics travel along the earth in the same manner as signals and are therefore subject to the same laws of attenuation. Their diurnal variation is explained principally by this fact.

8. Atmospherics apparently originate in discharges with sufficiently abrupt wave fronts to shock-excite circuits tuned to any radio frequency lower than 150 mc (or some higher limit; see next paragraph). Components also fall in the audible range with frequencies well below 1 kc. One class called "tweeks" has a limiting frequency between 1600 and 1700 cycles, suggesting multiple reflections of a pulse between the earth and a conducting layer 90 km above it. [Appleton, Watson-Watt, and Herd, *Proc. Roy. Soc.*, A, Vol. 111, 165 (1926); Burton and Boardman, *Proc. I.R.E.*, Vol. 21, No. 10, 1476 (October 1933).]

9. At 150 mc Schafer and Goodall ["Peak Field Strength of Atmospherics Due to Local Thunderstorms at 150 Megacycles," *Proc. I.R.E.*, Vol. 27, No. 3, 202–207 (March 1939)] found (*a*) that the peak intensity of disturbances varies 20 db between different storms at the same distance; (*b*) for nearby storms the inverse distance relation is a good approximation for the calculation of the variation of peak disturbance with distance; (*c*) the use of high instead of low receiving antennas increases the signal-to-disturbance ratio almost directly with height for storms within 10 miles; (*d*) the durations of some of the narrower peaks in any particular lightning discharge are as short as a few microseconds or shorter; (*e*) the maximum equivalent peak field for a storm 1 mile away was about 0.015 volt per meter with a band width of 1.5 megacycles. Although it is a common belief that atmospherics do not exist at microwaves, actual measurements do not seem to have been reported.

10. Frequencies in the band near 20,000 kc exhibit distinctly an aural difference between atmospherics from local and from distant sources. Atmospherics from local sources give the "crash" type; those from distant sources ordinarily give a fairly steady weak background. The difference is not the result of any dissimilarity in mechanism but is due to the skip effect which excludes disturbances from intermediate distances. The direction of arrival of the steady background corresponds with that observed on long waves (SW to SE near New York), and the disturbance is heard only when long-wave static is very strong. As the frequency is increased into the ultra-ionospheric range, the steady background disappears, so to speak, in the distance, leaving only the crashes due to occasional local storms. A weak hisslike disturbance apparently from a fixed direction in space and from distances beyond the confines of our solar system has been observed on 20,000 kc. [K. Jansky, *Proc. I.R.E.*, Vol. 20, No. 12, 1920 (December 1932), and Vol. 21, No. 10, 1387 (October 1933).] Jansky pointed out that this noise arrived from the direction of the galactic center (Sagittarius), and Reber [*Astrophysical Journal*, Vol. 100, 279–287 (1944)], at a considerably higher frequency which permitted high directivity, explored the region of the Milky Way and found noise contours corresponding to it. Black-body radiation from the sun has been studied by G. C. Southworth [*J. Franklin Inst.*, Vol. 239, No. 4, 285 (April 1945)] at a wavelength of 3 cm; it may be looked upon as resistance noise, the resistance being radiation resistance which has a high "temperature" when the antenna points at the sun. An enormous increase in this noise has been reported to occur at times of abnormal solar activity. [Pawsey, Payne-Scott, and McCready, *Nature*, Vol. 157, No. 3980, 158 (Feb. 9, 1946), and Hey and Stratton, *Nature*, Vol. 157, No. 3976, 47 (Jan. 12, 1946).]

11. The noise level differs in different parts of the sunspot cycle. At high frequencies there is a direct and at low an inverse relation to sunspot numbers.

12. Methods of combating atmospherics must be based on the use of some characteristic in which the wave of the signal differs from that of the disturbance. The most important of these are frequency, direction, and amplitude. In the first, selective circuits are used which suppress current of frequencies not present, or necessary, in the signal. Even with absolutely ideal selective circuits, an irreducible minimum of energy will pass through them, and this minimum increases linearly with the frequency range necessary for signaling. (Carson, *B.S.T.J.*, April 1925.) Directional discrimination has already been discussed in paragraph 6 above. As regards amplitude, the most obvious procedure is to increase the effective radiation toward the receiving terminal by increasing either the power capacity of the transmitting set or the effectiveness of the transmitting antenna. Another is the use of the "compandor" in telephony, by which the low amplitudes are raised above their natural value while passing from the transmitter (through the part of the circuit exposed to atmospherics) to the receiver, the normal values being usually restored subsequently.

An old method of discrimination against atmospherics of high amplitude uses opposed detectors, equally sensitive at high amplitudes but sufficiently different at low amplitudes so as not to cancel the signal. [Englund, *Proc. I.R.E.*, Vol. 16, No. 1, 27 (January 1928).]

With amplitude modulation (in which intelligence is carried by variations of the amplitude from its average value) improved signal-to-noise ratio can thus be obtained by limiting the range of frequencies received and by increasing the amplitude variation at the transmitter and simultaneously reducing the sensitivity of the receiver to changes in amplitude. Analogously with frequency modulation (in which intelligence is carried by variations of the frequency from its average value), the interfering effect of weak noises may be reduced by limiting the range of amplitudes received, and by increasing the frequency variation at the transmitter while simultaneously reducing the sensitivity of the receiver to change of frequency.

Some forms, such as ignition noise, occur only in bursts which are very short compared with the period of the signal being transmitted (e.g., in telephony, short compared with the period of the highest audio frequency). It is advantageous in this instance even with amplitude modulation to *widen* rather than *narrow* the frequency band of the receiver and to use limiters; this widening, it is true, permits more noise power to pass into the final detector, but it preserves the shortness of the impulse and permits the limiter to chop off the peak, leaving a pulse no greater than that of the signal and so short in duration as not to be harmful.

FADING. In its most general sense "fading" means a reduction of the signal for any cause, including, for example, the slow decrease in long-wave signal strength called the "sunset minimum," which may last an hour or so. Commonly the term refers to the more rapid variations encountered with medium and short waves. Probably the most important cause of fading is the interference of wave components following different paths in space, combined with variations of phase of one or more components with time. The existence of the different components can be due to multiple reflections or to double refraction due to the earth's magnetic field, and perhaps other causes. The changing with time of the relative phases can be due to change in the ionic density along the path or to changes in the magnetic field. Pulse experiments, which are able to resolve a complex signal into many components, show that, with the best resolution possible, the components themselves fade. Fading is therefore a very complex phenomenon.

An important example of fading occurs just outside the service area of a high-power broadcasting station. With increasing distance the sky wave finally becomes appreciable compared with the rapidly attenuating ground wave. Atmospheric vagaries make the relative phase of the components vary at random, causing the signal level to fluctuate. It may be further complicated by the reception of more than one sky-wave component. (See article 24.)

Rapidity of fading of ionospheric waves increases, in general, with frequency. Below 100 kc the phenomenon is scarcely noticed; such changes as do occur commonly require an hour or so. At 1000 kc the period is of the order of 1 minute, and the amplitude range extreme. At 10,000 kc the fading rate is 1 every few seconds. Fading due to interference between two or more components should show this characteristic, for a fade would then occur once for every change of 1 wavelength in the path difference. This relation, of course, can be only qualitative, since long waves and short waves usually travel over very different paths, are frequently not used at the same time of day, and do not employ the same number of paths.

A distorted frequency characteristic is one of the results of transmission over two or more interfering paths. Thus, if the times required for the waves to travel over the two paths differ by τ, and if the radio frequency is slowly varied, consecutive maxima and minima will be found, the frequencies of the maxima differing from one another by integral multiples of $1/\tau$. If $\tau = 0.0005$ second, a typical value, the maxima will be separated by multiples of 2000 cycles per second, and even the a-f characteristic may be seriously affected. There will now be fading provided that a change occurs in the medium. Being a function of radio frequency, such fading is called "selective." If τ were made very small, the frequencies of the maxima would differ so much that within the small band occupied by a telephone channel the response would be independent of frequency. This would be nonselective, or "general," fading. The selectiveness of fading is thus associated with the time difference over the two paths, whereas the rate of fading is related to the rate of change with time of path difference measured in wavelengths. It is common to have more than two components in a received wave. In some cases the wave is extremely complex. [Potter, *Proc. I.R.E.*, Vol. 18, No. 4, 581 (April 1930).]

As shown by Bown, Martin, and Potter [*Proc. I.R.E.*, Vol. 14, No. 1, 57 (February 1926)], this mechanism can produce serious distortion in a speech channel if the instantaneous frequency of the transmitter varies during the audio cycle.

The change in field strength with frequency at a single receiving location has its counterpart in a change with location for a constant frequency. The different paths differ not only in length but also in direction. Most important perhaps is the direction in the vertical plane, as shown in Fig. 7, but the directions in the horizontal plane are also significant. It is these directional differences which cause the difference in signal levels at nearby points, for the two waves give rise to a set of interference fringes. Fading does not therefore occur simultaneously at nearby points, and it is found in the high-frequency range that points separated by 10 wavelengths usually fade in an unrelated manner, whereas in some cases the separation need be no greater than 2 or 3 wavelengths. Advantage of these facts is taken in "diversity systems" of reception, which employ receivers operating on the same frequency from separate receiving antennas at different locations or different polarizations, or on different frequencies from the same antenna. [Beverage and Peterson, p. 531, and Peterson, Beverage, and Moore, *Proc. I.R.E.*, Vol. 19, No. 4, 562 (April 1931).]

The effect of fading is to degrade the performance of a circuit used in communication. This can be due merely to reduction of field during the fades, which leads to an inadequate ratio of the signal strength to the noise. It can be the result of the distorted a-f characteristic which was mentioned above; to the production of distortion products, as for example when the carrier in a double sideband system fades out, leaving the two sidebands to beat with each other; to the existence of fading so rapid that it cannot be compensated by such devices as the automatic volume control, and to other complications. Probably the most usual example of circuit impairment occurs when fading and noise contribute simultaneously. All such effects are the more serious the higher the standard set for the circuit.

SOLAR DISTURBANCES. Radio transmission is one of the terrestrial phenomena which may be correlated with solar activity; another is the variations which occur in the earth's magnetic field, extreme fluctuations having been given the name "magnetic storms." Except for daylight transmission with low frequencies (e.g., 60 kc) the effect of unusual solar activity is an adverse one. By day, low frequencies are then somewhat aided, but at night their fields are considerably reduced. The most marked effect, however, is produced on the high frequencies; in fact, very severe storms may completely eliminate their usefulness over some paths. These effects are illustrated in Fig. 13, which shows daytime field strength on two transatlantic channels, one (full line) on 18,000 kc and the other (heavy dashes) on 60 kc, together with the horizontal component of the earth's magnetic field (light dashes). [Anderson, *Proc. I.R.E.*, Vol. 17, No. 9, 1528 (September 1929).] A striking demonstration that rapidly moving ionic clouds are hurled into the ionosphere during magnetic storms has been given by Wells, Watts, and George of the Carnegie Institution of Washington by a technique of rapidly recording the reflections received over an extended frequency range.

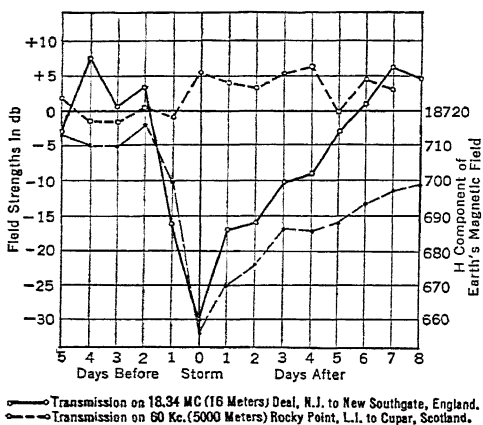

FIG. 13. Typical Effects Accompanying Magnetic Storms

The solar phenomena include sunspots, prominences, and flocculi which may be observed with a telescope or spectrohelioscope. The disturbing areas rotate with the sun once in every 27 days, this being the reason for the ill-defined "period" of 27 days in the terrestrial effects. In order to have a terrestrial effect it seems to be necessary that the disturbed solar area have a certain orientation with respect to the earth. The 27-day period in magnetic and radio effects forms the basis for a method of predicting future disturbances; these predictions, though not entirely reliable, are useful. Another periodicity in solar activity is the secular one, having a cycle of about 11 years. Since the last minimum and maximum occurred respectively in 1944 and 1947, it appears that the next will take place about 1954 and 1958.

Depending on the severity of the "storm," the effect may last one or several days, during which communication on short waves is erratic and difficult and sometimes impossible. At the same time, the aurora may be visible, earth potentials usually rise to relatively high values, and the earth's magnetic field may be seriously disturbed. Short-wave transmission along paths through equatorial regions are scarcely affected, however; it is in the auroral zone that the effects are produced, and, apparently, high-frequency transmission over any path, long or short, which requires reflection from the ionosphere in this zone, is adversely affected. At such times, experiments to determine virtual heights in these zones are impossible owing to the total absence of reflections. [Appleton, Naismith, and Builder, *Nature*, Vol. 132, No. 3331, 340 (Sept. 2, 1933).] The secular period in this effect has already been mentioned. Figure 14 illustrates this variation, which follows the 11-year sunspot cycle. [Austin, *Proc. I.R.E.*, Vol. 20, No. 2, 280 (February 1932).]

Another phenomenon associated with the sun is the radio fade-out, during which all sky waves except those of low frequency are suddenly weakened or obliterated over the earth's sun-lit hemisphere. It has been established that the fade-out is coincident with a bright solar chromospheric eruption, and the absence of the effect at night and its great intensity at the equator indicate ultraviolet light rather than particles as the means by which it is produced. A fade-out may last from a few minutes to a few hours. It is evidently caused by an unusually high electronic density produced below the *E*-region which operates by absorption due to the high collision frequency with neutral molecules at that level. [J. H. Dellinger, *Science*, Vol. 82, No. 2128, 351 (Oct. 11, 1935); L. V. Berkner, *Phys. Rev.*, Vol. 55, No. 6, 536 (March 15, 1939).]

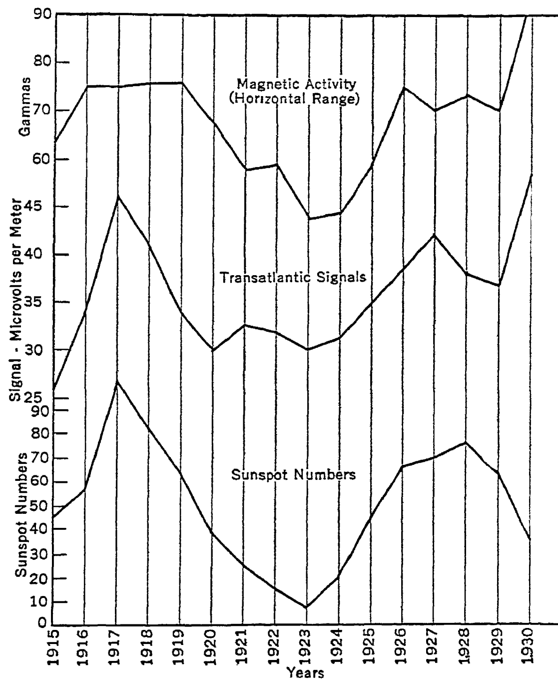

FIG. 14. The "11-year" Period in Sunspot Activity and Its Correlation with Magnetic Activity and Low-frequency Radio Transmission

An abnormality known as sporadic *E* layer reflections is of some importance as the cause of occasional long-distance transmission at frequencies above the usual ionospheric limit, sometimes as high as 60 mc. It occurs in patches rather than uniformly over the *E* layer and is not well understood. [L. V. Berkner and H. W. Wells, "Abnormal Ionization of the *E*-Region," *Ter. Mag. and Atmos. Elec.*, Vol. 42, No. 1, 73 (March 1937).]

24. RANGE OF RADIO STATIONS AND BROADCAST COVERAGE

The distance over which communication can be carried on, or the "range" of a radio transmitting station, depends on so many changeable phenomena and special details that the term is usually significant only as an order of magnitude or as a statistical mean. The range depends on transmission efficiency and noise (e.g., atmospherics), on the types of apparatus used at the receiving station, and on the standards of performance. More meaning attaches to the range of a ground wave, however, because of its steadiness relative to the ionospheric wave. The service range of a broadcast station may be set by noise due to atmospherics, to industrial or domestic electrical equipment, or to unavoidable random noise arising in the receiver itself. But even when noise is negligible it may be limited by fading due to the sky wave's being appreciable compared with the ground wave.

Considering noise as the limiting factor, we may start with representative noise data such as those given in Fig. 15. This figure gives approximate noise values (atmospherics, set noise, etc.) which we assume as typical for medium-frequency broadcast reception in northeastern United States in the summer. For reception the signal field must be greater than the noise by certain values which depend on the grade of service desired. This leads to a required signal field, and the distance at which it is obtained under certain conditions can be obtained by reference to Fig. 3. For example, to find the summer night range of the ground wave of a 100-kw transmitter operating on 1500 kc, we have:

Summer midnight noise on 1500 kc, Fig. 15	0.035 mv/meter
Signal-to-noise ratio assumed	100
Field required with 100 kw radiated	3.5 mv/meter
Field with 1 kw radiated $(3.5/\sqrt{100})$	0.35 mv/meter
Distance giving 0.35 mv/meter (51 db above 1 mv/meter) with 1 kw, $\sigma = 2 \times 10^{-13}$, Fig. 3	53 miles

Figures such as these, which are based on transmission data applying in the case of level terrain, cannot in general apply if there are large obstacles or other irregularities in the path. A striking example of this was described by Bown and Gillette, who found that sections of New York City in which there are large numbers of unusually tall buildings cast "shadows" for several miles [*Proc. I.R.E.*, Vol. 12, No. 4, 395 (August 1924)]. Dense areas of small buildings also reduce the range. There are other factors than noise, such as fading and interference from other stations, that complicate this problem and require considerable experience to assess. Field strength surveys of the actual territory to be covered are frequently required. [Standards of Good Engineering Practice, F.C.C., loc. cit.; R. F. Guy, loc. cit.; "An Analysis of Continuous Records of Field Intensity at Broadcast Frequencies," Norton, Kirby, and Lester, *Proc. I.R.E.*, Vol. 23, No. 10, 1183 (October 1935); "On the Use of Field Intensity Measurements for the Determination of Broadcast Station Coverage," Jansky and Bailey, *Proc. I.R.E.*, Vol. 20, No. 1, 62 (January 1932).]

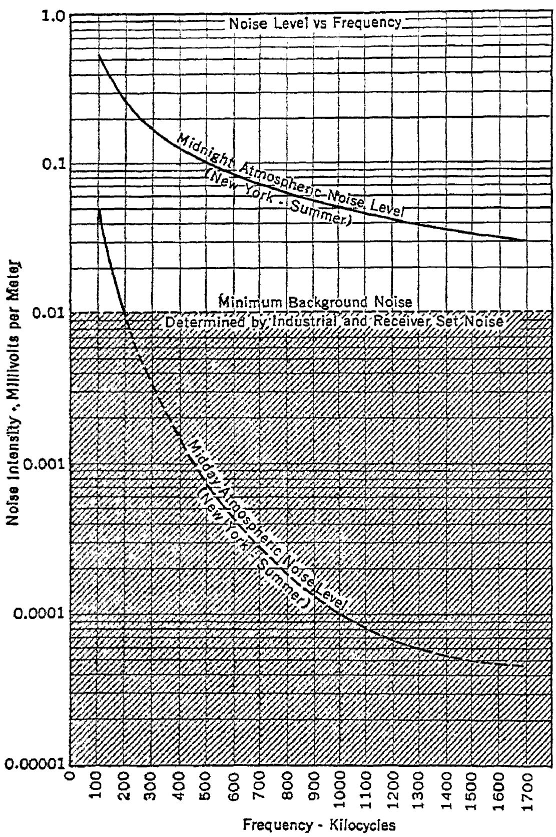

Fig. 15. Typical Noise Data, Broadcast Reception

Another limitation in the service area of a broadcast station in the evening is the existence of fading beyond a certain distance. This limiting distance depends on frequency and earth conductivity, and in general it is greater the lower the frequency and the higher the conductivity. Fading first becomes serious when the sky wave becomes appreciable compared with the ground wave. Figure 16 illustrates, as a function of frequency, how the distance range of broadcast stations depends on electrical noise and fading, an earth conductivity of 10^{-13} being assumed. [Report of Committee on Radio Propagation Data, *Proc. I.R.E.*, Vol. 21, No. 10, 1430 (October 1933).]

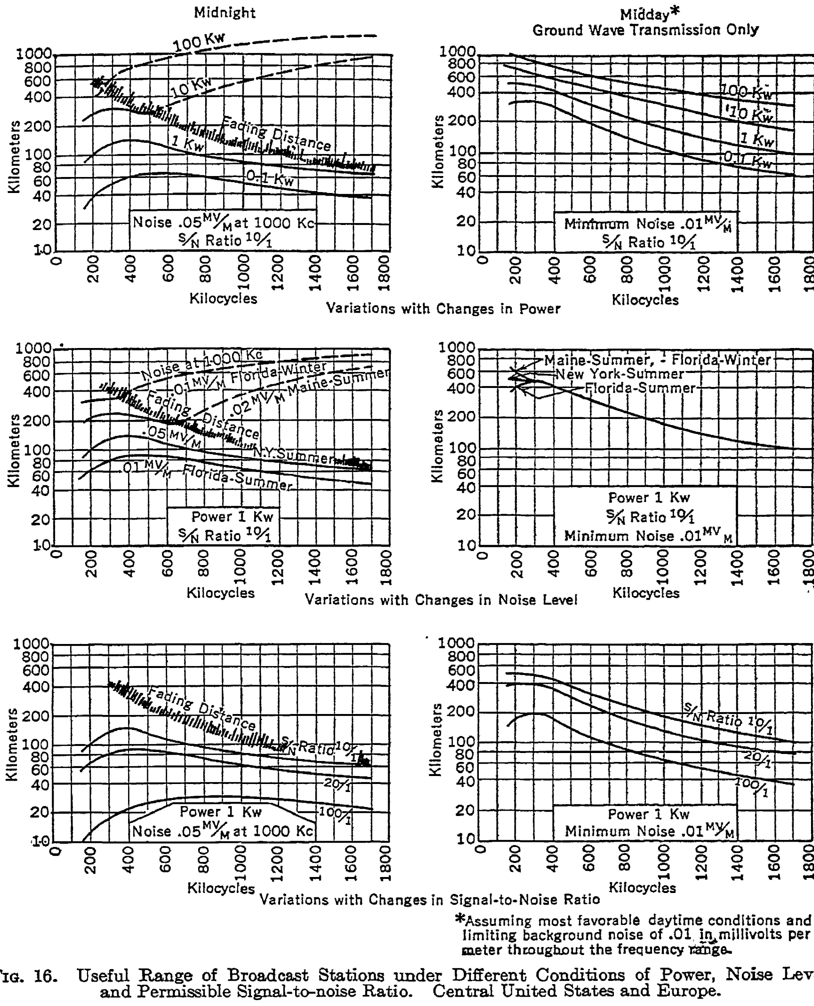

FIG. 16. Useful Range of Broadcast Stations under Different Conditions of Power, Noise Level, and Permissible Signal-to-noise Ratio. Central United States and Europe.

MECHANICAL FEATURES OF TRANSMISSION LINES

By John D. Taylor

25. TRANSMISSION-LINE CONSTRUCTION

POLE LINES are employed in aerial communication construction to support open wires and cables used in toll and exchange plant. The supporting structures are generally of wood but, for special requirements or where pole timber is not obtainable, may be of steel or other materials.

The use of wood poles generally throughout the United States and other countries is due principally to (1) availability, (2) economical type of construction, (3) ease of handling and maintaining, and (4) relatively long life.

The design of wood-pole lines is based primarily on (1) type of communication plant (toll or exchange) to be supported, (2) load to be carried, and (3) location and exposure to weather. The poles must be of sufficient strength (allowing for ground decay and economical life) and height (allowing for ultimate loads and required clearances) to meet the requirements for this type of construction in the most economical manner.

In exchange plant, initial pole-line routes largely determine the routes of distribution for succeeding types of construction, while for toll plant the large initial costs involved in building a toll pole line usually require its maintenance on the selected route, at least for its economical life or until other considerations such as right-of-way, growth, new developments or deterioration necessitate its removal or replacement. In planning new pole lines or rearrangements, it is important to so advise other pole-using companies in the area involved, in order that the plans of all the companies may be in coordination at all times.

The selection of the pole route usually entails advance surveys, acquiring the necessary right-of-way, and other considerations, which will provide the required pole line economically. Due regard must be given to the future adaptability and relation of the pole line with respect to the telephone system, serving the area, as a whole. Toll pole lines usually take the most direct, practicable route between terminating points, avoiding small towns, trees, and hazardous conditions as far as possible. Toll points, off the main toll route, are reached by branch (spur) lines. Along highways, one side should be occupied throughout, as consistently as conditions permit, avoiding unnecessary road crossings and leaving the other side of the highway for other wire-using companies.

Public right-of-way is less expensive initially, but private right-of-way for a particular section of pole line may result in lower annual charges and ultimate costs and most certainly will add to the permanence and safety of the line.

Joint use is generally desirable and economical in urban areas, rather than using separate pole lines for power and telephone facility distribution. The power circuit voltages in cities are usually low (not over 5000 volts), and the telephone equipment and subscribers are adequately protected in case of contact between the power and telephone circuits.

Joint use with rural or toll open-wire circuits is not, as a rule, desirable, because of the generally higher-power circuit voltages and of possible hazards to life and property from contacts. Consideration may be given, however, to such joint use in any particular case, and future developments may indicate its desirability for rural construction.

The selection of poles required for any particular pole line is based mainly on (1) the number of telephone or other aerial wires and cables to provide facilities over the expected service life of the poles, (2) the importance of these facilities, (3) the pole strength required to carry the initial and ultimate wire and cable loads under the weather conditions expected in the locality involved, and (4) governmental regulations.

Some companies have established classifications for open-wire and cable pole lines, in accordance with the service value of the line (relative importance and number of messages carried by the circuits on the line). Figure 1 shows the classifications used by the Bell System and the relative strengths assigned based on the System's experience. Lower percentages of ultimate stress are required for railroad, power, or similar crossings.

Classification of Line	Type of Service	Message-miles per day	Relative Strength Levels	Maximum Percentage of Ultimate Fiber Stress under Transverse Loading	
				For New Poles	At Replacement
A	Toll open-wire and cable of high service value..........	Over 30,000	100	45	67
B	Toll open-wire (average service value) and toll cable (not class A)	5,000 to 30,000	67	67	100
C	Exchange open-wire (over 10 wires), all exchange cable...	....	50	89	133
	Toll open-wire of low service value	Less than 5,000	50	89	133
R	Exchange open-wire (not over 10 wires)................	....	33	133	200
J	Joint power and telephone lines....................	....	88	50	75

FIG. 1. Classification and Strength Requirements of Pole Lines, Bell System Practices

In connection with the preparation of the National Electrical Safety Code (N.E.S. Code), National Bureau of Standards Handbook H32, studies were made to determine the frequency, severity, and effects of ice and wind storms throughout the country. On the basis of these studies, three general loading areas, *heavy, medium, and light,* were established for the United States, as shown in Fig. 2. For the same classification of line and other structural conditions, a heavier class of pole is required (particularly for average or greater loads) in the heavy than in the medium or light loading areas, and likewise in the medium as compared to the light loading area.

Basic conductor loadings have been assigned for the three loading areas, in order to derive pole loadings, considered appropriate for these areas, and with the various pole-line classifications and other data, to arrive at the class of pole required for any given line. Figure 3 shows these assumed loadings and associated constants, which latter, when added to the resultant of the vertical and horizontal loads, will result in effective conductor loadings, substantially the same for the Fifth Edition as for the Fourth Edition of the N.E.S. Code. Thus, it has been possible to avoid lowering past overall effective standards for pole-line strength requirements, and at the same time to reduce, in the Fifth Edition, the transverse loadings on the pole line to permit the use of allowable stress values more nearly representative of general engineering practices.

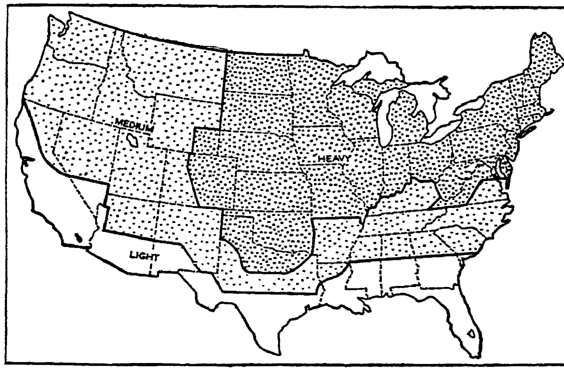

FIG. 2. Storm Loading Map of the United States (from N.E.S. Code, Fifth Edition, *Natl. Bu. Stds. Handbook H32*)

Assumed Vertical and Transverse Loadings

Storm Loading Area	Symbol	Radial Thickness * of Ice Coating on Conductors and Messengers, in.	Horizontal Wind Pressure at Right Angles to the Line, lb/sq ft of projected area
Heavy.........	H	0.50	4
Medium.......	M	0.25	4
Light..........	L	None	9

* *Note:* In computing transverse loading on poles and towers, ice coating on these structures is ignored.

Constants for Various Types of Conductors to Be Added to the Resultants of the Loadings Shown in above Table, pounds per foot

Storm Loading Area	Symbol	Temperature, deg F	Bare Copper, Steel, Copper Alloy, Copper-covered Steel, and Combinations Thereof	Bare Aluminum with or without Steel Reinforcement	Weather Proof and Similar Covered Conductors (All Materials)	Cable with Messenger
Heavy..........	H	0	0.29	0.31	0.31	0.6
Medium........	M	+15	.19	.22	.22	.4
Light..........	L	+30	.05	.05	.05	.2

Note: For telephone wires it is usually assumed that

$$P = 0.003V^2$$

where P = horizontal wind pressure in pounds per square foot of projected area.
V = actual wind velocity in miles per hour.

FIG. 3. Assumed Vertical and Transverse Loadings and Associated Constants (from N.E.S. Code, Fifth Edition, *National Bureau of Standards Handbook H32*)

Since pole lines carry various types of communication facilities and frequently (on joint lines) power conductors and equipment as well, it is necessary, in determining pole-line loads, to equate the various attachments to a common basis. Figure 4 gives wire equivalent data for the three loading areas in terms of effective 104 (mil diameter) telephone wires and of effective No. 4 covered power wires. In heavy and medium loading areas only,

Attachment	Telephone Wire Base (Effective 104 Tel. Wires)			Power Wire Base (Effective No. 4 Covered Power Wires)		
	Storm Loading Area			Storm Loading Area		
	Heavy	Medium	Light	Heavy	Medium	Light
Communication plant						
Bare open wire, 109, 104, or smaller, per wire	1	1	1	0.8	0.7	0.3
Bare open wire, 128, 134, or larger, per wire	1	1	1.3	0.8	0.7	0.4
Covered paired wire, per pair, or covered single wire, per wire	1	1	2.5	0.8	0.7	0.7
Strand, all sizes	2	2	5	2	2	2
Cable and 6000 lb (5/16 in.) strand	4	5	15	3	3	4
Cable and 10,000 lb (3/8 in.) strand	5	6	22	4	4	6
Cable and 16,000 lb (7/16 in.) strand	6	7	30	5	5	8

Fig. 4. Table of Wire Equivalents for Pole-line Loading Calculations (from N.E.S. Code, Fifth Edition, *National Bureau of Standards Handbook H32*)

when the actual number of wires on crossarms is more than 10, shielding reduces the effective number of wires to 67 per cent of the actual number. In light loading areas, loading is assumed on actual wires.

The selection of new poles for a given pole line requires that the following factors be known or assumed:

(a) Classification of pole line (determines the relative importance of the line).

(b) Loading area (determines the basic loadings).

(c) Fiber strength of timber to be used (see Table 1).

(d) Equivalent (effective) telephone wire or power wire load (see Fig. 4).

(e) Average pole spacing (depends on type and size of wire, usage, loading area, and class of line for open wire).

(f) Length of poles (determined by load and clearance requirements).

Table 1

Type of Timber	Fiber Strength, lb/sq in.
Northern white cedar	3600
Western red cedar	5600
Creosoted southern pine and Douglas fir	7400
Chestnut	6000
Lodge pole pine	6600
Juniper	4600
Cypress	5000

If tables are not available for determining directly the class of poles required under the above known or assumed conditions, the following formulas may be used for the purpose.

For *transverse loading* (pole acting as a cantilever beam)

$$C = \sqrt[3]{\frac{M_w + M_p}{0.000264fU}}$$

where C = minimum required ground line circumference of new pole in inches.

M_w = resistant moment on pole at ground line, due to wind pressure on wires, in ft-lb.
$= PDLNS.$

P = wind pressure, in lb/sq ft.

D = diameter of each wire, in ft, including ice coating, if any.

L = distance, in ft, between center of the load and the ground line section.

N = effective number of wires on the pole.

S = $^1/_2$ sum of the two adjacent spans, in ft.

M_p = resistant moment on pole at ground line, due to wind pressure on pole, in ft-lb.

$$= P\frac{h^2}{226.2}(2C_t + C_g)$$

where h = height of pole above ground, in ft.

C_t = circumference of pole at top, in in.

C_g = circumference of pole at ground line, in in.

U = maximum percentage of ultimate fiber stress expressed as a decimal (determined from the line classification, Fig. 1, or as required).

f = maximum allowable fiber stress of the pole timber, in lb/sq in.

For *vertical loading* (usually considered only for anchor guyed poles or stubs, where the vertical component of the stress in the guy may be large), the pole is considered to be a long column, and by Euler's formula for such a column

$$P_v = \mu E \frac{I}{l^2}$$

where P_v = vertical load on the pole, in lb.

$\mu = \pi^2$ for average conditions of a guyed pole or stub.

E = modulus of elasticity of the pole timber.

I = moment of inertia of the critical section (see note).

l = length of the column, in in., from the point of anchor guy attachment to the butt of the pole (for poles set in solid bases, such as rock or concrete, the length is taken from the point of anchor guy attachment to the ground line and $\mu = 2\pi^2$).

Note: The critical section in flexure for the average pole (of conical shape) is assumed to be at a distance of $^1/_3\, l$ below the point of anchor guy attachment. The circumference of this section should be computed from (1) its distance above a point, which is 6 ft from the butt of the pole, (2) the specification circumference 6 ft from the butt, and (3) the average circumferential taper for the timber under consideration.

In general, the size of line pole, selected for the ultimate load, is determined by the transverse stress, to which the pole may be subjected. There may be cases, however, where the vertical load, particularly where large transformers are mounted near the top of the pole, becomes a substantial factor in determining the pole strength required.

In such cases, both transverse and vertical stresses and their resultant stress may need to be determined, although the vertical and combined stresses can only be calculated approximately.

A wood pole is considered as a long tapering column, which, under a critical concentric vertical load, fails by buckling. The maximum load that the pole can safely carry depends on the degree of freedom of the pole ends, the distribution and arrangement of the vertical loading on the pole, the support given the pole by any wire or cable attachments, and other variable factors.

For wood, the maximum compressive strength is considerably less than the modulus of rupture and the maximum allowable stress for the combined compression and bending stress is intermediate between these two values.

Methods have been developed for determining approximately the combined stress on a pole at the ground line, due to vertical (axial) and transverse loads, under certain assumptions, but, because of their complexity, these methods are not discussed in this handbook.

Where it is desired to employ such methods, reference may be made to *Provisional Report No.* 24 (*Technical Report* 2G-2), A Study of Pole Strength in Jointly Used Poles, of the Joint Subcommittee on Development and Research of the E.E.I. and B.T.S. of August 22, 1938.

The minimum required ground-line circumference of the pole C having been determined, the class of pole actually selected from the ASA Specification Tables should have a ground-line circumference at least equal to the minimum required ground-line circumference C plus an amount of wood which, based on average decay rates for the timber and location involved, will provide the desired service life in accordance with the formula

$$C_s = C + y(L - T)$$

where C_s = minimum ground-line circumference of the new pole, in in., to provide desired service life.

C = minimum required ground-line circumference of new pole, determined as above.

y = average rate of decay of untreated timber in equivalent inches of circumference per year. (For the cedars and chestnut, this decay is about 0.45 in. for sapwood and 0.3 in. for heartwood per year. For southern pine the physical life is about equal to the effective period of treatment.)

L = desired physical life in years.

T = expected life of preservative treatment in years (probably roughly 20 years for initial treatment of butt-treated poles).

The ASA (American Standards Association) Specification Tables of Pole Dimensions, referred to above, are readily available and are based primarily on:

1. Fiber strengths of various timbers used.
2. Ten classes of poles (1 to 10) with minimum circumferences for 6 ft from the butt specified for classes 1 to 7, and minimum circumferences at the top of the pole specified for all classes.
3. Breaking loads 2 ft from the top for the first seven classes in approximate geometric progression as follows:

Class	Breaking Load, in lb
1	4500
2	3700
3	3000
4	2400
5	1900
6	1500
7	1200

4. All new poles of the same class and length (classes 1 to 7 only) to have about equal resistant moments at the ground line.
5. All new poles of the same class (classes 1 to 7 only) to be of such size as to have about the same breaking load, with the load applied 2 ft from the pole top and assuming that the break would occur at the ground line.

Treatment of poles to prolong their physical life is standard practice. The preservatives used may be creosote, greensalt, or other chemicals toxic to wood-destroying fungi and wood-boring insects. The creosote treatment may be applied the full length of the pole, as in southern pine, under a pressure and vacuum with a net retention normally of 6 to 8 lb of creosote per cubic foot of wood, and a penetration of not less than 2 1/2 in. or 85 per cent of the sapwood. Greensalt is also applied to poles by the pressure method, and it has some advantages over the creosote treatment. Butt-treated poles, such as the cedars, are usually processed in open tanks of hot and then cold creosote, the ground-line section being incised to assist penetration, which averages about 0.4 in. or more.

The spacing of poles depends largely upon the type of the wire or cable load, location, transposition scheme, and exposure to storms. For important backbone toll routes the spacing is generally about 130 ft for open wire and from 150 to 300 ft for toll cable.

The guying of pole lines is necessary at points of above average stress, such as at corners having substantial pulls, dead-end poles, and poles carrying unusual loads. Guying is also applied on toll lines at periodic intervals along the line to assist the pole-line structure in withstanding storms. The ratio of lead to height of guys should be about 1.0 to 1.25, the guy stress then being about 1.4 to 1.28 times the horizontal stress.

Cross-arms are designed to carry from 2 to 10 or 12 wires, as may be required for any particular case, and may be fitted with locust or steel pins, usually spaced from 6 to 12 in. for telephone and 10 and 11 1/4 in. for telegraph wires (16 to 30 in. for pole pairs). The cross-arms are usually spaced 24 in. apart vertically on the pole and vary in number per pole from 1 to 6 or more.

OPEN WIRE, supported on insulator-equipped cross-arms or brackets, which are in turn mounted on poles or fixtures, has been employed since the invention of the telegraph and telephone to connect individual instruments to wire centers or offices, and one office to another. However, wire conductors enclosed in lead sheaths (cables) have practically superseded open wire in built-up communities and cities and in large measure, for telephone communication, have replaced or supplemented open-wire lines between the principal cities.

The types of open wire employed for telephone communication circuits, as discussed in Section 17, consist principally of 104, 128, and 165 hard-drawn copper and some 104 and 128 copper steel (40 per cent cond.) for toll circuits, 080 copper steel (40 per cent cond.), and 080 and 109 high-tensile steel for exchange circuits in outlying areas (all given in mil diameter). High-tensile steel wire, because of the pole economies realized, its greater strength, and its equally good service performance, is being employed for new construction generally in place of the various grades of mild steel and iron wire.

The types of open wire employed for telegraph communication circuits consist mainly of 114 hard-drawn copper, 162 copper steel (40 per cent cond.), and some 165 iron for important facilities.

Drop wires of various types are used for both services.

Table 2 shows some of the important physical properties and the electrical resistance of wire, classed as open wire, for both telephone and telegraph circuits. Other electrical characteristics of various types of wire are discussed in Section 17.

Table 2

CABLE, consisting of insulated, annealed copper conductors, enclosed in a cylindrical lead sheath, is employed in both toll and exchange telephone and in telegraph plant, where the number of circuits required along a given route, plant economies, or interfering conditions preclude the use of open wire. Cable is used generally in toll plant in urban areas and, supplementing open wire, between principal traffic centers throughout the country, either as toll entrance facilities for open-wire lines or as toll cable facilities directly connecting large switching centers.

Telephone and telegraph cable is manufactured in various sizes and gages, of which representative types and associated data are given in Table 3. For both types of service,

Table 3. Representative Cables—Mechanical Characteristics

Type	(3) No. of Pairs	(1) (2) Gage of Conductor	Conductor Insulation	Sheath Thickness, in.	Outside Diameter, in.	Weight per Foot, lb	Type of Core

Notes: (1) All conductors are annealed copper.
(2) Some 28 gage exchange cable was made during World War II to conserve copper in sizes 11 to 303 pairs.
(3) The smallest and largest sizes of exchange cable are shown, as used in the Bell System.
(4) Toll entrance and toll cable may have optional groups of non-quadded exchange pairs. The cable data given assume no shielding or sheath protection or exchange conductors.
(5) Insulation resistance required to exceed 500 megohms per mile.
(6) Some 13 gage is used in both telephone and telegraph service.

paper or wood-pulp insulated conductors are grouped together to form a core, either in layers or 51 and 101 pair units, various colors being used in the insulation and binding strings to permit readily distinguishing between different layers, units, quads, or pairs, for installation or maintenance purposes. Figure 5 shows the method of core construction for both layer and multiple-unit type cores of telephone exchange cable (24 gage-type DSM).

Exchange conductors are generally associated in pairs (2 conductors twisted together), although some exchange trunk cable is quadded (2 pairs twisted together as a 4-conductor unit group, called a quad). Toll conductors are usually quadded for phantom circuit operation, although toll cables frequently contain some non-quadded pairs for program or other toll services. In addition, complements of exchange pairs are frequently included in the toll cable. The lead sheath enclosing the paper-wrapped core of insulated conductors normally contains about 1 per cent of antimony to strengthen the sheath, the thickness of which varies with core diameter and type of cable from about 0.06 to 0.125 in.

Cross-talk must be carefully considered in cable design, particularly for toll cables. In non-quadded cables the conductors are twisted together in pairs. The twists in adjacent pairs within a layer and in adjacent layers are of different lengths to provide the necessary capacitance balance between pairs. In quadded cables the conductors are twisted together in pairs and the pairs are twisted together with different lengths of twist to form quads of as many as 9 types, each of which has a different length of twist. Exchange pairs (non-quadded) are usually random spliced within their color groups (spliced without testing to determine the pair numbers), so that any given pair in the cable is adjacent to any other pair in as few cable sections as practicable. Toll pairs, because of their greater importance, wider range of operating energy levels and frequency assignments, are carefully spliced where sections of cable join. The splicing is carried out according to a plan which provides for limiting the cross-talk between circuits.

Segregation, to reduce couplings at carrier frequencies between oppositely transmitting pairs or quads used for cable carrier, is usually accomplished by assigning oppositely bound groups to separate cables. Segregation of pairs used for open-wire carrier is obtained by using alternate layers or by metallic layer or unit quad shields in the same cable, as may be required to prevent excessive cross-induction between them.

Sheath protection is provided in various degrees, as may be required, by using: (1) layers of Sisalkraft paper and jute covering, where soil corrosion may occur; (2) layers of thermoplastic compound covered by longitudinal copper tape, flooded with asphalt compounds, for a lightning shield; (3) layers of Sisalkraft paper, two steel tapes, and jute, for gopher-infested areas; (4) layers of Sisalkraft paper and a layer of rubber or asphalt-back fabric tape for corrosion protection in conduit; (5) a thermoplastic compound layer and outer covering of impregnated fabric tape for corrosion protection when buried near pipe lines; (6) two helical wrappings of tape armor and a cushion of jute to protect against ring cutting, stone bruises, or to provide shielding for low-frequency induction for aerial cables; and (7) single and double armor wires with a jute cushion for submarine cables. Other special protection may be provided as required.

Spiral-four disk-insulated cable is used, under certain conditions, to provide entrance facilities for open-wire carrier systems operating at a maximum frequency of about 140 kc. The individual units contain 4 copper conductors of 16 gage, insulated from each other by composition disks having uniformly spaced peripheral notches which hold the wires spaced at the corners of a square, each oppositely positioned pair of wires forming a pair of the quad. Shielding is provided over a spiral-4 unit consisting of a copper tape and two steel tapes. A toll entrance cable may contain up to 7 such units, each with its own metal sheath, or a combination of units and standard paper-insulated quads and pairs which provide other communication facilities.

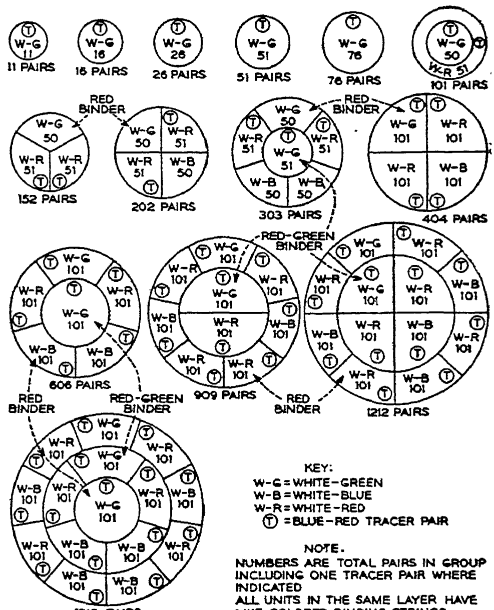

FIG. 5. Diagrams Showing Typical Layer and Multiple-unit Type Exchange Cable Cores (Courtesy Bell System)

Coaxial cable, of latest design, for use with the carrier and other high-frequency systems, consists of up to 8 units. Each unit is composed of a 100.4-mil conductor (inner conductor) positioned in the center of a single 12-mil copper tape (outer conductor) with longitudinal seam to form a 0.375-in. (inner diameter) tube, over which are lightly wrapped two 6-mil steel tapes. The outer conductor is supported by polyethylene disks, 0.085 in. thick, spaced about 1 in. apart along the inner conductor. The outer and inner conductors form a metallic circuit. With the 8 units, other standard paper-insulated quads of conductors (up to about 78 quads of 19 gage or equivalent) may be included in the same overall lead sheath. Further details regarding this cable and its characteristics are given in Section 17.

Both exchange and toll cables are *placed aerially and underground*, depending upon the location and other factors affecting any given cable.

When cables are placed aerially on poles or towers, the required strength of the supporting structures must be carefully determined on the basis of loading area, exposure to weather conditions, load carried, importance of the cable to service, and other factors such as apply in open-wire construction. When cables are placed underground, the main factors to consider are the type of underground housing, if any, to employ, as well as the possibilities of damage from corrosion or other external sources, and the proper routing. Underground cables may be placed in vitrified clay conduit, fiber, or other types of ducts or buried directly in a trench in the ground or plowed into the ground. In any event, suitable protection from underground hazards must be provided.

Loading coils are provided in cable circuits (aerial or underground) wherever required for transmission reasons (see Section 17).

Loading coils are generally assembled in groups in steel cases for either aerial or underground installations, and some designs are suitable for office relay rack mounting. Lead sleeve cases are used for loading small complements of toll and exchange conductors. Also single coils (in a small metal case) are designed to be connected and enclosed in cable splices.

UNDERGROUND STRUCTURES, consisting of conduit, manholes, vaults, and other construction, are designed to provide suitable housings for underground cable plant. These structures are a necessity in cities and to some extent in the smaller communities (assuming that aerial cable plant is not practicable or economical in a given case), since the underground cable plant must be readily accessible to permit additions, changes, removals, and repairs. Some underground exchange cable has been buried (placed directly in the ground) in built-up locations, but this is not the general practice. Toll cables, suitably protected, are frequently plowed into the ground or are buried in trenches. This type of construction has been employed for long distances over transcontinental and other important toll cable routes.

Underground conduit may be of vitrified clay, fiber composition, creosoted wood, or iron pipes. Clay conduit is most generally employed for main routes because of its relatively low cost and satisfactory performance when buried and properly protected. It is manufactured in single or 2-, 3-, 4-, 6-, 8-, and 9-duct multiple units, and is usually laid in one or more units in a compact arrangement. The conduit is placed in a trench, which may vary in depth to avoid other underground structures or hazards (sharp changes in direction are avoided), on a solid base with or without concrete. It may be encased completely in concrete or only at the top or bottom, or plank may be used, in the judgment of the engineer as to the type of construction needed.

Conduit may be placed along a street under paving or the sidewalk, or between the curb and sidewalk, or in parking in the center of the street, as conditions permit. Costs and a satisfactory permanent location, least likely to be disturbed, are primary considerations in placing conduit over a selected route. Subsidiary ducts of wood and of vitrified clay, sewer or iron pipe are commonly used from manholes to underground cable poles or buildings.

Manholes are required at junction points of conduit runs and other locations where it is desirable that the underground cable plant be made accessible, and to provide for practicable cable section lengths. Manholes are preferably located at one side or the other of street intersections to avoid interfering with traffic, when working in them. Manholes vary in size from the small service boxes, placed mainly for the purpose of pulling cable, to the standard 2-, 3-, and 4-way and center rack types, having dimensions ranging from 3 ft 6 in. width by 6 ft length by 5 ft 6 in. headroom to 8 ft width by 9 ft length by about 6 ft or more headroom. In addition, special type manholes and cable vaults of various sizes are required in many cases to accommodate concentrated conduit entrances, as at central offices and loading coil installations. Concrete construction is usually employed, with or without reinforcement. Manhole frames and covers of cast iron, placed in the manhole roof to provide a suitable entrance of 27-in. diameter or more to the manhole, are designed to support surface traffic safely. Drainage may or may not be provided in manholes, as required.

The underground cables are supported on galvanized-metal racks, mounted vertically along the sides or through the center of the manhole, and are separated by a few inches to permit splices to be made and opened as required.

26. ELECTRICAL PROTECTION OF TRANSMISSION LINES

Lightning and power circuits are two unlike sources of electrical power, which, under certain conditions of exposure or contact encountered in practice, occasionally cause damage to communication plant.

Communication lines and equipment are necessarily grouped closely together because of space limitations and other economic considerations. These facilities will carry their normal operating voltages and currents with ample margins of safety, but the insulation employed on cable conductors, between conductors and the cable sheath, and in various equipments is not sufficient, in general, to withstand lightning or power circuit potentials without protection.

EXCHANGE CABLE PROTECTION against lightning for any given exchange cable plant usually requires a study of the plant layout and exposure conditions involved. The aerial cable sheath is usually grounded through the underground cable plant or at the central office and at various other locations at irregular intervals, such as at underground dips or private cable entrances.

The working cable conductors are grounded by operation of the station protection and through the loops connecting to them. Cable conductors may serve subscriber stations at one or more intermediate points along the conductors but lie idle in other sections of the cable beyond these points. Other conductors may lie idle throughout their length, and groups of conductors will terminate at various points where cable sizes change. All these conditions have a direct bearing on potentials in exchange cables due to lightning.

Lightning currents may, in general, be impressed on exchange cables by (1) inductive coupling between the cables (or between conductors connected to them) and the lightning path, (2) direct stroke, or (3) metallic connection with entering open-wire or drop loops, carrying lightning potentials, as a result of a direct stroke or other causes. Lightning currents from metallic connections (by conduction) are usually the principal consideration in the design of exchange cable protection.

Lightning current may appear on the open wire, connected to the cable, from such sources as direct strokes to the line, conduction from service drops or guys, or from arcs from power-system ground wires. Figure 6 shows the results of crest current measurements at exchange cable-open wire junctions.

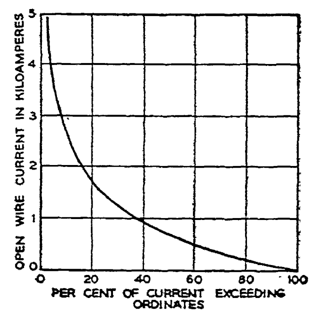

FIG. 6. Crest Current Distribution for Lightning Currents at Exchange Cable—Open Wire Junctions (Courtesy Bell System)

Although lightning currents reach cables over both connected drop and open-wire loops, it appears that the currents on the drop loops will probably be greater than those on the open wire. However, cable plant with drop loops is generally located in built-up areas having low-resistance public water systems and various types of shielding, whereas open-wire plant extends mostly into rural areas where direct lightning strokes are more likely to occur and where grounding conditions are not as favorable as in built-up areas. Thus, cable damage from lightning currents is more likely to result from open-wire than from drop loops. In some locations where cables extend into rural districts and are subject to the same lightning exposure as the open wire the current received by the cable from the drop loops may be of greater importance than that received from the open-wire loops connected to these cables.

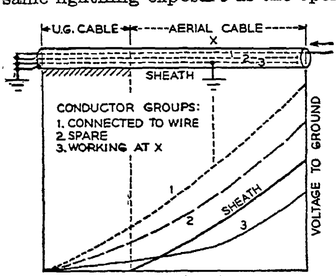

FIG. 7. Voltage Distribution along Conductors and Sheath for Current Delivered from Open Wire—No Protector Blocks on Conductors (Courtesy Bell System)

Lightning currents, reaching exchange cable from any source, produce potential differences between conductors and between the sheath and conductors which, if protection is not provided, may seriously damage the sheath and the enclosed conductors.

The potential differences within the cable, resulting from current on the conductors, depend largely on the current wave form. For steep wave-front surges, the relatively high self and mutual surge impedances are important in determining the potential differences; for slower surges or short cables (about 1 to 2 miles) these potential differences depend more upon the conductor resistances. Frequently, the slower surges produce the lower potential differences. Figure 7 illustrates the voltage distribution along conductors and sheath for current delivered from an open-wire loop with no protector blocks at the junction of the open wire and cable. The aerial cable is not grounded, except through the underground section and the office ground, and contains a group of conductors (1) connected to open-wire loops, (2) spare, and (3) working at an intermediate point, x, along the cable.

Potential differences in cables, unless several times the breakdown voltage of the cable insulation, do not, in general, cause permanent damage, although the insulation may be punctured in numerous places. Remedial measures are, therefore, designed to reduce the applied voltages between conductors and between conductors and the sheath and to limit or distribute the current so that permanent failures are unlikely even though punctures do occur. Such measures may consist of (1) connecting protector blocks between conductors and sheath where potential differences are most likely to be high and occur frequently, (2) providing means of diverting from the cable a substantial part of the current which might reach the cable over open-wire or drop loops serving installations exposed to lightning strokes, such as radio and fire towers, and (3) placing conductors parallel with the sheath, thus increasing the conductivity and reducing the *IR* drop along the sheath.

Protector Blocks. One type of protector block, commonly employed between cable conductors and the enclosing sheath at the junction of open-wire or drop loops and cables, consists of a porcelain block with a small carbon block insert held in place by a quick-melting glass cement. The porcelain block is held against a solid carbon block (which rests against a grounded metal plate) by a metal spring bearing against the small carbon insert. The insert is positioned to provide an air gap between it and the grounded carbon block of about 0.006 in. One set of these blocks is provided for each of the two conductors of the cable pair. When the current in the air gap is sufficient to melt the cement, the metal spring, which is connected to a cable conductor, forces the carbon block insert against the ground block, thus grounding the loop wire and cable conductor to which the loop wire is connected.

These protector blocks break down when steep wave front voltages of 1000 to 1500 volts are impressed, this voltage range being generally somewhat below the steep wave front voltage necessary to puncture exchange cable insulation. Protection is thus provided for the cable conductors, having protector blocks, against dielectric failure near to the point where these blocks are connected. However, damaging potential differences may occur between the protected conductors and other conductors at the point of protection and between conductors and sheath at other points. Lower-breakdown protector blocks for cable protection do not appear to offer an important improvement in protection and generally react unfavorably from the standpoint of maintenance and service.

Protector blocks applied to working conductors at the junction of open-wire and aerial cables (not grounded at intermediate points) reduce potential differences between such conductors and the sheath and other conductors, as shown by a comparison of Figs. 7 and 8. The curves in these figures are not drawn to scale, and actually the reductions obtained are much larger than can be indicated conveniently. With working conductors thus protected (Fig. 8), the maximum potential difference within the cable usually occurs at the open-wire junction between the sheath and spare pairs, and the next highest potential difference appears at the junction of the aerial and underground cable between the sheath and protected conductors.

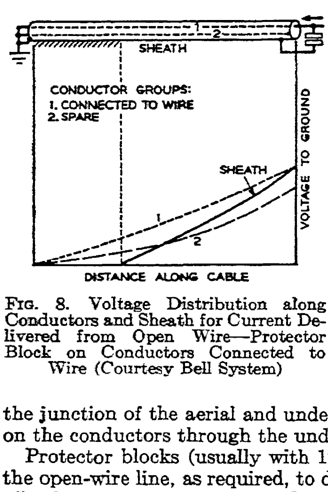

FIG. 8. Voltage Distribution along Conductors and Sheath for Current Delivered from Open Wire—Protector Block on Conductors Connected to Wire (Courtesy Bell System)

When protector blocks are applied to all conductors at the junction of open-wire and aerial cables, the potential differences between conductors are eliminated throughout the cable (assuming an ideal condition of no grounds on the conductors through station blocks at other points). The only potential difference existing in the cable under this condition is between the sheath and all conductors, being a maximum at the junction of the aerial and underground cable sections and about equal to the *IR* drop on the conductors through the underground section.

Protector blocks (usually with 10-mil air gaps) for all wires may also be placed along the open-wire line, as required, to divert current from the cable. This results in increased effectiveness for a given ground impedance, due to increasing the impedance between the ground point and the underground cable, over what it would be for a single sheath ground at the open-wire junction, and it avoids the adverse effects of a single ground on the sheath. Experience indicates that improvements usually result when the open-wire protection is placed within about 700 to 3000 ft of the cable terminal and the ground resistance at the protection does not exceed about 30 ohms.

Grounds may consist of several hundred feet of buried wire in high-resistivity areas, or rods may be used effectively in low-resistivity areas. Grounds of limited extent have impedances about equal to their d-c resistances, but for lengths of wire or pipe greater than about 200 ft the d-c resistance decreases with length faster than the impedance. Figure 9 shows, for homogeneous earth, the variation of resistance with length of buried wire, the earth resistivity being 100 meter ohms. Large variations may be expected in these values where the soil has a highly variable resistivity. For grounds of equal d-c resistances, the ground of least extent is considered best for grounding purposes, although, practically, the neutral of a well-grounded common neutral power system or water piping system, if available, will probably provide a better ground than a made ground.

Shielding conductors placed on the pole line along with the cable or buried below it will reduce conductor-to-conductor and sheath-to-conductor potentials by about 50 per cent or more. The effectiveness of shielding depends upon diverting part of the current from the sheath. This method of current diversion has been limited because more practicable methods are available.

Increasing sheath conductivity by placing bare conductors along the sheath and in contact with it will reduce the IR drop along the sheath and potential differences within the cable.

Other remedial measures include:

(*a*) Increasing core to sheath dielectric strength. This method is of major importance in toll cables, where the voltages between core and sheath appear most frequently, but for exchange cable, where the voltages between conductors are of more concern, this method is of lesser importance.

(*b*) Employing pole protection wires on exchange cables extending into rural areas where cable terminals are infrequent.

(*c*) Bonding to power system common neutrals at frequent intervals in built-up areas where many working drops are connected through protector blocks to the cable sheath. In such cases, the cable sheath becomes closely tied in with the neutral through the drops, station protector grounds, and power secondary services. By proper bonding (at about 1/4-mile intervals or less) between sheath and neutral (assuming the neutral to be continuous and well grounded), the neutral forms a parallel path with the cable for lightning currents and provides effective shielding. Under such conditions, cable damage from power contacts or lightning tends to be restricted to a section between the two bonds immediately adjacent to the power source. Bonding to the neutral also lowers the sheath impedance and thus assists in prompt de-energization of the power circuit in the event of power-circuit contact with the sheath. Frequent bonding to the neutral is useful for cable noise mitigation.

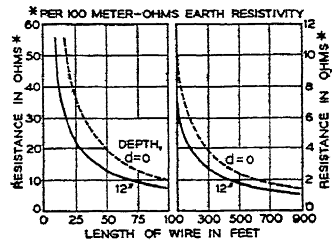

FIG. 9. Approximate Resistance to Ground of a Buried Wire (Courtesy Bell System)

Where bonding between the aerial cable and power neutral is objectionable, with respect to corrosion on the associated underground cable plant (as where drainage is used), the bonded aerial sheath may be isolated from the underground sheath by installing an insulating joint at their junction, reliance being placed in the bonding for the aerial sheath protective grounding.

Experience indicates that it is advisable, in lightning affected areas, to protect all working conductors at any terminal, serving any open wire or drop loop over 1/2 mile in length, this length being based principally on judgment.

Some companies (not Bell System) employ, in some cases, fuses (usually 5- or 7-amp rating) in conjunction with protector blocks to form a unit-type protector which is usually assembled in multiples and mounted in a terminal housing for installation at the junction of open-wire or drop loops and the cable. The protector blocks ground the open-wire or drop loop when lightning or excessive power circuit potentials are applied, and the fuses open the circuit when the current coming into the cable over the loop exceeds the fuse rating.

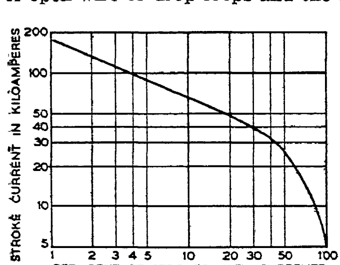

FIG. 10. Distribution of Lightning Stroke Crest Currents (Courtesy Bell System)

TOLL CABLE PROTECTION (against lightning) requirements are similar to those of the exchange plant except that the distances are greater, particularly between grounds. Experience indicates that the rate of lightning troubles on *aerial toll cables* apparently does not differ greatly from such troubles in *buried cables*, but the ease of locating and clearing these troubles in aerial cables as compared to underground cables indicates less need for comparable remedial measures on the aerial cables.

Figure 10 shows the distribution of lightning stroke crest currents, based on a large number of measurements in the ground structures of power-transmission lines, the crest value varying over a wide range. Measurements indicate that the crest value is reached in 5 to 10 microseconds and that it decays to half its maximum value in 25 to 100 microseconds. The crest value and decay time to half value of the current, rather than wave front steepness, are of primary importance with respect to voltages between the sheath and conductors of aerial or buried toll cable.

At a point remote from ground connections, the surge impedance to ground of an aerial cable sheath (any size) is about 200 ohms (400 ohms in each direction from the lightning stroke). For a crest current of 20,000 amp the sheath-to-ground voltage would be 4 million volts. The conductors within the sheath attain about the same potential to ground as the sheath, owing to capacitive and inductive coupling between the sheath and core conductors. However, some voltage difference does exist between the sheath and core, due to the IR drop along the sheath, resulting from the flow of lightning current on the sheath. This voltage difference is greatest at the stroke point, decreasing as the distance from the stroke point increases. The higher the sheath resistance, the greater this voltage difference between sheath and core will be for a given lightning current.

The dielectric strength between core and sheath, for normal-dielectric-strength cables, is for surges about 2000 volts. For high-dielectric-strength cables (having an extra core wrap), a 4000-volt value for surges may be assumed.

After an initial puncture in the insulation near the stroke point, other punctures will thus usually occur some distance away in either or both directions. Such puncturing may or may not cause permanent failures, depending on the current through the fault.

A sheath-to-core voltage of breakdown magnitude may develop, owing to: (1) a large sheath current for a relatively short distance, (2) a smaller sheath current over a longer distance, or (3) a combination of (1) and (2), depending on the ground paths from the sheath and their locations with respect to the lightning stroke. Permanent damage is likely to result from the large current transfer through the punctures in condition (1) but is not so likely in (2) because of the smaller transfer of current from sheath to conductors under this condition.

The voltages in buried cables are usually due to large sheath currents over short distances (less than 1/2 mile), so that permanent damage is likely at puncture points.

The protection of aerial toll cables may consist of (1) pole protection wires (wires bonded to the sheath and extending down the pole to the pole butt or to a point near the ground line), (2) aerial shield wires, (3) buried shield wires, (4) high-dielectric-strength cable (with double core wrap), (5) shields within the cable, or (6) protector blocks at open-wire junctions or out from the junction about a mile on the open wire.

Pole protection wires may serve not only to protect poles against splintering but also to provide protection to aerial cables in lightning exposures. Data show that for such wires, properly spaced along an aerial cable line, the voltage between sheath and core, due to a stroke, decreases as the number of such wires increases up to about 10 for 100 meter ohm resistivity and up to about 20 for 1000 ohm resistivity. However, in uniform exposures, the effectiveness of these wires decreases for aerial cables having both toll and exchange conductors as the interval (of the order of 1 mile) between subscriber drop locations decreases, owing to the low-breakdown path from sheath to ground over the drop loops which substantially short-circuits the pole protection wires.

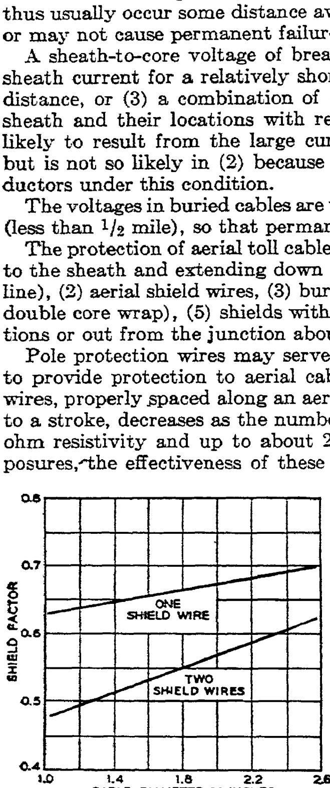

Fig. 11. Shield Factors for Aerial Shield Wires (Courtesy Bell System)

The effectiveness of these wires may be lowered where a large number of them are employed, as the result of current distribution along the sheath to such grounds from the stroke point increasing the net sheath-to-core voltage. By using proper length gaps in the wires, the number of conducting grounds may be limited to an optimum value.

Where pole protection wires are not adequate to give required lightning protection to aerial cables, aerial or buried shield wires may be of advantage. The reduction in core-to-sheath voltage by aerial shield wires which are bonded to the sheath at each pole is normally substantial, as shown by the shield factors, Fig. 11. When an aerial cable is provided with buried shield wires, the voltage from a direct stroke is about the same as that for a buried cable of the same size with similar shield wires.

High-dielectric-strength cables should generally be employed in new installations. The choice of this type of cable may obviate the necessity of other remedial measures, but in any event its higher dielectric strength is an advantage since, if the strength is doubled, the stroke current must be increased 3 times to puncture the insulation.

Communication plant may be damaged by contact with high-voltage wires or power distribution circuits. The most important consideration in protecting cables from power-wire contact is to so locate, construct, and maintain the communication and power circuit plant that contacts will not occur.

Aerial cables are grounded at offices, through their connection to the underground cable plant, underground dips, and private cable entrances, as well as other frequent grounding, such as, in some cases, to multigrounded power circuit neutrals. This practice contributes to provide a low-impedance ground to de-energize the power circuit promptly in case of contact with the cable plant.

27. CABLE SHEATH CORROSION

ELECTROLYSIS. Electric currents, flowing in the earth, may result from (1) stray currents from d-c street-car (trolley) or electrified railway systems, (2) stray currents from commercial d-c power distribution systems, (3) differences in the chemical composition of films on the cable sheath at different locations, (4) differences between the composition of films on sheaths of different cables at the same location, (5) differences in the electrolyte at different places, or (6) a number of other conditions. These currents passing through damp ground cause chemical changes to take place at electrode surfaces, such as cable sheaths, which may or may not affect the electrodes.

Cable sheath corrosion may, in general, be considered as occurring in:

1. Stray-current areas.
2. Non-stray-current areas.

The principal causes of cable sheath corrosion are:

1. Stray current-anodic action.
2. Stray current-cathodic action.
3. Localized action.
4. Galvanic action.
5. Chemical attack.

Stray-current areas are commonly designated as those in which the cable-to-earth potentials and sheath currents are established principally by currents straying from the rails of d-c transportation systems and utilizing other paralleling paths of relatively low resistance in the earth, such as cable sheath or public water piping.

Where the stray current enters the sheath the cable is negative (cathodic) to the earth, and where it leaves the sheath the cable is positive (anodic) to the earth.

Non-stray-current areas are those in which corrosion may occur from other than stray currents. Currents in these areas usually result from potential gradients due to such causes as differential aeration, differential electrolyte concentrations, non-uniformities in the sheath metal, or potential differences between different metals.

Current from stray-current areas may flow in non-stray areas, such as along an underground toll cable sheath extending between cities where street cars operate. Current, usually considered as "non-stray" current, such as that resulting from galvanic potentials, may also be present in stray-current areas, although its effect is largely overshadowed by the stray currents in these areas.

Anodic corrosion, due to stray currents, results because:

1. The metal becomes positively ionized and goes into solution.

$$\mathrm{Pb} - 2e \rightarrow \mathrm{Pb}^{++} \quad (e = \text{electron})$$

2. The anions (ions bearing negative charges and migrating to an anode) in the electrolyte are attracted to and contact the sheath, where they lose their charge, become chemically active, and attack the lead sheath.

If the ions are chlorine

$$\mathrm{Cl}^{-} - e \rightarrow \mathrm{Cl}$$

and

$$\mathrm{Pb} + 2\mathrm{Cl} \rightarrow \mathrm{PbCl_2} \quad \text{(lead chloride)}$$

Note: A positive ion, in the case of Pb^{++}, is an atom from which two electrons have been removed; a negative ion, in the case of Cl^{-}, is an atom to which one extra electron has been added.

In anodic action, a corrosion product does not always adhere to the sheath, and a clean corroded area on the sheath is regarded as due to such action. The corrosion product, if present on the sheath, is usually lead chloride or lead sulfate or both. The sheath potential, being positive, attracts chloride and sulfate ions in the ground water to the sheath, and these ions react with the lead. Under severe anodic conditions lead peroxide, PbO_2, may be formed. This product has a chocolate color; the products of chloride, sulfate, and carbonate of lead are white.

Cathodic corrosion, due to stray currents, though not as yet reproduced in the laboratory, might possibly occur when the cables are negative to earth and the surrounding earth contains alkali or salts of sodium, potassium, calcium, or magnesium. Hydrogen ions in the electrolyte, under such conditions, are attracted to the sheath, lose their charge, and are liberated, resulting in a decrease in hydrogen-ion concentration and making the electrolyte alkaline. The alkali forms most rapidly and with greatest concentration at points of maximum cathodic current density. The attack on the sheath is, therefore, not uniform and usually affects only a relatively small part of the sheath.

In the case of sodium salts, the reaction with the lead is:

$$H^+ + e \rightarrow H$$

$$Na^+ + OH^- \rightarrow NaOH \quad \text{(sodium hydroxide)}$$

The sodium hydroxide forming at the sheath dissolves the lead, and the final reaction usually results in the formation principally of *lead monoxide*, PbO, lead carbonate, and sodium carbonate. The sheath pitting may be similar to that caused by anodic action, but the cathodic corrosion is characterized by the usually bright orange-red color of the lead monoxide.

Galvanic action usually results when two dissimilar metals are in electric contact with an electrolyte and also are metallically connected. Where cables and bare copper or galvanized cable rack supports are present in a flooded manhole, galvanic action may occur. Lead is anodic to copper and cathodic to the zinc galvanizing, the anode corroding in each case. Corrosion may appear, in the presence of moisture, on wiped joints and soldered seams on cable sleeves, where the solder may be anodic to the lead.

When two dissimilar metals in an electrolyte are connected metallically, the metal with the higher solution pressure becomes the anode and corrodes. Current passes from the anode through the electrolyte to the cathode and completes the circuit to the anode through the metallic connection.

In alkaline solutions, lead tends to become electronegative and may be anodic with respect to another metal such as iron. Thus, lead corrosion may result where cable is installed in iron conduit and such solutions are present. Under these conditions current may pass from the lead through the solution to the iron and return to the lead at points of metallic contact between the iron conduit and the sheath.

Local action between adjacent areas of the sheath may result from variations in sheath material, such as foreign particles in the lead, and from differences in surface conditions due to abrasion. Corrosion from the action, under anodic conditions, may occur in spots rather than uniformly over the sheath surface, and if the action continues for a period of years sharply defined pits may appear in the sheath.

Concentration cells may be formed by a change in the concentration of the salts in an electrolyte, causing corresponding changes in the potential of a given electrode in contact with the electrolyte; or by two electrolytes, with equal concentration of different salts, producing different electrode potentials on the same metal. Such a cell might be established by waste products from a factory or sewer entering a sloping conduit (with cable) at a conduit joint and concentrating along a section of sheath. The cell might then result between the section of sheath having the concentration and an adjacent section not affected by the waste.

Differential aeration, which may be considered a special form of concentration cell, results in sheath corrosion, owing to a variation in the concentration of dissolved oxygen in the electrolyte in contact with the sheath. Where a sheath is continually wet by water dripping or condensing on it, there will be more oxygen in the moisture exposed to the air than where the moisture is shielded by an absorbent material such as a layer of silt on the sheath. The cable sheath in contact with the electrolyte with a deficiency of oxygen will be anodic and subject to corrosion.

Battery action in the soil might result in sheath corrosion where the sheath was not one of the cell electrodes but acted as a conductor of the local current. As an example, if an iron pipe passed through a bed of cinders which acted as a carbon electrode, and the adjacent section of pipe was in contact with ordinary soil, a cell would be established with the carbon electrode negative to the adjacent section of pipe. Part of the resulting current from this section might enter a nearby paralleling cable sheath and leave the sheath near the cinders, at which point sheath corrosion might result.

Protective films formed over the sheath by natural processes are usually helpful in preventing sheath corrosion. Films formed from silicates are generally continuous, adherent, insoluble, and helpful, whereas films resulting from nitrates in the soil tend to prevent film formations and thus aid corrosion.

REMEDIAL MEASURES for controlling corrosion are varied and often complex, because the problems of corrosion may differ over a wide range of causes and conditions and extend over relatively large areas.

Generally, the first considerations in the control of cable sheath corrosion are electrical, involving a thorough study of electrical conditions affecting the cable plant. Chemical control can sometimes be used successfully where electrical methods are not practicable. The general attack on sheath corrosion problems by electrical methods consists of:

1. Limiting current entering the sheath to the extent practicable.
2. Providing metallic paths by which current entering the sheath may leave it without damage to the sheath or other metallic structures.

Protective arrangements of any nature should be such as to minimize the probability of impressing current on other underground plants, either privately or publicly owned.

The limitation of current pick-up by a given underground cable sheath requires that the sheath be kept free of all connections to other grounded metallic structures except those connections specified as part of the general remedial plan, and that the sheath should not be made more negative to earth in any area than is necessary under practical design.

The cable sheath should be maintained at slight negative potential to earth to (1) limit current pick-up which increases with increase in negative potential, (2) lessen the possibility of large positive pipe-to-cable voltages, and (3) reduce the chances for cathodic corrosion.

The increasing use of bonding between aerial cables and multigrounded power neutrals for noise induction and protection reasons increases the tendency to discharge current to the underground cable plant. Insulating joints may be used at underground-aerial cable junctions, where required, and electrolytic capacitors may be employed to bridge the insulating joint if capacitors are necessary for noise induction or protection purposes.

Cathodic corrosion of sheaths may occur where the cable-to-earth potential exceeds a few tenths of a volt negative. In the presence of salts this potential may not be over 0.2 volt; under other conditions cathodic corrosion will not result at any potentials encountered, where an effective drainage system exists.

For this type of corrosion, it is essential to maintain low negative cable-to-earth potentials by using (1) an adequate drainage system, (2) insulating joints shunted by resistors if necessary, (3) corrosion-protected cables for replacement of cables which fail, (4) periodic flushing of ducts which accumulate alkali, or (5) reverse drainage employing controlled currents *to* the cables by connecting to positive points on rail systems or to pipes (experience limited).

Other underground structures, such as public water or gas piping, are also drained in many areas. A metallic piping system in direct contact with the earth usually has a very low leakage resistance, and any reduction in its potential by drainage tends to lower the earth potential in its immediate vicinity. Where the earth potential is thus lowered, the current discharge from nearby telephone cables tends to increase. This condition may complicate the telephone cable drainage scheme, but generally, owing to the low leakage resistance of the piping system, the adverse effects are not extensive. A coordinated drainage plan for all underground systems is usually necessary where two or more systems serve the same general area affected by stray currents.

Anodic corrosion, which is the only type of corrosion that has been found so far in non-stray areas, results from current leaving the cable sheath for any reason. This type of corrosion may be due to: (1) currents flowing from the cable into the electrolyte in the duct and back to the cable without leaving the duct, as a result of differential aeration, differential electrolyte concentration, or non-uniformity of the sheath composition (though this type of corrosion is local, many such *local cells* may exist along a cable and cause corrosion over a long section of the cable); and (2) currents flowing from the cable to the electrolyte in the duct, thence to the earth outside of the duct, and finally returning to the cable at some relatively remote point. In (2) the driving electromotive forces may result from the same causes as given in (1) above, but the cells are materially lengthened and the currents are known as *long cell currents*. Such electromotive forces may result from potential gradients in the earth due to currents associated with corrosion cells on long paralleling piping or to other natural causes, including magnetic storms; or they may result from a potential established as a result of sheath contact with other metal, such as copper or iron piping; or they may result from remote railway currents flowing into the non-stray area.

TESTING METHODS AND MITIGATIVE MEASURES, as employed in non-stray-current areas, are, in general, somewhat similar to those employed in stray-current areas, but various testing refinements are usually required in the non-stray areas. For example, in determining the *IR* drop or direction of current flow in the earth as it may affect underground cable sheath, it is necessary to employ electrodes, for contacting the earth, which are identical in potential or differ by a known and constant potential. Such an electrode, designated a *half-cell*, consists of a non-conducting container enclosing a metallic electrode suspended in an electrolyte. The electrolyte fills a porous cap, which forms the bottom of the container and through which the cell makes contact with the earth. This cell makes use of the fact that the potential difference between electrolytes varies over a very small range as compared to the potential difference between metals when used as electrodes.

Experience has shown that corrosion is not usually a problem with respect to buried jute-protected, tape-armored, and thermoplastic-covered cables in non-stray areas. Electrical tests on such cables in non-stray areas are not, in general, considered necessary.

Forced drainage has been successfully employed in anodic areas in the protection of underground cable plant in non-stray areas. Random contacts between telephone cables and other metallic structures, such as water piping and steel buildings, usually interfere with effective drainage of the cables and should be eliminated, although other considerations, particularly noise induction and protection, may impose numerous difficulties and problems in such eliminations.

Forced drainage requires a separate d-c source of potential, such as a rectifier (commonly used) or a battery, with the negative terminal connected to the cable sheath and the positive terminal connected to a negative bus or special ground. Current is forced from the sheath to the bus or ground.

Rectifiers available for drainage purposes have suitable d-c voltage and current outputs and usually operate from either 115- or 230-volt a-c commercial supply. They are made in several types, including dry-disk and tube types, by a number of electrical equipment manufacturers.

Galvanic anodes requiring no external power supply may provide the required amount of forced drainage under favorable conditions when buried in the ground and connected to the sheath by copper wire. The anodes may consist of a metal negative to lead, such as zinc, aluminum, or magnesium. Magnesium appears favorable, because of its relatively high negative potential (about 1 volt) to lead. The anode, being buried in the soil and discharging current, will gradually be consumed.

To be effective, the anode must have a low resistance to ground, and this depends on its shape and the surrounding earth resistivity. For a cylinder 4 in. in diameter by 20 in. long, the resistance to ground (without special environment) is about equal to the earth resistivity in meter ohms.

Chemical attack usually requires an analysis of the corrosion products and a determination of the source of the chemical attacking the cable sheath in order to apply suitable remedial measures. Chemists may be of assistance, in difficult cases, in determining the nature of the attacking chemicals. Lead monoxide corrosion is indicative of cathodic action or alkali attack. Very few cases show a definite single cause of corrosion. The previous history of corrosion of the affected cable may be of value in arriving at the causes of the corrosion.

Alternating current, principally because of its rapid and equal reversals of potential between positive and negative values, is not considered an important cause of cable sheath corrosion.

Corrosion-protected cable for installation in underground conduit can be made available with the same core make-up as the plain lead-covered cable with which it may be associated. This protected cable may be useful where the lead sheath would be subject to corrosive action without the protection and where it is more attractive than other remedial measures. This type of cable may be employed in situations such as (1) near chemical plants or other locations where chemical attack has been experienced or may occur, (2) where alkaline attack (cathodic action) might develop, or (3) where corrosion has occurred in subsurface dips.

One type of protection consists of two reversed layers of Sisalkraft paper and an outer layer of rubber-filled tape, the sheath and each layer being flooded with an asphalt compound. A non-adhesive coating is applied on the outside covering to prevent sticking in handling. The protection increases the cable diameter about 0.2 in.

Suitable alarms and pilot wires to a centralized maintenance center may be employed, when facilities are available and as required, to indicate critical changes in potentials and current flow affecting the cable plant.

COORDINATION OF COMMUNICATION AND POWER SYSTEMS

By John D. Taylor and Howard L. Davis, Jr.

28. FOREIGN WIRE RELATIONS

In order to insure safety to persons and property, economy of operation, and good service, in areas served by both overhead communication and power systems, it became evident, as the systems began to expand, that the companies involved should establish and follow a plan of cooperation in the construction and operation of their respective plants. For a number of years individual cooperative efforts were carried on, but the specific solutions of the problems that developed were not applicable in a general way.

Early in 1921 steps were taken by both interests on a nationwide scale to formulate a basis of common understanding and to establish permanent joint committees and subcommittees for study and recommendations relating to mutual problems. As a result of continuous study and research by these subcommittees and sponsors, the Joint General Committee of the Edison Electric Institute and Bell Telephone System prepared, and the representative interests approved, several general reports, of which the following are the principal ones in effect today:

1. *Principles and Practices for the Inductive Coordination of Supply and Communication Systems*, Dec. 9, 1922.*
2. *Principles and Practices for the Joint Use of Wood Poles by Supply and Communication Companies*, Feb. 15, 1926.*
3. *Inductive Coordination—Allocation of Costs between Supply and Communication Companies*, Oct. 15, 1926.*

In general, the *Principles and Practices* provide, in addition to other important items, that

(*a*) All supply and communication circuits with their associated apparatus should be located, constructed, operated, and maintained in conformity with general coordinated methods based on the concept of rendering either service without interference.

(*b*) Where general coordinated methods will be insufficient, suitable specific coordinated methods should be applied, most conveniently and economically, to prevent interference with either service, present and known future factors being taken into account.

(*c*) The companies serving any given area should fully cooperate with each other in carrying out the accepted principles, based on arriving at the best engineering solution of each situation, as it arises, for all the companies involved.

(*d*) Where conditions and the nature of the supply and communication circuits permit, joint use of poles (particularly in urban areas) is generally preferable to separate lines, when justified by considerations of safety, economy, and convenience, and assuming that a satisfactory agreement is reached between the parties concerned.

(*e*) When supply and communication facilities occupy the same section of highway and joint use is not desirable, each type of facility should be confined to one side of the highway, as far as practicable, thus avoiding unnecessary crossings and expensive guying.

(*f*) In the design, construction, and operation of supply and communication circuits and equipment, all factors contributing to inductive influence, inductive couplings, or inductive susceptiveness under normal or abnormal operating conditions should be limited to the extent necessary and practicable.

(*g*) Each utility shall be the judge of the quality and requirements of its own service and the type and design of its own facilities.

(*h*) Coordination costs in any given situation of proximity, assuming that satisfactory results have been attained under the best engineering solution, will generally be allocated, so that each company involved bears its equitable portion, including its own betterments.

The basis for cooperation, as set forth in detail in the *Principles and Practices*, has contributed immeasurably to the excellent foreign wire relations existing among the many wire-using companies who supply electric and communication services throughout the country.

The cooperative plan was later extended to provide for a Joint General Committee of the American Railway Association (now Association of American Railroads) and Bell Telephone System in 1929, a Joint General Committee of the Edison Electric Institute

---

* These reports are now combined as *Reports of Joint General Committee of Edison Electric Institute and Bell Telephone System on Physical Relations between Electrical Supply and Communication Systems*, reissued July 1945.

and Western Union Telegraph Company in 1935, and a Joint General Committee of the Association of American Railroads and Edison Electric Institute.

When power and communication facilities serve the same areas and are supported on overhead structures and where the two types of facilities are in close physical relation or inductively coupled or both, situations of proximity generally are unavoidable. Communication facilities, operating at relatively low voltages and currents, are not designed to withstand the normal or abnormal power circuit voltages and currents which may be impressed upon them by direct contact or, in severe influences or couplings, by induction. In some cases of contact or induction, the service may be only interrupted or degraded, but in more severe situations the service may be interrupted and the facilities damaged with or without personnel hazard.

It is thus imperative that the *Principles and Practices* be closely adhered to, in order that both services may be furnished the public in a safe, economical, and satisfactory manner.

The design and application of coordinative measures by the wire-using companies involve two broad fields of coordination, structural and inductive. Both fields have been for a number of years and will continue to be under intensive study, directed toward improving methods and securing further economies without sacrificing but, when practicable, bettering present safety and service.

29. STRUCTURAL COORDINATION

Structural coordination, as the name implies, consists of planning, designing, constructing, and maintaining the physical overhead plant of each company, with due consideration for the plans and plant of all other companies involved, so that safety and overall economy will be attained.

SITUATIONS OF PROXIMITY are created when power and communication lines are so located with respect to each other as to parallel, cross-over, occupy the same poles (joint use), or require consideration of line wire, guy, or pole-mounted equipment clearances. The overbuilding of one type of service by the other is considered objectionable, joint use usually being the better solution, with the power wires in the upper position in all cases of proximity.

The National Electrical Safety Code, Fifth Edition, Part 2 (*National Bureau of Standards Handbook* H32), issued Sept. 23, 1941 (hereinafter referred to as the Code), which has been approved by the American Standards Association, presents Safety Rules for the Installation and Maintenance of Electric Supply and Communication Lines. These rules embody specific minimum requirements, and, though not complete, they are intended to cover those points which are most important for the safety of employees and the public. This code is acceptable to the various wire-using organizations throughout the country and, except as modified by more exacting state or local regulations, is applied, together with the *Principles and Practices* discussed previously, generally throughout the country. Where a certain coordinative problem arises, not specifically covered in the Code, the companies involved agree on the best engineering solution for the problem. The Code also provides for modifying or waiving its requirements in any given case where such requirements are inapplicable, not justified, or impracticable, or where equivalent or safer construction can be more readily provided by other means. It is, therefore, a practicable and flexible guide.

Structural requirements and clearances between electric, railway, and communication structures, wires, and equipment must be adequately provided for, as set forth in the Code. Owing to the large amount of detailed information necessary in specifying these requirements under the numerous conditions encountered in practice, they will not be given here, but they may readily be obtained from the Code.

Certain fundamental concepts (other than those previously enumerated under *Principles and Practices*) in this work are generally accepted as good engineering practice and may be stated in general terms:

(*a*) The mechanical design and construction of electric (supply) and communication systems should conform to good modern practice.

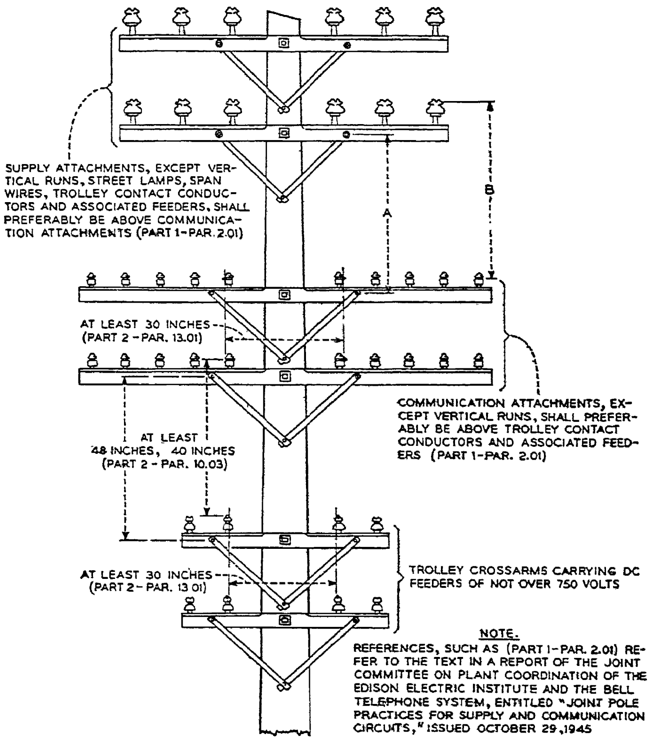
(*b*) When changes are made in systems or methods of operation, consideration should be given to decreasing inductive influences and susceptiveness, when practicable.

(*c*) Coordinated systems should be maintained, so that abnormal conditions affecting either service will be minimized and prompt action will be taken to eliminate such conditions when they do occur.

(*d*) Supply, communication, and trolley circuits should occupy levels in the order named, with supply circuits at the top level. Also, where supply lines carry different voltages, the higher-voltage lines are usually placed above those of lower voltage.

(*e*) Joint use should be considered when it can be employed with reasonable safety and convenience, economically, and without appreciable service detriment.

JOINT USE of poles is a very desirable means of coordinating supply and communication facilities where this type of construction is feasible. Various types of construction are employed, depending upon the types of facilities involved, but in any case the construction is designed to conform to the latest practices and safeguards.



VOLTAGE OF SUPPLY CIRCUIT CONCERNED	DIMENSION	MINIMUM CROSSARM SPACING IN INCHES	DIMENSION	MINIMUM SEPARATION BETWEEN CONDUCTORS IN INCHES
0-8,700	A	48	B	40
OVER 8,700		72		60

(PART 2- PAR. 10.03)

FIG. 1. Relative Position of Attachments, Showing Vertical Clearances and Climbing Space (Joint Pole Practices for Supply and Communication Circuits, Oct. 29, 1945)

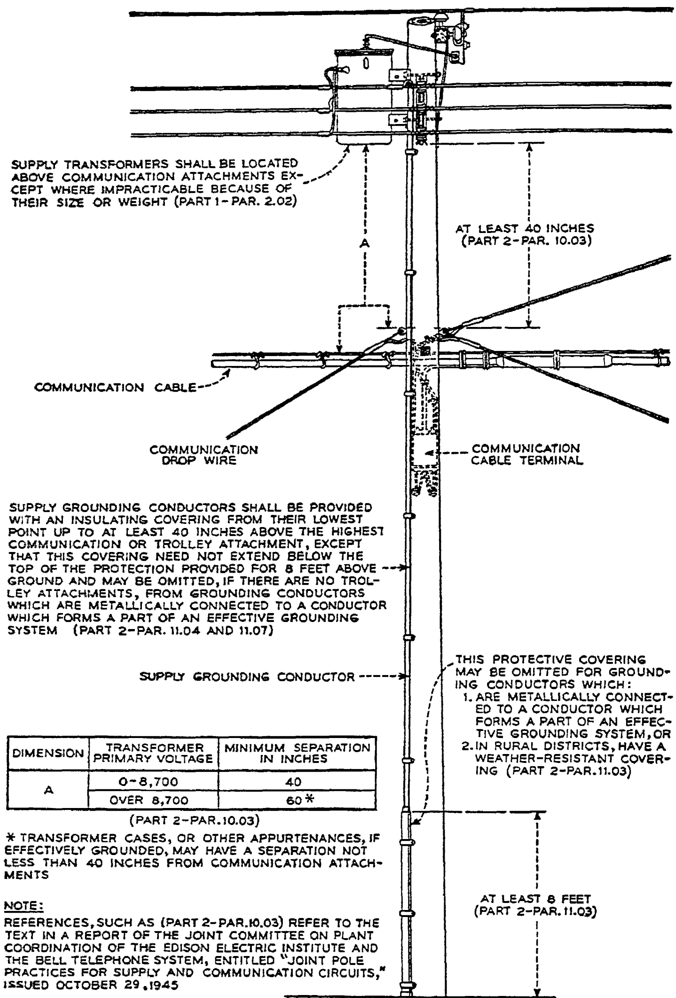
For joint-use construction, commonly employed in urban areas for local distribution, Figs. 1, 2, 3, and 4 show the usual typical construction features and clearances considered good modern practice and meeting Code requirements. Adequate clearances are essential for the protection of personnel and property.

Normal joint-use construction is applicable to construction involving communication cables or conductors and supply cables or conductors of the following types:

(*a*) Constant-potential a-c supply circuits normally operating at voltages between 750 and 5000 volts between conductors and not over 2900 volts to neutral or ground.

(*b*) Constant-current supply circuits of not more than 7.5 amp regardless of the voltage, and of more than 7.5 amp where the open-circuit voltage of the supply transformer is not more than 2900 volts.

(*c*) Constant-potential a-c supply circuits normally operating at more than 5000 volts between conductors or more than 2900 volts to neutral or ground, and constant-current



DIMENSION	TRANSFORMER PRIMARY VOLTAGE	MINIMUM SEPARATION IN INCHES
A	0-8,700	40
	OVER 8,700	60 *

(PART 2-PAR. 10.03)

* TRANSFORMER CASES, OR OTHER APPURTENANCES, IF EFFECTIVELY GROUNDED, MAY HAVE A SEPARATION NOT LESS THAN 40 INCHES FROM COMMUNICATION ATTACHMENTS

NOTE:
REFERENCES, SUCH AS (PART 2-PAR. 10.03) REFER TO THE TEXT IN A REPORT OF THE JOINT COMMITTEE ON PLANT COORDINATION OF THE EDISON ELECTRIC INSTITUTE AND THE BELL TELEPHONE SYSTEM, ENTITLED "JOINT POLE PRACTICES FOR SUPPLY AND COMMUNICATION CIRCUITS," ISSUED OCTOBER 29, 1945

FIG. 2. Supply Transformer Installation, Showing the Separation from Communication Cables and Conductors (Joint Pole Practices for Supply and Communication Circuits, Oct. 29, 1945)

supply circuits of more than 7.5 amp where the open-circuit voltage of the supply transformer is more than 2900 volts, provided that:

1. The supply and communication circuits are so constructed, operated, and maintained that the supply circuits will be promptly de-energized, both initially and following subsequent breaker operations, in the event of contact with the communication plant.

2. The voltage and current impressed on the communication plant, in the event of a contact with the supply conductors, are not in excess of the safe operating limit of the communication protective devices.

Note: Where conditions 1 and 2 above are not met, special joint-use construction is required, unless the parties concerned agree that the additional protection, required under (*c*) above, is unnecessary or except in the case of certain drop wire attachments.

(*d*) Any effectively grounded supply cables, located above communication cables or conductors or carried on effectively grounded suspension strand, where the supply voltage between conductors is more than 750 volts.

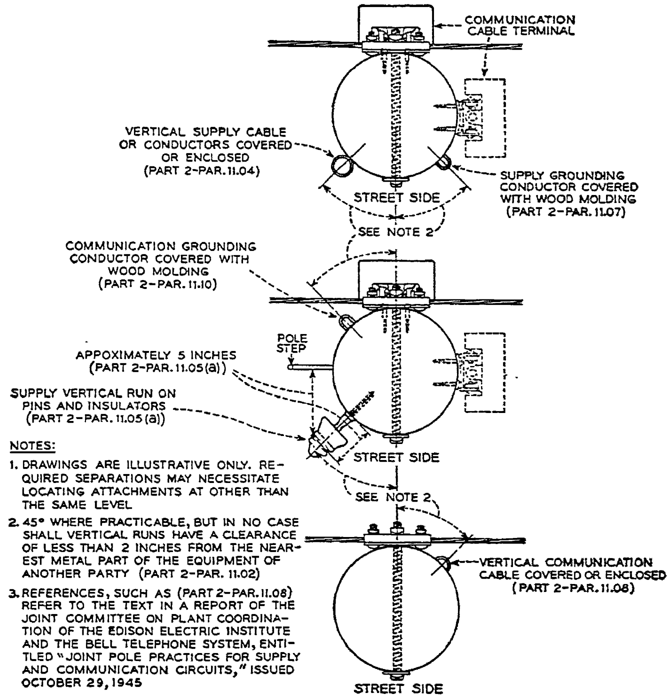


FIG. 3. Location of Vertical Runs (Joint Pole Practices for Supply and Communication Circuits, Oct. 29, 1945)

The requirements for normal and special joint use conform to Code Grade C and B construction, respectively, applying mainly to supporting structures, supply conductors, and clearances.

JOINT-USE RURAL LINE CONSTRUCTION at the higher voltages (above 5000 volts) for power and telephone services, though recognized for some time as the best engineering solution for many situations of power and telephone lines along the same route and though employed in various specific cases, has presented a number of problems in coordination. In particular, the longer spans and higher voltages for the power circuits and the increased noise induction from the longer exposures than are normally encountered in joint-use urban construction are main factors. The rapid growth, within about the last decade, of rural electrification has greatly emphasized the necessity for a study and solution of these problems, to permit a more general application of rural joint-use construction.

For the purposes of study of safe and economical rural joint-use construction at the higher voltages, several projects of this type were completed and placed in service before 1947 in Alabama, in the light-loading district, and in Minnesota and South Dakota, both in the heavy-loading district.

The NES Code (Fifth Edition of Part 2) provides that, if the supply circuit will be promptly de-energized in the event of accidental contact with the telephone plant, and the resulting voltages on the telephone plant from such a contact will be within the operating capabilities of the telephone protective equipment, Grade C construction may be employed in joint use. This provision of the Code has an important bearing on the problems involved in long-span rural joint use.

For long-span construction, high-strength line wires are necessary; they are generally of stranded copper or aluminum with one or more strands of steel for power circuits, and of high-strength solid steel or copper-covered steel for telephone circuits. The minimum size of power wire for Grade C construction under the Code is No. 8 AWG medium-hard drawn copper.

With high-strength line wires for both power and telephone conductors, it was assumed that their sag characteristics would be sufficiently alike to prevent contacts in the span under ice or wind loadings or temperature changes, with reasonable minimum separations of the two classes of conductors at the poles. It was also assumed that a very large percentage of rural power circuits would consist of one phase wire on a pin at the top of the pole and a multigrounded neutral below it on a pin or secondary rack, or that the primary circuit would consist of two or more primary wires on a cross-arm at the top of the pole and that the multigrounded neutral, if present, would be located on the same cross-arm or below it.

Where joint rural lines cross fields or other property, which is or is likely to be traversed by loaded vehicles or farm machinery, adequate wire clearances should be provided.

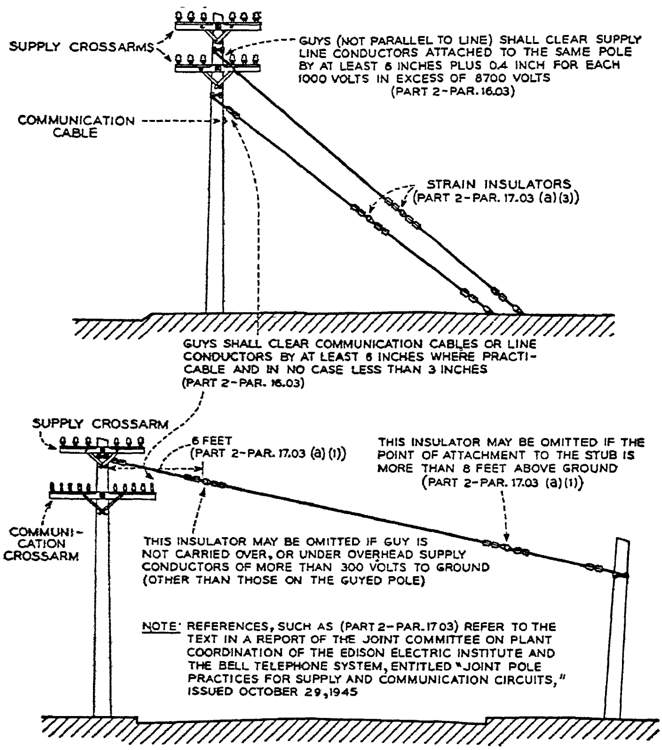

FIG. 4. Use of Strain Insulators in Ungrounded Guys (Joint Pole Practices for Supply and Communication Circuits, Oct. 29, 1945)

Span lengths in the Alabama installations of rural joint use average about 400 ft with maximum spans of 600 to 800 ft. In Minnesota and South Dakota, the loading conditions being more severe, the average and maximum span lengths are about 320 ft and 400 ft respectively.

For noise induction reasons, the separations between the power and telephone circuits should be kept as uniform as practicable without incurring undue costs or construction difficulties. (See article 31.)

Electrical protection, to meet requirements, should provide: (*a*) fuses, circuit-breakers, or other devices, which will promptly and reliably de-energize the *power circuit*, if a ground fault of relatively low impedance occurs; (*b*) protective gaps, to be connected between the *telephone circuit* and the common neutral (or other low-resistance ground) at such intervals that the impedance to ground of the telephone plant, in case of a power wire contact, will be low enough to permit proper operation of the power protective devices.

As experience indicates that the frequency of contacts is very low, the power protective arrangements are usually more than adequate to meet the above requirements. The telephone circuits in the joint projects, referred to above, employ protectors having a 3-kv (rms) breakdown to ground, placed at about $^1/_2$-mile intervals, thus providing a low-impedance path to ground. The current-carrying capacity of the protector must be sufficient to meet the discharge which may result from a contact.

As a means of limiting induced 60-cycle open-circuit voltages (under normal operation) on telephone circuits, which are occasionally disconnected from the central office equipment and entrance cables, a drainage device, consisting of a 0.25-μf condenser in series with a 10,000-ohm resistor from each wire to ground, may be used.

Although experience at present is limited, the feasibility of higher-voltage long-span joint use in rural areas has been established, and economic studies in progress indicate that worth-while economies are possible for most new extensions and sometimes even where power lines have already been built.

HIGHER-VOLTAGE CROSSINGS (involving supply lines of more than 5000 volts between wires or 2900 volts to neutral or ground) are given special consideration to minimize possible contacts between supply and communication circuits. The Code requirements for spacings, clearances, and strength of construction are considered to be minimum and represent the generally accepted practices (except as modified by more exacting state or local regulations) throughout the United States.

RURAL POWER LINE CARRIER TELEPHONE SYSTEMS, where applicable, are being placed in operation throughout the country as a means of providing telephone service to rural subscribers who are accessible from rural power-line systems but not readily so from rural telephone lines. Although these carrier telephone systems are still in their early trial periods, it appears that they will eventually be economically useful in furnishing telephone service to distant farms and ranches which would otherwise require costly telephone-line construction to reach. Joint practices and agreements covering this type of operation are in the formative stage.

A more detailed description of this carrier system and its associated installation and operating features is given in Section 17.

30. INDUCTIVE COORDINATION

Inductive coordination, as it applies to supply (electric) and communication companies, embraces the principles and practices, agreed upon by these companies, for the design, location, construction, operation, and maintenance of their respective systems, located in the same general territory, in such manner as to prevent interference with the furnishing of either the electric or communication service.

Since much of the general public throughout the country receives both electric and communication service by means of overhead construction, it is inevitable that many situations of proximity between the two services will be created under a wide variety of construction and operating conditions. Also, telephone circuits usually transmit relatively low amounts of electrical speech power (varying from less than 1 to a few milliwatts), whereas electric transmission and distribution circuits transmit power ranging from a few to hundreds and thousands of kilowatts. Owing to the much greater amounts of power carried by these circuits, not only at the fundamental but also in many cases at harmonic frequencies within the voice-frequency range, inductive effects from power circuits may, under certain conditions of proximity and operation, severely affect communication service, if proper control is not provided.

The control of inductive interference in communication circuits, to permit giving a satisfactory service, is accomplished through the application of general coordinated methods, or, when required, by applying specific coordinated methods, as set forth in the *Principles and Practices*, discussed in article 28.

There are two general classifications of inductive interference, namely: (*a*) noise frequency (induction from power harmonics within the voice-frequency range); (*b*) low-frequency (induction from the power fundamental frequency, usually 60 cycles, during abnormal power circuit conditions).

Inductive effects between power and communication circuits arise from the fact that power wires, transmitting relatively large a-c voltages and currents, establish strong electric and magnetic fields in their vicinity, which, owing to their varying character, set up in nearby communication wires alternately increasing and decreasing electric voltages and currents of the same frequencies as those in the power wires. Induction from communication to power wires would have no noticeable effect in any event on power service, because of the small amount of power carried by the communication wires and the nature of the power service.

It is often desirable to consider effects of magnetic and electric induction separately, particularly in the technical analyses of specific problems. This is not only because the physical processes and the effects of voltage and current induction are quite different but also because the power-circuit voltages and currents are often affected differently by changes in conditions. Electric induction is due to the voltages on the power line; magnetic induction is due to currents on the power line.

Theoretically, electric and magnetic induction are produced as described briefly below.

A simple method of visualizing *electric induction* is by means of the capacitances involved with a single power wire and a single telephone wire, as shown in Fig. 5. Neglecting the impedances outside the exposure (shown dotted in Fig. 5), the voltage of the power wire to ground (E_P) divides over the capacitances C_{TP} and C_{T0} in proportion to their impedances (that is, in inverse ratio to their capacitances). The induced voltage (E_T) on the telephone wire may therefore be expressed mathematically as:

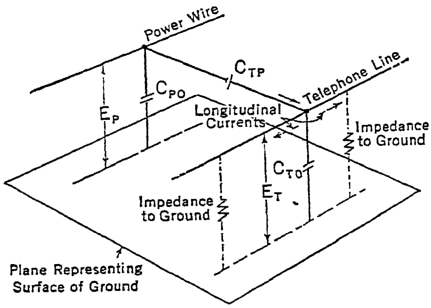

FIG. 5. Diagram Showing Couplings between Power and Telephone Wires for Electric Induction

$$E_T = \frac{C_{TP}}{C_{T0} + C_{TP}} E_P \qquad (1)$$

Where there are numerous power and telephone wires, capacitances exist between every possible combination of wires, and of wires and ground, resulting in a complicated network, but the principles involved are the same as in the simple case discussed above.

The potential of the telephone wire tends to be the same all along its length. If the wire is perfectly insulated from ground, extends only through the length of the exposure, and has no equipment on it, this potential is independent of the length of the exposure (the condition shown in Fig. 5 if the impedances to ground are neglected). This is true because, whereas all the capacitances in the above equation are proportional to exposure length, the ratio $C_{TP}/(C_{T0} + C_{TP})$ is independent of length. However, in practice, the circuits usually extend beyond the exposure and have equipment connected between them and ground, so that there are impedances to ground outside the exposure through which longitudinal current will flow. Since the impedance of C_{TP} controls the total longitudinal current, this current will be practically independent of the telephone-circuit impedances to ground and will be proportional to exposure length. It will also be proportional to the frequency of the harmonics in the inducing voltage. Hence, for given telephone-circuit impedance conditions (outside the exposure), the voltage to ground will be proportional to exposure length and to the frequency of the inducing voltage in a uniform and electrically short exposure.

In *magnetic induction*, the current in the power wire sets up a magnetic field which alternates at the frequency of the current. If a communication wire is located in this field, a *voltage is induced along it* which is proportional to the rate of change of the magnetic flux. This phenomenon is illustrated in Fig. 6. The voltage between the telephone circuit and ground varies from point to point along the circuit and depends on the distribution of the impedances to ground as well as on the distribution of the induced voltage. Also, since the voltage acts along the circuit and the part induced in each short length adds directly to those in all other short lengths, the total induced voltage is directly proportional to the exposure length in a uniform and electrically short exposure. Further, as the rate of change of magnetic flux is proportional to frequency, the induced voltage will be proportional to the frequency of the inducing current.

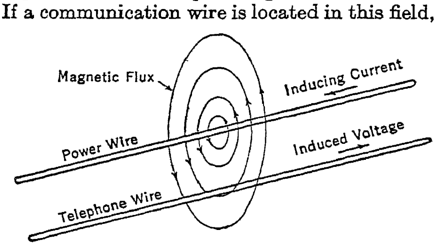

FIG. 6. Diagram Showing Coupling between Power and Telephone Wires for Magnetic Induction

In the foregoing, the factors discussed apply to both noise and low-frequency induction. However, these two general types of problems are discussed separately.

31. NOISE FREQUENCY INDUCTION

Noise frequency induction, in communication circuits, for a given situation of proximity, depends upon:

(*a*) Inductive influence of the power circuits, as determined by their electrical characteristics.

(*b*) Inductive coupling between the power and communication circuits, as determined by their physical relation.

(*c*) Inductive susceptiveness of the communication circuits, as determined by their electrical characteristics.

INDUCTIVE INFLUENCE. Two characteristics of a power system of primary importance in determining its inductive influence are wave shape and balance.

The wave shape of the voltage or current on a power line is a function of the magnitudes and frequencies of the harmonics, which may induce voltages of frequencies within the range ordinarily used in telephone circuits. Induced voltages at such frequencies have much greater interfering effects than the voltage induced at the fundamental frequency.

The approximate relative interfering effects of telephone line voltages and currents is shown in Fig. 7 for certain subscriber sets and instruments employed in the Bell System.

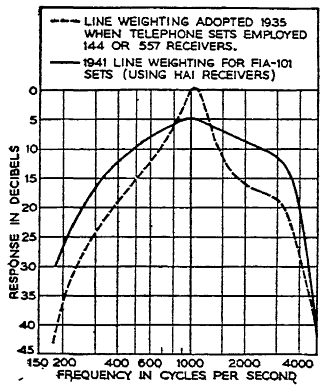

FIG. 7. Line Weightings for Telephone Message Circuit Noise (Relative Interfering Effects of Telephone Line Voltages or Currents) (Report 45, J.C.P.C.)

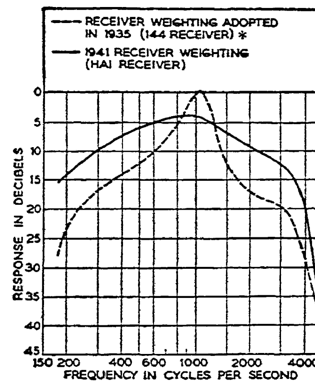

* Also applicable to 557 receiver for estimating receiver noise.

FIG. 8. Receiver Weightings for Telephone Message Circuit Noise (Relative Interfering Effects of Telephone Line Voltages or Currents at Receiver) (Reports 32 and 45, J.C.P.C.)

The solid curve shows the line weighting adopted in 1941 for the present-day anti-sidetone set having a relatively flat response over the useful voice-frequency range. This curve also takes into account (1) the possible utilization, in future telephone receiving elements, of a larger part of the wide-band toll transmission attained in the later-type carrier toll circuits, (2) a more uniform response within the transmission band, and (3) the attenuation at frequencies near 3000 cycles and higher, relative to that at 1000 cycles, caused by various types of switching trunks used in toll connections, as compared to the distortionless trunks used in the tests on which this curve is based. The two curves cannot be compared on an absolute basis, since the acoustic output per volt input at 1000 cycles is not the same for the different sets.

Receiver weighting curves for telephone message circuit noise are shown in Fig. 8 for certain instruments employed in the Bell System. These curves differ from the line weighting curves, principally as a result of taking into account the voltage loss, relative to that at 1000 cycles, caused by the trunk, loop, and telephone set, between the toll board (at which point the line weightings apply) and the telephone set receiver.

Each harmonic voltage or current induced in a telephone circuit by a paralleling power circuit will individually react in the telephone circuit, over which a conversation may be in progress, and in such a manner that the listener hears the combined effect of all the harmonics, which is termed noise. Different frequencies in this noise have different interfering effects, depending on the characteristics of the telephone circuits, type of receiver, the human ear, and other factors. Relative interfering effects (Fig. 8) are called noise weightings and have been determined by extensive tests.

Since the effects of electric and magnetic couplings are directly proportional to frequency, the relative noise influence of power-system voltages and currents is proportional to the product of noise weighting and frequency. For any frequency, this product times a constant gives the telephone influence factor, TIF. TIF weightings versus frequency are shown in Fig. 9 for three different periods, reflecting changes in transmission-frequency characteristics of telephone circuits and instruments from 1918 to 1941. The 1941 curve has not yet been standardized. It will be noted from Fig. 9 that the TIF values at 60 cycles are very low.

While a great deal of inductive coordination work makes use of single harmonic frequency data, there are cases where it is desirable to evaluate the overall influence of a voltage or current in a power circuit in terms of a single measure. Such a measure may be obtained by multiplying the magnitude of each harmonic present (amperes for current

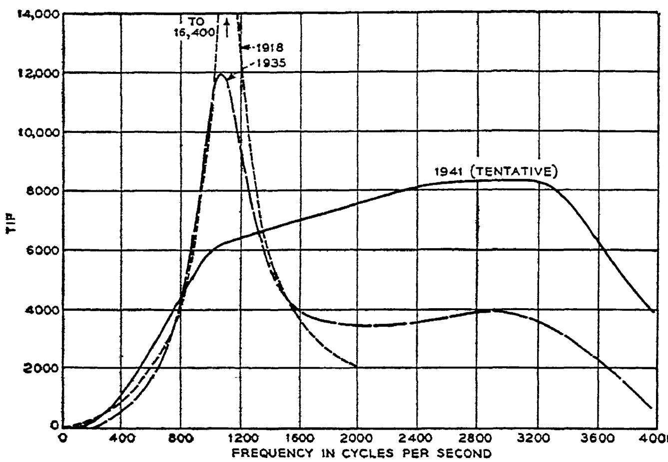

Fig. 9. TIF Weightings for Periods 1918, 1935, and 1941 (Courtesy A.I.E.E.)

and kilovolts for voltage) by its TIF weighting, and taking the rss value (square root of the sum of the squares) of these products. The result for current is the I·T product, and for voltage it is the KV·T product.

These products can be measured directly with a suitable noise-measuring set and a current or voltage TIF coupler, the latter having a transmission-frequency characteristic directly proportional to frequency.

The magnitudes and frequencies of the harmonic currents and voltages on a power line depend on the characteristics of the apparatus and associated equipment and on the impedance of the supply line at each of the harmonic frequencies. The wave shape at various points on the power system depends on the way in which the various harmonic currents and voltages are propagated over the system. Since power systems are usually very complex electrically, the propagation effects may vary greatly for different frequencies and for different systems.

It is impracticable to construct rotating electrical machinery or power transformers entirely free from harmonics, although marked progress has been made in this respect. Also, it is inherent in the operation of rectifying devices (and some other types of devices where the current is not directly proportional to voltage) that harmonics are produced. Generally speaking, the factors affecting the production of harmonics in these general classes of apparatus are as follows:

Motors and Generators. Harmonics are affected by the distribution of air-gap flux, variations in the air-gap flux due to the slots in the rotors and stators, the distribution of the windings on the armature, and, in multiphase machines, connections of the windings.

Transformers. The degree of saturation of the iron in the core affects the harmonics materially. In polyphase transformer banks, the connection of the transformers in the bank affects some of the harmonics, particularly the triple. In a 3-phase transformer the arrangement of the core also affects the triple harmonics.

Rectifiers. Owing to the flat-top wave shape of rectifier anode currents, the a-c line current, taken by the rectifier, has a step-type wave shape, as shown in

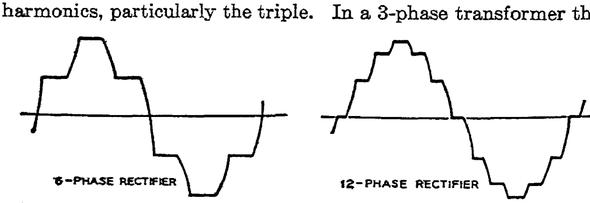

Fig. 10. A-c Line Currents Taken by 6 and 12 Phase Rectifiers (Courtesy A.I.E.E.)

Fig. 10 for a 6- and 12-phase rectifier. This wave shape results in the production of harmonic currents and voltages in the a-c line. Table 1 shows the order of these harmonics (multiples of the fundamental frequency) for various multiphase rectifiers with balanced operation, and also the reduction, with increase in phases, of the number of harmonics which are of importance.

The magnitude of any harmonic which is present with any particular number of phases is the same as for a 6-phase rectifier, assuming all other conditions to be the same. Thus, the magnitude of the twenty-third harmonic is the same for the 6-, 12-, and 24-phase rectifiers. Also, the magnitudes of the harmonic currents bear a definite relation to the rms value of the total rectifier current and decrease in value with increase in frequency. For a given kilovolt-ampere input to a rectifier, the higher the a-c line voltage the lower is the a-c line current, with a corresponding reduction in the magnitudes of the harmonic currents and usually in the harmonic voltages resulting from them. Furthermore, there are generally, under modern practices, fewer long closely coupled exposures with the high-voltage transmission circuits than with the lower-voltage power distribution networks.

Table 1. Harmonics Arising in Rectifiers

Orders of Harmonics in Line with Balanced Operation						Corresponding Harmonic Frequencies on 60-cycle System
Rectifier Phases						
6	12	18	24	36	48	
5						300
7						420
11	11					660
13	13					780
17		17				1020
19		19				1140
23	23		23			1380
25	25		25			1500
29						1740
31						1860
35	35	35		35		2100
37	37	37		37		2220
41						2460
43						2580
47	47		47		47	2820
49	49		49		49	2940
53		53				3180
55		55				3300
59	59					3540
61	61					3660

Note: Higher harmonics are also present for all types listed.

Phase control, employed on rectifiers for reducing the d-c output voltage below that obtained without phase control, is accomplished by retarding the firing point of the anodes in the alternating-voltage cycle, through grid or firing control. The power factor at the a-c line terminal of the rectifier transformer is lowered. The magnitude of the harmonic components increases in the a-c line current for a given kilowatt output of the rectifier. Also, with phase control, the anode currents have a steeper wave front at the beginning and end of the anode firing period, during commutation between successive anodes, resulting in harmonics of higher magnitude. Phase control should, therefore, be limited to actual requirements, particularly at full load and overload ratings of rectifiers, in order to limit the possible inductive interference.

Balanced and Unbalanced Currents. In a multiphase, *balanced* power circuit the voltages between the several phase conductors and between the phase conductors and ground, and also the several line currents, are vectorially equal to zero.

When the currents or voltages do not vectorially equal zero, they contain a set of single-phase components, all in the same phase relation, which are termed residual components. Any system of voltages or currents can be resolved into its balanced and residual components, and the effects of each can be analyzed separately. The balanced components are confined wholly to the phase conductors; the residual components act in a path consisting of the phase conductors and an external return as, for instance, a metallic neutral or through the earth. Since the coupling for the residual components is usually much larger than for the balanced components, the former are usually of greater importance in coordination problems.

Single-phase branches on three-phase distribution systems are, of themselves, inherently unbalanced. On grounded neutral systems the residual voltage on a single-phase branch is practically equal to the phase-to-neutral voltage. On isolated neutral systems the residual voltage on a single-phase branch depends on the particular system layout. The single-phase branches also introduce residual currents and voltages on the 3-phase system.

With the present methods of analyzing noise induction problems, the balanced and residual currents and voltages are usually considered separately. In the general case of exposures of overhead lines of the multigrounded neutral type to subscribers' cable circuits, a knowledge of the residual currents is sufficient, the effect of the balanced currents being relatively unimportant.

INDUCTIVE COUPLING. The coupling between power and communication circuits is determined by the degree of their proximity, but it may be greatly modified by the balance of the two classes of circuits to each other and by the proximity of grounded linear circuits or metallic objects.

Table 2

Types of Induction	Transpositions Tending to Reduce Induction {T = Telephone, P = Power}
A. Metallic-circuit (direct)	
1. From balanced currents	T
2. From balanced voltages	T
3. From residual currents	T
4. From residual voltages	T
B. Longitudinal-circuit (indirect metallic-circuit) *	
5. From balanced currents	P
6. From balanced voltages	P
7. From residual currents	P } Only if residuals are
8. From residual voltages	P } thereby reduced.

* This component of induction can result in noise in the metallic circuit, because of the reaction of such longitudinal induction upon self-unbalances (high-resistance joints or leakage) or mutual inductance or capacitance unbalances to other wires on the line or to ground.

In determining coupling, it is desirable to differentiate between the effects of the balanced and residual components in the power circuit, between the effects of voltages and those of currents, and, on the telephone line, between induced voltage which acts directly in the metallic circuit, termed *metallic-circuit induction*, and that which acts in the circuit composed of the wires in parallel with ground return, termed *longitudinal-circuit-induction.*

Types of Induction. Eight components of power induction, shown in Table 2, need to be considered in noise induction problems. These components vary in their importance, as noise factors, for different situations and for the reasons discussed above.

Transpositions are employed in open wires within exposures (parallels) between power and communication circuits as an aid in neutralizing induced power-circuit noise in the latter circuits. Transpositions are required generally in open-wire communication circuits, whether or not power-circuit exposures exist, to limit intercircuit cross-talk.

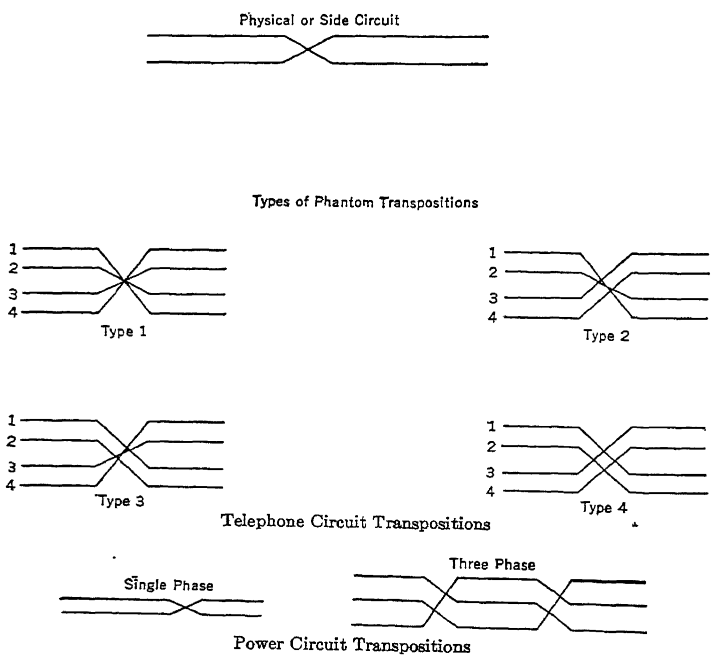

FIG. 11. Diagrams Showing Wire Arrangements at Transposition Points

Transpositions are made by interchanging in a uniform manner the positions of the wires comprising a circuit, so that each wire of the circuit occupies all the pin positions occupied by the circuit, for distances (usually equal) as determined by the transposition design. Figure 11 shows the changes employed in the position of the wires (both telephone and power) at transposition points. Telephone transpositions may be of the physical or side circuit types involving two wires or of any one of four types of phantom transpositions involving four wires. Power transpositions may be of the single-phase type involving two wires or of the 3-phase type, involving three wires.

Identical 3-phase power transpositions, when placed at the $^1/_3$ and $^2/_3$ points in a given uniform section of power line, establish a *power circuit barrel,* since each wire is rotated 120° in phase position and in the same direction of rotation at each transposition. Single-phase power transpositions rotate the wires 180° in phase position. Likewise, for metallic-circuit induction, telephone transpositions change the phase of the induction by 180°.

Figure 12 shows a simple arrangement of telephone and power transpositions within a unit exposure length, L, containing one power barrel. In this arrangement, which is

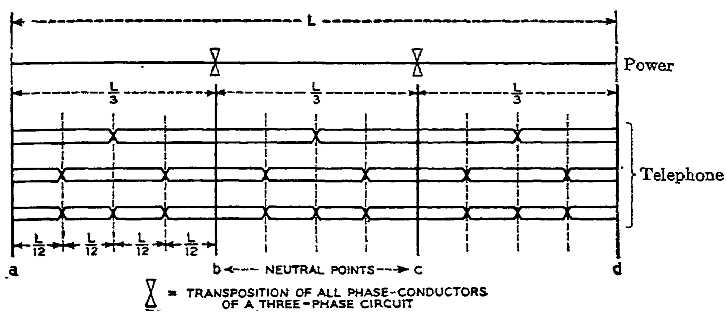

FIG. 12. Simple Balanced Arrangement of Telephone and Power Transpositions in a Unit Exposure Length, L (Courtesy Bell System)

commonly employed, the 3-phase power transpositions are located at neutral points with respect to the telephone transpositions, and the telephone transpositions are so arranged as to reduce the direct metallic-circuit induction (from both balanced and residual components) within each section of exposure between power transpositions, as well as to limit inter-cross-induction.

Telephone circuit transpositions tend to

(*a*) Reduce intercircuit mutual effects, known as cross-induction or cross-talk.

(*b*) Reduce direct metallic-circuit induction from both balanced and residual components of power circuits, within exposures, especially when coordinated.

(*c*) Balance the two sides of the telephone circuit with respect to earth and with respect to all other wires on the telephone line, considered as one longitudinal circuit (Sigma).

These transpositions, by themselves, are not effective in reducing the longitudinal-circuit induction from either the balanced or residual components of the power-circuit voltages and currents. However, within an inductive exposure, such transpositions tend in some measure to equalize these inductive effects by exposing each conductor of the telephone circuit equally to the power-circuit influences.

For telephone-circuit transpositions to be reasonably effective in reducing metallic-circuit induction, the relation between the power and telephone circuits within each coordinated section of exposure (with respect to each other, to ground, and to other circuits present) must be substantially uniform. Thus, points of discontinuity within an exposure, such as sharp changes in separation, crossings, or changes in power-circuit configuration, must be considered in inductive coordination work.

Power-circuit transpositions, within the exposure, tend to reduce the longitudinal-circuit induction from balanced voltages and currents and, as a result, that component of metallic-circuit noise arising mainly outside the exposure due to the action of the longitudinal-circuit induction (from balanced components) upon any unbalances affecting the telephone circuits.

Notes. 1. Power transpositions, in the usual case, do not appreciably affect the direct metallic-circuit induction.

2. That part of the direct metallic-circuit induction which results from residual voltages and currents is not affected by power-circuit transpositions except in so far as such transpositions may reduce the power-circuit residuals

INDUCTIVE SUSCEPTIVENESS. The degree to which telephone transmission is adversely affected by noise-frequency induction depends not only upon the magnitudes of the induced noise voltages, as determined by influence and coupling factors, but also upon the susceptiveness factors of the telephone system. These include the manner in which the induced voltages and currents are propagated to the circuit terminals, together with the reactions of the circuit unbalances (thus relating the current in the terminal apparatus to the induced voltages), the sensitivity of the receiving apparatus, and the operating power level of the telephone circuits.

Propagation Effects and Balance. Important differences exist with respect to propagation effects and balance between open-wire and cable circuits and between toll and exchange systems.

As pointed out in the discussion of coupling, only the magnetically induced longitudinal voltages and currents are important, under the conditions usually encountered, in producing noise in telephone cable circuits. Because of the negligible effects of electric induction and direct metallic-circuit induction and because of the important shielding effects exerted by the cable sheath and the various telephone circuits on each other, telephone cable circuits are much less susceptive than open-wire circuits.

In open-wire telephone systems, consideration must be given both to electric and magnetic induction and to voltages induced directly in the metallic circuit as well as to those induced in the longitudinal circuit. In a line composed of a number of circuits, the currents set up in any one circuit depend not only upon the voltage induced in that circuit and its impedance but also upon the currents and voltages which are set up in the other telephone circuits on the line. It is not possible, therefore, to calculate precisely the induced currents merely from a knowledge of the magnitude of the currents and voltages on the power circuits and the coupling between the power circuits and isolated pairs of wires on the telephone line, considered independently.

Estimates of receiver noise for a particular type of subscriber set and receiver connected to a given line circuit, in which noise currents are assumed to be present, may be made as discussed below.

On the basis of the definition of reference noise, in absolute terms, as an electrical power of 10^{-12} watt at a frequency of 1000 cycles dissipated in a receiver (for all types of receivers), Table 3 gives the currents in three types of receivers and the voltages across them at 1000 cycles for reference noise (0 db) and representative values of the receiver impedances.

Table 3

Receivers (W.E. Co. types)	Current, micro-amperes	Voltage, micro-volts	Impedance, ohms
144	0.0795	21.60	$158 + j221 = 272/54.5°$
557	0.1414	19.70	$50 + j130 = 139/69°$
HA1	0.1210	16.56	$68 + j118 = 136/60°$

At frequencies other than 1000 cycles, the voltage for reference noise is the voltage across the receiver producing an interfering effect equal to that produced by the reference noise voltage at 1000 cycles. For a given receiver, the voltage for reference noise at a frequency other than 1000 cycles may be obtained from the 1000-cycle reference voltage and the proper noise weighting curve for receiver voltages (if available). Figure 8 shows such weighting curves for the three receivers listed in Table 3. Also, for a given receiver, the receiver current for reference noise at a frequency other than 1000 cycles may be obtained from the relation between the voltage for reference noise across the receiver at the given frequency and the receiver impedance at the same frequency. Values of receiver currents and corresponding voltages for reference noise at various odd harmonics of 60 cycles, obtained in accordance with the above procedure, are given in Fig. 13.

From the current for reference noise at a given frequency f and the susceptiveness factor at the same frequency for a subscriber set, the receiver noise (in decibels) for 1 volt to ground on the set at that frequency is given by the expression

$$N_f \text{ (receiver noise in db)} = 20 \log_{10} \left(\frac{I_f}{I_r}\right)$$

where I_f = receiver current in microamperes per volt to ground at the subscriber set at frequency f = susceptiveness factor for set involved.

I_r = receiver current in microamperes (for the type of receiver involved) for reference noise at frequency f (Fig. 13 for three different receivers).

Values of N_f for the 144 receiver, calculated by the above expression, require no corrections, since present receiver noise transmission impairments are related to noise magnitudes in this type of receiver. Values of N_f so calculated for the 557 and HA1 types of receivers are not representative of the interfering effect on the present standard decibel scale of noise for the 144 receiver. For the final results of all three receivers to be on approximately the same basis as to noise transmission impairments, it is necessary to adjust the N_f values of the 557 and HA1 receivers by factors of +4db and −4db, respectively, which factors are based on the results of judgment tests. By such adjustments, the readings are in *dba*, a term that can be interpreted as representing the quantity that results after properly "adjusting" the decibel reading of the noise measuring set. When the reading is thus adjusted all noise results will be on a common basis.

Receiver →	Currents			Voltages			Receiver →	Currents			Voltages		
	144	557	HA1	144	557	HA1		144	557	HA1	144	557	HA1

FIG. 13. Receiver Currents and Voltages Corresponding to Reference Noise.* (Report 46, J.C.P.C.)

* Weighted currents and voltages based on representative receiver impedances and definition of reference noise as 10^{-12} watt dissipated in each receiver at 1000 cycles.

Power Level and Sensitivity. The susceptiveness of telephone circuits to induced noise from power-supply circuits or other outside influences depends to a considerable degree on the levels of the voltages and currents used in speech transmission and in the efficiency of the telephone terminal apparatus in converting electrical into sound power. Power level, as discussed here, refers to the level of speech currents (with respect to reference level of speech transmission) and not to a level measured in watts.

Speech power, and consequently electrical power generated by a subscriber set telephone transmitter, which is actuated by speech power, varies over a wide range of values and frequencies. This variation will occur with any one speaker and is usually different for different speakers. Electrical power also varies in different toll and exchange circuits, owing to the different types of lines and apparatus encountered and line length. In one investigation, the average acoustic power of speech produced by 16 talkers was of the order of 10 microwatts. The average ratio of the maximum instantaneous power to the average power, for the various vowel sounds only, was of the order of 15 to 1, whereas the ratio of the maximum to average power for a continuous sine wave is 2 to 1, thus showing the much wider variation of speech power as compared to generated electric power.

The power on commercial telephone circuits is conveniently determined by a device known as the volume indicator. This device consists primarily of a rectifier-type indicating meter of specific dynamic characteristics. When measuring speech power, the meter deflections fluctuate continually in response to the variations of speech power. Because of this varying deflection, it is necessary to specify a standard method of interpreting the indications, which involves adjusting a calibrated potentiometer, associated with the meter, to maintain the meter needle deflections approximately in a specified range on the scale. When these deflections correspond to the specified reading, with the volume indicator connected across 600 ohms, and the potentiometer is set at zero, the power indicated by the meter in the circuit being measured is zero VU (volume units).

Since, by the action of the carbon granule transmitter, a relatively large amount of electrical power is controlled by movement of the diaphragm, the electrical power delivered to a telephone circuit is much greater (of the order of several hundred times) than the acoustic power delivered to the transmitter. This amplification is of value in maintaining speech power at satisfactory levels above induced power current levels.

Transmitter developments have tended to raise the response level for some frequencies in order to give a more nearly flat frequency characteristic over the voice range without materially increasing the maximum level output of the transmitter. Such a characteristic improves the articulate qualities of the speech and hence effective transmission.

Receiver developments have also increased receiver efficiency over the earlier periods of operation, in addition to flattening its response over the voice range. However, its actual efficiency (electrical power input to acoustic power output) is relatively low. The power loss in the receiver at low frequencies, such as 25 and 60 cycles and their lower harmonics, is much greater than at frequencies in the higher voice range. The combination of amplification of voice currents in the telephone transmitter with noise current loss in the receiver permits delivering to the subscriber satisfactory speech power while keeping within tolerable limits the sound levels due to ordinary amounts of induced noise.

Speech levels on toll circuits are, in general, maintained at about specified levels by means of telephone repeaters (not usually employed on exchange circuits), which amplify the speech as well as any noise currents and voltages induced in the toll circuits. These repeaters are usually spaced at suitable intervals on a toll circuit to provide the proper speech level without overloading the amplifier and without causing cross-induction between adjacent circuits, due to excessive or inadequate levels.

The trend toward improved balance of party-line subscriber sets and some parts of central-office circuits permits increasing the speech-to-noise level ratio in exchange plant. Any betterments of this type, within limits, which increase the signal-to-noise ratio tend to decrease the noise effects in telephone circuits.

32. NOISE INDUCTION MITIGATION

Noise induction mitigation usually involves careful consideration of at least several of a large number of factors, which may be broadly classified under the headings: (*a*) influence factors; (*b*) coupling factors; (*c*) susceptiveness factors.

COOPERATIVE PLANNING in connection with the design and location of lines and systems is of great importance. These cooperative plans generally are directed toward: (*a*) coordinating the locations of lines; (*b*) incorporating in the design of both systems those features which will limit the influence and susceptiveness.

By cooperative planning, not only can the number of exposures be limited but also the general designs of the systems can be made such that treatment of individual exposures is materially simplified. Furthermore, in connection with new construction or changes in either system, coordination can be considered before expenditures or other commitments are made.

CONTROL OF INFLUENCE FACTORS. Residual currents and voltages of the triple-harmonic series can be controlled by one or more of the following means:

(*a*) Opening the neutral-to-ground connection of the machine or transformer bank where the triples originate. This can be done only where other system grounding arrangements, adequate from the standpoint of power system stability and relaying, are available.

(*b*) Opening the neutral-to-ground connection of transformer banks through which triples from another source complete their path. System stability and relaying must also be considered in this connection.

(*c*) Providing a path for triples (such as with a wye-delta bank), which tends to shunt them out of the exposure.

(*d*) The use of wave traps (anti-resonant circuits tuned to the important harmonics), reactances, or other devices in the neutral-to-ground connections at locations where triples originate.

(*e*) The use of transformer connections (such as wye-delta or delta-delta) through which triples will not pass.

(*f*) The use of rotating machines, which have a low influence factor.

Note: The last two measures are usually of the greatest importance in connection with cooperative advance planning, since to change existing equipment to these types may be unduly expensive.

Residual currents and voltages of the non-triple harmonic series can be controlled by:

(*a*) Reduction of the unbalance which gives rise to them, as by changing single-phase taps to 3-phase, balancing single-phase taps among the phases of the 3-phase line, or balancing loads among the 3 phases, where neutrals are multigrounded.

(*b*) Absorption by wye-delta banks or other means.

In addition to the design of power apparatus to limit harmonics as far as practicable, and the avoidance of excessive magnetic densities, frequency selective devices, to filter out harmonics, have been used in some situations, for example:

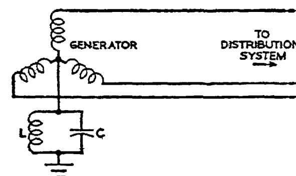
(*a*) On the d-c sides of trolley rectifiers.

(*b*) On the a-c sides of rectifiers.

(*c*) Across the terminals of rotating machines to reduce important balanced harmonic currents and voltages.

(*d*) In the neutral-to-ground connections of generators, synchronous converters, and other power devices, to reduce triple-harmonic voltages and currents, an example of which is shown in Fig. 14.

CONTROL OF COUPLING FACTORS. One highly satisfactory method for the control of inductive coupling, when it can be employed, is the complete physical separation of the power and telephone lines. However, in built-up communities both types of service are required by the public, making it necessary to utilize the same routes for distribution. For intercity toll lines, which are usually important backbone routes for long-haul communication traffic, frequently reasonable separation from power transmission systems can be obtained, particularly with the proper cooperative advance planning.



Frequency which trap is tuned to suppress

$$= F = \frac{10^3}{2\pi \sqrt{LC}}$$

L = inductance (henrys)
C = capacitance (microfarads)

FIG. 14. Wave Trap in Grounded Neutral of Line-connected Generator (Report 12, J.C.P.C.)

Where power line parallels with open-wire communication lines (toll or exchange) are created, transpositions are usually effective in controlling the resulting inductive couplings, and these may be required on a coordinated basis.

Whether the coordination of telephone transpositions with the discontinuities in the exposure, or the use of power-circuit transpositions, or both, is desirable in a specific case will depend on the relative importance of direct metallic-circuit induction and longitudinal-circuit induction acting on telephone-circuit unbalances, and on the importance of the induction from the balanced and residual components of the power-circuit voltages and currents.

Telephone transpositions must also be effective in controlling cross-induction (cross-talk) between telephone circuits. Standard transposition arrangements have been devised to meet this requirement for different classes of open-wire facilities. Two of such arrangements, which are available, are shown for four arms of wire in Figs. 15 and 16.

Sometimes, unavoidable irregularities occur in the spacing of poles, in distances between power and telephone circuits, in the presence of shielding objects such as other communication lines and trolley systems, and in heights of the circuits, which it is not practicable to take into account in the transposition design. Where these irregularities are large, the effectiveness of the transposition arrangements is correspondingly impaired.

Possible benefits are illustrated by noise measurements in the rural joint-use exposures, established in Alabama, Minnesota, and South Dakota (see article 29). The ratio of receiver noise to noise-to-ground is a good indicator of the effectiveness of noise-reduction measures, and such measurements, made under normal conditions, gave ratios of the order of -36 db (about 1 to 60 in voltage), where the IT (effective power harmonic currents in the line times the voltage interference factor) is fairly high. A ratio of this order is adequate with respect to noise, except in extreme exposures, and should result in noise on rural joint-use circuits comparable to that on urban party-line circuits in cable.

The favorable noise results in these instances are due partly to the effectiveness of the transposition scheme used, which employs frequent, point-type transpositions on tandem brackets and an average wire spacing of only about 7 in. Also in many of the exposures the power circuit is of the single-phase common-neutral type with vertical configuration, for which, in joint use, the direct metallic induction into a horizontal telephone circuit is inherently low. Of course, low values of receiver noise are not obtainable unless the telephone circuits are well balanced.

Shielding. When either or both of the telephone and power facilities are enclosed in metallic cable sheath, having a relatively low resistance to ground, the sheath acts as an effective shield against both electric and magnetic induction. For magnetic induction, the induced longitudinal currents flow along the sheath, which has a finite resistance per unit of length, different from the enclosed conductors, and complete shielding from such currents is thus not obtainable.

Present trends are toward bonding local distribution aerial cable to multi-grounded power neutrals, where these neutrals are well bonded to extensive public water systems, since, in the usual case, the cable sheath becomes quite closely associated with the common power neutral through the telephone drops, station protector grounds, power secondary services, and telephone company practices of placing protector blocks between working lines and the cable sheath. Frequent bonds between the common neutral and cable sheath (about every 1/4 mile or less) are not only advantageous from a protection standpoint but also useful for noise mitigation.

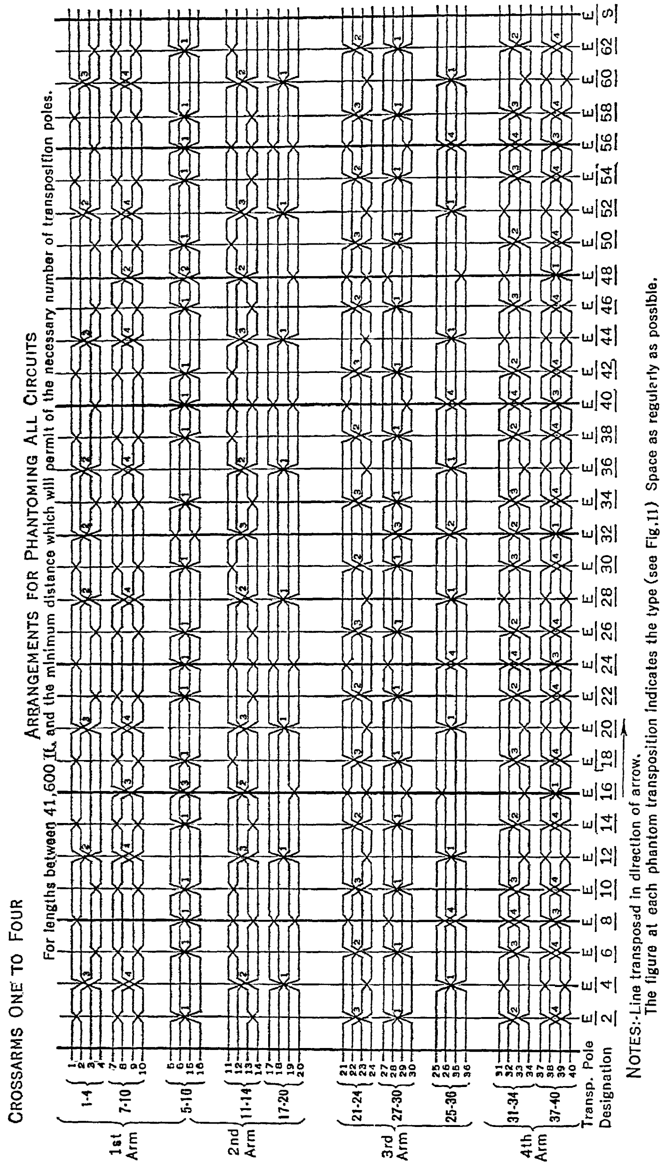


Fig. 15. Typical Transposition Scheme for Phantomed Circuits Suitable for Use in Inductive Exposures (Courtesy Bell System)

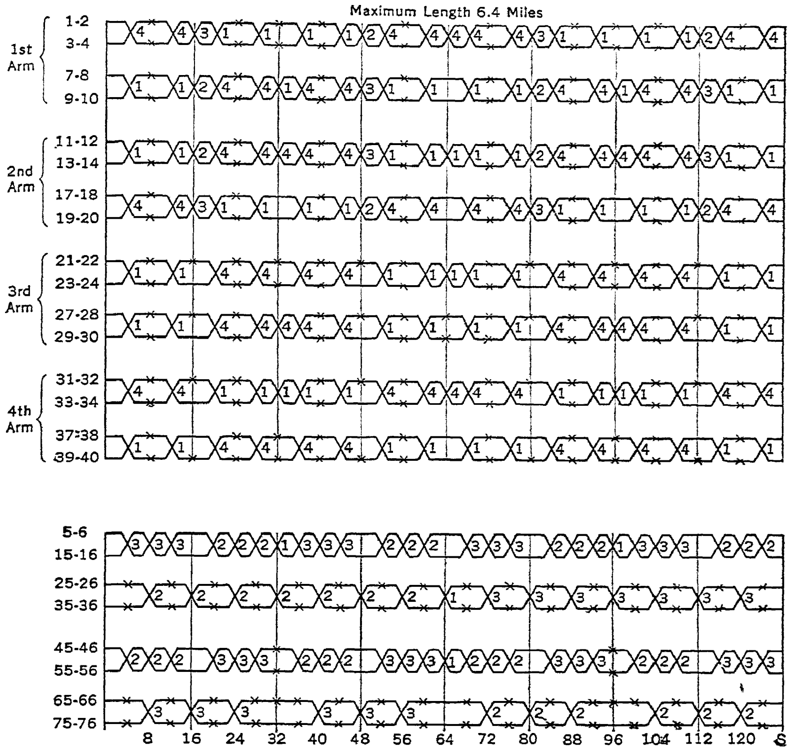
Such bonding usually results in an average reduction of subscriber receiver noise of the order of 2 to 1 for station sets equipped with single condensers and low-impedance ringers to ground. The average reduction in noise to ground is about 3 to 1. In non-public water-pipe areas the noise reductions obtained by bonding to the neutral depend upon the resistance to ground of the neutral conductor: the lower the resistance, the greater the reduction.

For power systems of the 2.3/4.0-kv type, increased potentials on the telephone sheath may generally result from bonding to the power neutral, but tests indicate no cable insula-



NOTE:—The figure at each phantom transposition indicates the type (see Fig. 11).

FIG. 16. Typical Transposition Scheme (Improved Type) for Phantomed Circuits Suitable for Use in Inductive Exposures (Courtesy Bell System)

tion failures due to this potential increase. In trolley areas, additional direct current will usually be transferred to the underground telephone cable sheaths because of power neutral bonding, but the increase in sheath current will probably not require additional corrective measures for electrolysis.

The effectiveness of shielding is expressed in terms of a *shield factor*, which is the ratio of the noise in the shielded to the noise in the non-shielded condition. Figure 17 shows observed shield factors in four public water system areas obtained with telephone cable sheaths bonded to a multigrounded power circuit neutral at a number of places.

CONTROL OF SUSCEPTIVENESS. In toll circuits, which are designed to be symmetrical with respect to earth, the reduction of unbalances is usually a matter of correcting conditions which are the result of deterioration or maintenance, although situations occasionally arise where the design of apparatus is involved. The former includes:

(*a*) High-resistance joints. The remedy is to make a new joint.

(*b*) Leakage caused in open-wire circuits

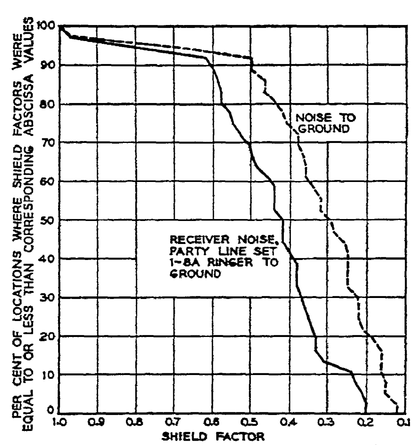


FIG. 17. Shield Factors—Telephone Cable Sheath Bonded to Power Circuit Neutral (Courtesy Bell System)

by trees or broken or missing insulators. In cable circuits, leakage is usually caused by moisture entering at a sheath break.

(*c*) Capacitance unbalances in open-wire circuits. The remedy involves a careful check of the transpositions either by inspection or by suitable electrical testing means.

(*d*) Incorrect connections or unbalanced arrangements of apparatus at terminals. For example, composite sets should not be placed on one side circuit of a phantom group without similar sets being placed on the other.

(*e*) Incorrect connections in entrance cables, such as split pairs or quads.

In regard to design, the causes of unbalances are usually in terminal apparatus, where the elements in the two wires of a circuit (or the two sides of a phantom group) are not sufficiently alike in impedance at noise frequencies. Modern apparatus is usually designed so that the series impedances and admittances to ground are very closely similar for the wires in a pair or quad. In some of the older designs, however, the degree of balance may not be sufficiently high. Sometimes, improvements can be secured by selecting among existing equipment the units having similar characteristics and grouping them together on pairs or quads. In some instances, there may be unbalances in entrance cables or office cabling, for example where phantomed circuits are routed through non-quadded cables.

In the exchange plant, unbalances due to connections of ringers to ground can be reduced by the use of high-impedance ringers or by other subset apparatus with improved balance. Central-office-circuit unbalances may need to be improved by modifications in or replacements of existing apparatus of the older types and of unsymmetrical design. The more recently designed central-office equipment is better balanced, and further improvements in this respect may be expected.

Sometimes improvement can be secured by inserting a balancing impedance in the other side of the circuit. Through cooperative advance planning, apparatus having improved balance can be introduced in an orderly manner.

Isolation of equipment unbalances can sometimes be secured by inserting between the apparatus and the line a well-balanced repeating coil without ground connections or with ground connections so arranged that longitudinal voltages and currents are not transmitted. It is necessary to arrange the circuit so that signaling and supervision will not be interfered with. A less effective but sometimes adequate method of isolation consists of inserting between the apparatus and the line a well-balanced coil so connected as to be non-inductive to the metallic circuit but to present a high longitudinal impedance. A well-balanced repeating coil, with the windings suitably connected, will frequently serve this purpose. This method has the advantage that it can be readily arranged so as not to interfere with d-c signaling and supervision. In both the toll and exchange plants, it is frequently necessary to guard against interconnection of balanced and unbalanced circuits through cord circuits not containing repeating coils, since such a connection would be unbalanced. This can be done by avoiding the use of such cord circuits for these connections or by isolating the unbalanced lines by repeating coils.

Figure 18 shows a schematic of a typical local step-by-step connector circuit in the talking condition, with a long line circuit inserted adjacent to the line in order to prevent longitudinal current flow from the calling line causing noise, due to possible unbalances in relays *A* and *D* and in the 2-μf series condensers. This is one means of preventing longitudinal circuit noise reaching the called subscriber from a connected line which is affected by power induction.

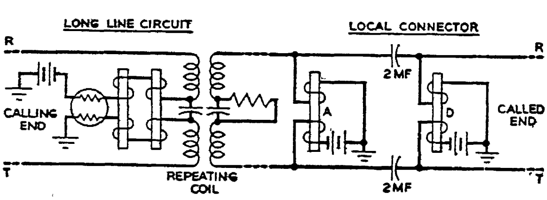

Fig. 18. Schematic of Typical Local Step-by-step Connector Circuit in Talking Condition Associated with a Long Line Circuit (Courtesy Bell System)

Transmission Levels. The effect of noise is lowered as the power level of the voice currents of telephone circuits is raised. In the toll plant, this fact has had a marked bearing on the sizes of wire used and the location of repeater stations. One of the limitations on the degree to which levels can be raised on toll circuits by repeaters is the difficulty of avoiding cross-talk between circuits on which there are large level differences. Subject to this limitation, however, advantage may sometimes be taken in specific situations of allocating repeater gains in such a way as to use the highest practicable level through inductive exposures.

In the exchange plant, telephone repeaters are normally not employed, so that the control of levels in connection with specific noise situations is a less practicable procedure.

However, the desirability of utilizing the highest practicable levels has had an important bearing in the development of instruments, cables, and other facilities.

Other Devices. In special cases, neutralizing transformers, resonant shunts, or resonant drainage to ground, applied to the telephone circuits, offer possibilities as coordinative measures for the reduction of noise induction.

The neutralizing transformer is employed, primarily, in local communication circuits serving power stations to limit voltages to ground at such stations when power-line faults

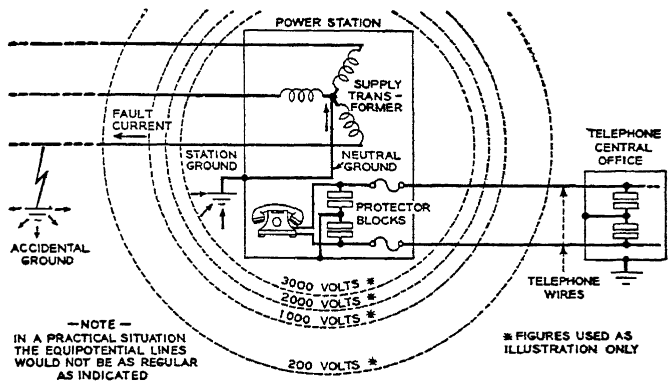

FIG. 19. Diagram Illustrating Rise in Station Ground Potential Due to Power Line Fault (Report 44, J.C.P.C.)

occur. Without the transformer, the rise in potential of the power station ground, and consequently the telephone set protector ground, would frequently be enough to break down the protector blocks and disable telephone service, as shown in Fig. 19. With the transformer, differences of potential between the communication circuit and nearby grounded structures are materially reduced, as indicated in Fig. 20, thus minimizing hazard to personnel, cable troubles, and service interruptions.

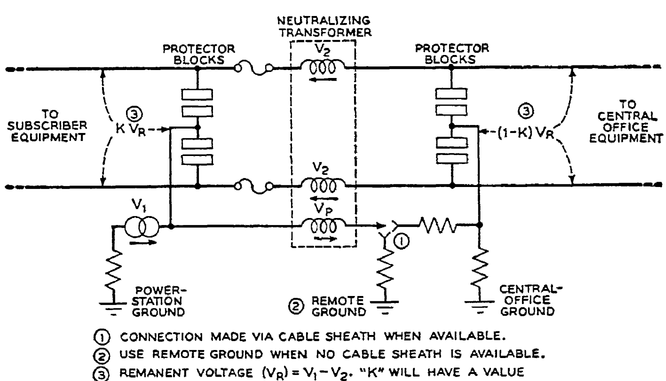

FIG. 20. Diagram Illustrating Action of Neutralizing Transformer in Neutralizing Voltages on a Circuit Subject to Ground Potential Rise (Report 44, J.C.P.C.)

Ground Return Circuits. Ground return telephone circuits, being inherently unbalanced to ground, require methods of coordination with power circuits different from those employed for metallic telephone circuits, such as previously discussed in this section. Ground return power circuits are not considered standard practice but are frequently operated as single-phase grounded neutral circuits in rural power systems. Coordinative measures are available for this type of power circuit with metallic telephone circuits, such as control of power-circuit influence factors and transpositions, drainage coils, or high impedances (to predominating harmonics) inserted in the telephone circuit.

33. LOW-FREQUENCY INDUCTION

Low-frequency induction, under *normal balanced power system operation,* rarely creates a noise problem in communication systems. However, under some normal operating conditions, the induced ground-wire (for lightning protection) current flow at the power-circuit fundamental frequency may be objectionable, particularly in telegraph operation.

When an abnormal condition, such as a grounded phase wire, occurs on a power circuit, relatively large currents at the fundamental frequency flow from the power circuit to ground for *grounded* power systems. This may result in excessive low-frequency induction in any paralleling communication circuits. This condition also obtains in an *isolated* power system when two or more phases are faulted.

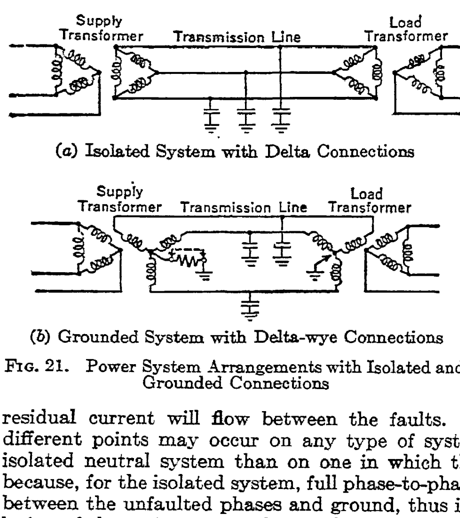
The magnitude of the voltage induced in a telephone circuit at the time of a power-circuit fault depends chiefly on the magnitude of residual currents and on the exposure conditions.

Residual Currents. If 1 phase of a 3-phase power line develops a fault to ground the currents in the 3 phases become unequal, and their vector sum, which is the residual current, is no longer zero. In most low-frequency induction problems, residual current is far more important than residual voltage.

The relatively large inductive influence of residual current is due to the fact that it exists in a circuit consisting of the line conductors in parallel as one side and the earth as the other side. Since much of the return current is deep in the earth, its neutralizing action is small.

The chief factors that determine the magnitude of the residual currents are (1) the power-circuit voltage, (2) the line and apparatus impedances, (3) the fault and earth impedances, (4) the impedances of the neutral ground connections, (5) the type of ground wire, if used, and (6) the circuit configuration including ground wires.

In analyzing the impedances controlling fault current, two general types of power systems must be considered: the *grounded neutral*, and *isolated neutral* systems. These are illustrated in Fig. 21. In the *grounded neutral* system, the neutrals of one or more transformer banks are grounded directly or through impedance so that, in the event of a fault, a path for current is established from the fault through the earth and returning through the neutral-to-ground connections. In the *isolated neutral* system, there are normally no grounds on the system so that, in the event of a fault, the path for fault currents is through the capacitances of the unfaulted phases to earth. Hence, for a single fault, the fault current is limited to the charging and leakage current.



(*a*) Isolated System with Delta Connections

(*b*) Grounded System with Delta-wye Connections

FIG. 21. Power System Arrangements with Isolated and Grounded Connections

If, in an isolated neutral system, a second fault to ground occurs on another phase while the first persists, a residual current will flow between the faults. Simultaneous faults on two phases at different points may occur on any type of system but are more likely to occur on an isolated neutral system than on one in which the neutral is solidly grounded. This is because, for the isolated system, full phase-to-phase or possibly higher voltage is impressed between the unfaulted phases and ground, thus increasing the voltage stress on the insulation of the entire system during the time of fault.

A system grounded through a neutral impedance has some of the characteristics of an isolated neutral system. Generally, the addition of neutral impedance tends to reduce the fault current, this effect being proportionately larger for faults near the neutral grounding points. This reduces the voltage induced on nearby telephone lines and may have advantages to the power system. On the other hand, increasing the neutral impedance may introduce problems in power system relaying. It may also increase overvoltages on the power system.

The duration of residual current is also important, since the length of time that the induced voltage persists has important reactions on its effects. For example, with the carbon block protectors, the chance of their becoming permanently grounded, with consequent interruption of service, depends not only upon the amount of current through the protector but also upon its duration. Likewise, other effects which are described later are materially affected by the duration of the induced voltage. Since, except for self-clearing faults, the duration of fault current is determined by the time of operation of the power-current interrupting devices, their reliability and speed of operation are important.

COUPLING FACTORS. Coupling is proportional to the length of the exposure for uniform separation. It varies with separation in a manner which is affected, among other things, by the structure of the earth. This effect can be summarized as follows:

Under the conditions of low-frequency induction, the telephone wires comprise one side of a loop, the other side of which is the earth. Likewise, the power wires comprise one side of a loop, the other side being the earth. The magnetic coupling between two parallel loops at a given separation increases as the size of the loops increases. The sizes of the loops are determined by the distribution of the return current in the earth. Generally speaking, the greater the resistivity of the earth, the more the current will spread and the greater will be the coupling to an adjacent circuit.

The effect of earth resistivity on coupling is much greater for wide separations than where the lines are close together. Consequently, with high-resistivity earth, not only is the coupling higher at all separations than with low-resistivity earth, but (except for very wide separations) the percentage reduction secured by increasing the separation a given amount is smaller.

Figure 22 shows, for several earth resistivities, the variation of mutual resistance, reactance, and impedance with separation, based on calculations using Carson's formula and a frequency of 60 cycles, without shielding.

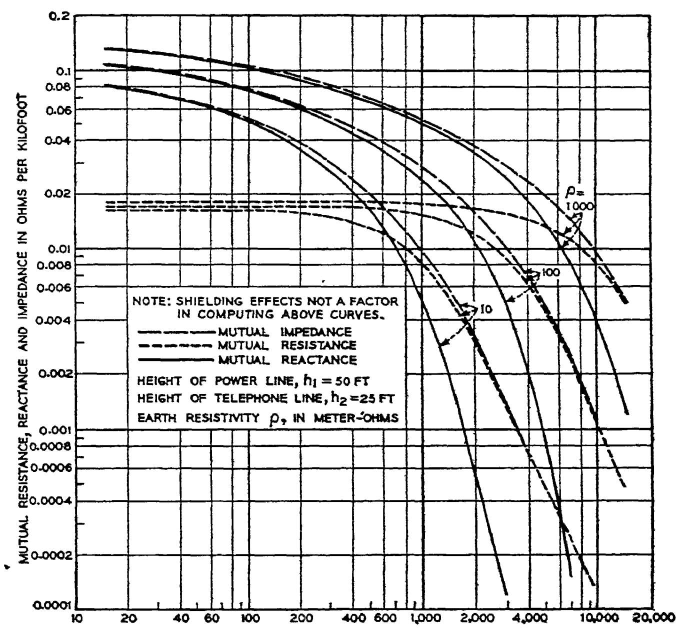


FIG. 22. Variation of Mutual Resistance, Reactance, and Impedance with Separation (at 60 cycles) (Report 14, J.C.P.C.)

SHORT-CIRCUIT CURRENTS, during power-line faults, may be calculated by several *approximate* short-cut methods, one of which may briefly be described as follows:

(*a*) Prepare a diagram of the power-system network, showing lengths, location, and kva capacities of large generating sources and transformer banks; location, kva capacities, and connections of grounded neutral transformer banks; and magnitudes of neutral impedances, if any.

(*b*) Show the location and separation of the telephone-circuit exposure or exposures to the power-system network.

(*c*) Show the line-to-line operating power voltage.

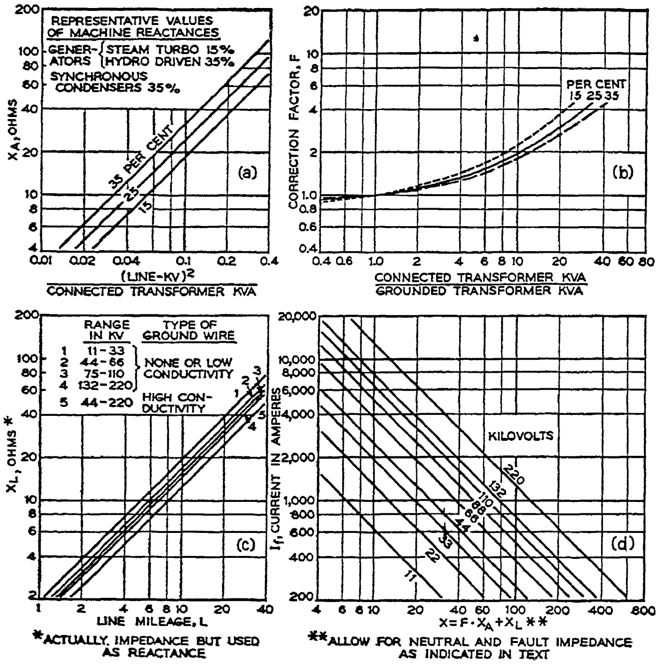

FIG. 23. Curves for a Quick Approximation of Fault Current Resulting from Single-phase Faults to Ground on Three-phase Systems (Courtesy Bell System)

(d) Using the various curves a, b, c, and d in Fig. 23, determine for a given situation:

1. X_A from $\dfrac{(\text{line kv})^2}{(\text{connected transformer kva at source supplying fault})}$, using Fig. 23a.

2. $F \cdot X_A$ from $\dfrac{\text{connected transformer kva}}{\text{grounded transformer kva}}$, using Fig. 23b.

Note: Connected transformer kva and grounded transformer kva refer respectively to (1) total connected capacity, irrespective of transformer connections, and (2) transformer banks, which will pass zero sequence current.

3. X_L = apparent reactance (actually impedance) of equivalent power line mileage from source to fault. (Use actual mileage, if only one power circuit is involved), using Fig. 23c.
4. $X = F \cdot X_A + X_L$.
5. $Z = \sqrt{R^2 + X^2}$, where R = neutral and fault resistances, if any.
6. Short-circuit (fault) current I_f, using Fig. 23d.

Notes: If connected generator kva is more or less than the connected transformer kva by a factor of 2 or more, use connected generator kva supplying fault, for Figs. 23a and b.

If a reactance X_N is used in the grounding neutral, replace X with $X + X_N$.

Figures 23a, c, and d are based on the following assumptions:

1. A single 60-cycle generating station.
2. Radial transmission line.
3. Total connected transformer kva at station equals connected generator kva.
4. Line side neutrals of all transformer banks are grounded and will pass zero sequence current.
5. All transformer and generator capacities are so bussed as to be effective in supplying faulted line.
6. All transformers have 8 per cent reactance, based on kva rating of bank.
7. Representative average conductor spacings and sizes.
8. Earth resistivity of 100 meter-ohms (in the case of Fig. 23c).

The above procedure is not to be considered an exact method of short-circuit current calculation, since it usually provides only a rough determination, the method of symmetrical components being the proper one for more accurate results (see *Electrical Engineers Handbook*, Vol. 1, Electric Power, H. Pender and Wm. A. Del Mar, John Wiley & Sons).

Having determined the mutual impedance Z_M, and short-circuit current I_f, for any given situation and power line fault, the longitudinal induced voltage E_f, on the adjacent communication aerial open wires or cable, is given by the expression

$$E_f = I_f \cdot Z_M \cdot \eta$$

(Z_M from Fig. 22 or similar curves; η = shield factor.)

SHIELDING. Another important factor in determining the net coupling is the effect of grounded wires or other linear grounded metallic structures along the exposure. Voltages are induced in such grounded metallic structures in the same way as they are induced in telephone wires, and these voltages establish currents. The induced currents flowing in

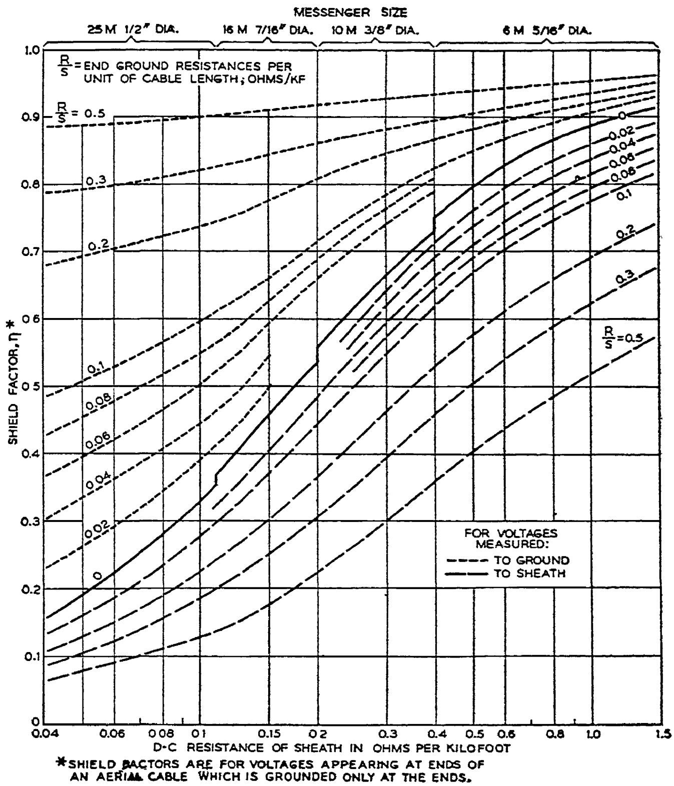

FIG. 24. Shield Factors for Aerial Lead Cable at 60 Cycles (Report 48, J.C.P.C.)

these structures set up magnetic fields, which generally oppose those from the power wires and reduce the induction in the telephone circuit. The effect of such currents in grounded structures is known as shielding.

The magnitude and phase relation of the current in a grounded conductor, and thus the shielding provided by it, depend on the impedance of the conductor with earth return. Hence, the shielding is increased, when the resistance of the conductor and its ground connections is reduced. Metallic cable sheaths comprise an important type of shielding conductor, as shown in Fig. 24 for aerial cables with plain lead sheath at 60 cycles; R is the sum of ground connection resistances at both ends of the cable sheath (in ohms) and S is the length of cable circuit between terminals or grounds (in kilofeet). With increasing end-ground resistance, the shield factors for voltages measured to ground increase, while the shield factors for the voltages to sheath (between sheath and conductors) decrease.

The earth resistivity was assumed to be 100 meter-ohms. Figure 25 shows shielding effects at 60 cycles from grounded telephone open wires.

In analyzing the distribution of induced voltage between a telephone circuit and ground, assume first that no protectors are operated. Under this condition, the voltages to ground on the telephone wires at various points are determined by the impedances between the wires and ground along the line and at central offices where equipment is connected to them. The voltage to ground at either end of the exposure is equal to the product of the longitudinal current and the impedance to ground seen looking away from the exposure at that end. In practice, the variety of impedance distributions encountered is almost infinite, and the corresponding voltage distributions vary over a wide range.

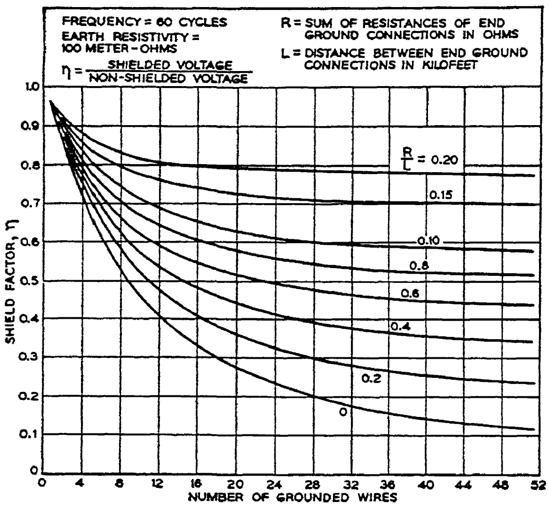

FIG. 25. Shielding Resulting from the Grounding of Conductors of an Open-wire Telephone Line (Courtesy Bell System)

If voltage to ground at any point where protectors are located exceeds the operating voltage of the protector, the protector operates and three things happen:

(*a*) The voltage to ground at the point of protector breakdown is reduced to a low value. This causes an increase in voltage across the protectors at the opposite end, and in most cases they also will operate.

(*b*) The operation of the protectors at the two ends completes a loop consisting of the telephone circuit and ground, so that the induced voltage will cause current to flow through both protectors.

(*c*) The voltages to ground on the circuits on which protectors have operated are changed and redistributed, and the voltages on the other telephone circuits are also changed and redistributed, owing to shielding.

All these effects take place within a very short time after the induced voltage is applied, so that, for all practical purposes, they can usually be considered instantaneous.

ACOUSTIC DISTURBANCE. Strictly the term "acoustic disturbance" should be used only with reference to the effect of an abnormally loud sound on a person subjected to it. The term has also come to designate a noise (usually transient) in a telephone receiver, the intensity of which is considerably higher than that of speech. It is produced by an excessive voltage across the terminals of the receiver.

Although induced voltages usually appear in equal magnitudes on the two sides of a circuit, the protector gaps on the two sides of the circuit discharge in an unsymmetrical manner, with the result that a voltage higher than normal appears across the circuit. When this occurs, a loud noise is produced in the receiver of a telephone set bridged across the circuit, causing acoustic disturbance. This may be produced by low-frequency induction, lightning, contacts between power and telephone circuits, and by other causes.

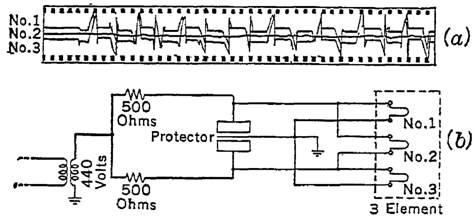

FIG. 26. Oscillograms Showing Protector Performance with Impressed Potentials across the Protector Blocks

Figure 26 shows oscillograph traces of voltages measured across operating protector blocks. Each outside trace shows the voltage across its related block to ground. It will be noted that the two traces are not identical. The middle trace shows the resulting voltage across the circuit. It is this voltage that may cause acoustic disturbance. The very jagged outline of these traces indicates that many frequencies are present.

PROBABILITY FACTORS. In the preceding discussion, a number of factors were mentioned which may vary between different occurrences in the same exposure. Among them are:

(*a*) The impedance in the faulted circuit. This varies with the location of faults, effective fault resistance, and other factors, with consequent effect on the magnitude of the fault current.

(b) The duration of the fault current. This varies with conditions that affect the speed of operation of the power-circuit interrupting devices.

(c) Longitudinal voltage, voltage to ground, and current through protectors. These may vary widely with small variations in the locations of faults when they occur within the exposure.

(d) Shielding due to the operation of protectors on telephone circuits. The number of protectors that operate may vary widely, depending on their characteristics and the magnitude of the induced voltage.

LOW-FREQUENCY INDUCTION CONTROL, though not usually required under normal operating conditions, must be planned for in advance where service may be affected by abnormal power-circuit conditions and where prompt action must be taken to restore normal operating conditions when abnormal conditions arise. Cooperative advance notices of construction and coordinative plans are essential in controlling the generally serious effects of low-frequency induction.

The low-frequency coordination of power and communication systems may be accomplished by (1) measures in the power system to limit the influence, (2) measures in the communication system to limit the susceptiveness, and (3) coordinated location of lines or other means to reduce coupling. In a specific situation, one measure may be sufficient or two or more measures may be required, depending on the conditions.

POWER SYSTEMS. Measures to reduce the inductive influence of power systems should be directed to limiting the magnitude of unbalanced currents and voltages, particularly under abnormal conditions, and to reducing the duration and frequency of occurrence of faults. Of such measures, some are concerned with questions of line and system design and must be incorporated in the construction plans and others may be added later, if found necessary as the result of operating experience.

Fault-resistive Design and Construction. Since lightning is a major cause of faults on power systems, the developments in methods of lightning protection have substantially aided the low-frequency coordination problem.

Fault-current Lmitation. Resistors or reactors in the neutrals of power systems provide a means of limiting the magnitude of the residual currents except when double faults occur.

Shielding. Ground wires on a power line, though they may increase the total residual current, provide shielding by reducing the strength of the external electric and magnetic fields. Under fault conditions, ground wires generally reduce the voltages induced in paralleling communication circuits. The effectiveness of such shielding depends on the impedance of the shielding conductor and its ground connections. Under favorable conditions, the induced voltage at 60 cycles may be reduced about 40 per cent by the use of one wire, and about 60 per cent by the use of two wires. However, such shield wires may increase the normal 60-cycle induced voltage, and this reaction may be important where ground-return telegraph circuits are involved.

High-speed Circuit Breakers and Relays. High-speed relay and switching systems have been developed that reduce the time duration of a power-line fault to the order of $^1/_5$ second or less under favorable conditions, thus tending to minimize the effects of induction. Because of the expense, high-speed switching can seldom be justified except on important high-voltage transmission systems.

Improvement in Balance. Low-frequency induction between power and communication lines is sometimes experienced under normal operating conditions. On grounded telegraph and signal lines, the trouble usually manifests itself by a chattering of telegraph instruments or by false signals. Sometimes power-line transpositions will aid in these situations.

COMMUNICATION SYSTEMS. In general, coordinative measures, applicable to the communication system, take the form of arrangements or devices for removing or counteracting the voltages, the voltage to ground, or the current through telephone protectors.

Relay Protectors. The short-circuiting relay (SCR) protector is designed for application to open-wire telephone lines which may be subjected to low-frequency induction of sufficient magnitude to warrant the costs of providing it. This device employs, for each open-wire circuit, a relay which short-circuits the usual protector blocks associated with the circuit and grounds the circuit. In one device of this type (Fig. 27), a master relay controls operation of all of the individual circuit relays, the master relay operating in about 0.01 second and the individual relays about 0.15 second later, after any one of the line protector blocks operates. The master relay operates when about 1 amp or more of 60-cycle current flows through the primary winding of the saturating transformer to ground. This produces a voltage across the secondary of the transformer, operating the master "J" type relay, causing the short-circuiting relays to operate and short-circuit each line and its associated protector blocks. The master relay can be adjusted to release on about 0.8 amp of line current. Thus, with operation of the pilot relay, all relays operate on about 0.5 amp direct current and ground all wires on the line at the locations where this equipment is installed. The equipment may be installed at any outside point on the open-wire line or in the central office, as desired. It is assembled in groups for application to 10 to 50 or more wires and, together with the dry-cell batteries for operating the circuit relays, is housed in standard cable terminal boxes.

Acoustic Disturbance Reducers. One of the most effective ways of reducing acoustic disturbance to operators is to shunt their receivers with a device that will have a high impedance at speech level and a low impedance at acoustic-disturbance level. One such device that has proved effective consists of oppositely poled copper oxide rectifier disks connected across the receiver. These have the property of greatly diminishing impedance with increasing voltage.

Shielding. Shielding on a telephone line may be effected by special grounded conductors, by working conductors, or by cable sheaths. Miscellaneous structures, such as pipe

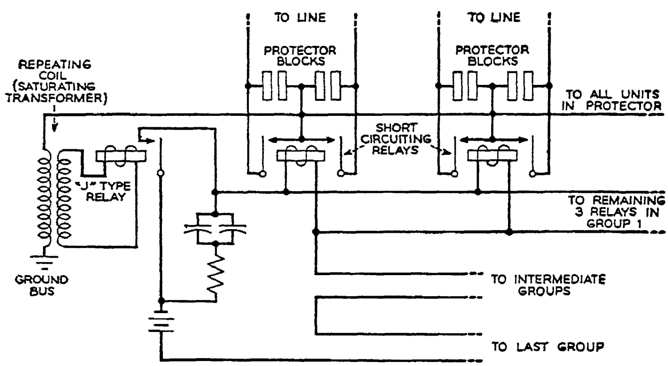

FIG. 27. A-c Type Short-circuiting Relay Protector Circuit—Multi-grounding (Report 41, J.C.P.C.)

lines or rails in the immediate vicinity of an exposure, also introduce shielding. A high-conductivity shield wire, well grounded at the ends of the exposure and at intermediate points, may reduce the induced voltage by as much as 40 per cent at 60 cycles.

The lead sheath of a 2 $^5/_8$-in.-diameter aerial telephone cable, if effectively grounded at the ends, reduces the voltage induced in the conductors within the cable by about 50 per cent at 60 cycles. The shielding secured from the sheath of an underground cable of this size is also about 50 per cent. The large number of conductors in a cable affords mutual shielding which varies from a negligible to a considerable amount (sometimes exceeding 95 per cent), depending upon many factors, important among which is the extent of the cable beyond the ends of the exposure and the grounding conditions on the circuits at their terminals. If two or more cables are close together through an exposure, each benefits by the shielding action of the others, so that the shielding increases with the number of cables.

If the lead sheath of the cable is surrounded by magnetic material, as by armoring or placing cable in iron pipe, the shielding may be largely increased. With a form of iron tape armored cable, shielding at 60 cycles may be 80 per cent or more, assuming effective grounding.

Other Measures. Sometimes drainage and neutralizing transformers may be of use. Drainage is achieved by grounding the midpoint of a coil connected between the two sides of the communication circuit, the coil being wound in such a way that it presents a low impedance to longitudinal currents and a high impedance to alternating currents in the metallic circuit. The voltage to ground on the communication circuit at the point where the drainage is connected is limited to the voltage drop over the impedance of the coil and ground connection.

The neutralizing transformer introduces into the exposed communication wires a voltage in opposition to the disturbing voltage, thereby partly neutralizing it, as described under "Noise Induction Mitigation" in article 32.

On account of the cost and the operating limitations that these measures impose on the use of carrier, d-c telegraph, and testing, they have only occasionally been employed in the commercial telephone plant. Neutralizing transformers have, however, been used on telegraph circuits and for special protection purposes on other types of communication and signal circuits.

1. DEFINITIONS

By *frequency* is meant the number of times any periodic phenomenon recurs in a standard unit of time. In general it is stated as the number of complete vibrations, or oscillations, or revolutions performed in 1 sec.

Occasionally other units of time are used, but usually they are specified so there is little or no ambiguity. Thus, we speak of revolutions per minute. Sometimes tuning forks are stamped DV or VS after the number designating the frequency. DV, which stands for "double vibrations," means frequency as defined above, that is, the number of complete periods per second. VS, which stands for "vibrations per second," designates twice the true frequency.

The *period* of a cyclic or periodic phenomenon is the time duration of one complete cycle. The rates of slow periodic phenomena are usually expressed in terms of the period. For example, the period of a "seconds" pendulum is 2 sec.

Frequency may also be designated as *angular velocity*, especially in expressions representing the rate as a trigonometric function of time. Thus in expressions of the type

$$I = I_0 \sin (\omega t + \alpha)$$

the constant, $\omega = 2\pi f$, may be considered as an angular velocity.

Frequency may be expressed in terms of *wavelength* when the velocity of wave propagation in a medium is assumed. This is most often used in discussions of electromagnetic radiation where the velocity is approximately that of light, $c = 2.998 \times 10^{10}$ cm per sec. The general relationship between frequency, velocity, and wavelength is

$$f \text{ (or } \nu) = \frac{\text{Velocity}}{\text{Wavelength}} = \frac{v}{\lambda}$$

A standard of frequency differs from most other working standards in that it is a *rate* and cannot be represented completely by a physical body that can be preserved. Although the frequency of a bar, or other simple shape, can be defined approximately for a given mode of vibration in terms of its dimensions, density, elasticity, and coupling to other bodies, the effects of these factors will not remain constant with as great accuracy as that to which the resultant frequency can be measured in terms of astronomical time, that is, in terms of the rate of the earth's rotation on its axis.

In the present system of measurements, the *primary standard* of frequency is the rate of the earth's rotation, since all measurements of frequency are referred directly or indirectly to the *second* of the cgs system which is by definition 1/86,400 of a mean solar day.

By the application of recently discovered atomic or molecular resonance phenomena to the measurement of frequency and time it may be found possible eventually to place all such measurements on a more nearly absolute basis, quite independent of the stability of masses of matter such as now comprise the control elements in reference standards of frequency and time, and independent of variations known to exist in astronomical time itself. Some of these atomic and molecular resonance phenomena are in the range for which continuous oscillations at ultra-high frequency may be produced by modern vacuum-tube means, indicating the possibility of making frequency comparisons of high precision throughout the entire range of continuous magnetic waves. The possibility of so using these resonance phenomena was discussed by Professor I. I. Rabi in a talk before the American Physical Society and the American Association of Physics Teachers in January, 1945.

The great importance of this impending development lies in the idea that the atomic and molecular resonance phenomena, being properties of independent elementary particles of matter, appear to be in certain cases completely independent of temperature, pressure, and other ambient conditions, which in various degrees affect the behavior of all existing practical standards of frequency and time.

Table 1. Some Useful Frequency Formulas

1. A-c generator with alternate N and S poles: $f = \dfrac{\text{No. of poles} \times \text{rps}}{2}$

   Inductor generator: $f = \text{No. of poles} \times \text{rps}$

2. Electrical resonant circuit with L and C: $f = \dfrac{1}{2\pi\sqrt{LC}}$

   Same with L, C, and R in series: $f = \dfrac{1}{2\pi\sqrt{LC - (R^2/4L^2)}}$

3. Frequency of electromagnetic radiation (λ = wavelength): $f = \dfrac{3.00 \times 10^{10}}{\lambda(\text{cm})}$

   Frequency of sound vibrations in any medium: $f = \dfrac{1}{\lambda}\sqrt{\dfrac{\text{Young's modulus}}{\text{Density}}}$

4. If a condenser is charged to voltage E and completely discharged f times a second into a current-measuring device: $f = \dfrac{\text{Mean current}}{C \times E}$

5. The period T of a simple pendulum with double amplitude $= 2\theta$: $T = 2\pi\sqrt{\dfrac{l}{g}}\left(1 + \dfrac{1}{4}\sin^2\dfrac{\theta}{2} \cdots\right)$

   The frequency for small amplitude: $f = \dfrac{1}{2\pi}\sqrt{\dfrac{g}{l}}$

   Conical pendulum (angle θ to vertical): $f = \dfrac{1}{2\pi}\sqrt{\dfrac{g}{l\cos\theta}}$

   Vertical pendulum (mass supported on spring): $f = \dfrac{1}{2\pi}\sqrt{\dfrac{\text{Stiffness}}{\text{Mass}}}$

   Torsion pendulum: $f = \dfrac{1}{2\pi}\sqrt{\dfrac{\pi\eta R^4}{2lI}}$
   where η, l, and R are the torsion modulus, length, and radius of the supporting member, and I is the moment of inertia of the mass.

6. Stretched string: $f = \dfrac{1}{2l}\sqrt{\dfrac{\text{Tension}}{\text{Mass per unit length}}}$
   Overtones are $2f$, $3f$, etc.

7. Uniform rod, free-free, longitudinal: $f = \dfrac{1}{2l}\sqrt{\dfrac{\text{Young's modulus}}{\text{Density}}}$
   Overtones are $2f$, $3f$, etc.

8. Uniform round rod, free-free, torsion: $f = \dfrac{1}{2l}\sqrt{\dfrac{\text{Torsion modulus}}{\text{Density}}}$
   Overtones are $2f$, $3f$, etc.

9. Long air column open at both ends: $f = \dfrac{1}{2l}\sqrt{\dfrac{\gamma\cdot\text{Pressure}}{\text{Density}}}$
   γ = ratio of the specific heats.
   Overtones are $2f$, $3f$, etc.

   Long air column open at one end: $f = \dfrac{1}{4l}\sqrt{\dfrac{\gamma\ \text{Pressure}}{\text{Density}}}$
   Overtones are $3f$, $5f$, etc.

10. Straight free-free bar in flexure: $f = \dfrac{9\pi k}{8l^2}\sqrt{\dfrac{\text{Young's modulus}}{\text{Density}}}$

    k is radius of gyration of section.
    Overtones are $(5/3)^{2f}$, $(7/3)^{2f}$, $(9/3)^{2f}$, etc.

    For flexural vibrations in general, tuning forks, reeds, etc., having uniform section: $f = K\dfrac{t}{l^2}\sqrt{\dfrac{\text{Young's modulus}}{\text{Density}}}$
    where K is a constant for a given shape and mode of vibration.

11. For any note in the equally tempered scale where n is the total number of semitones above (+) or below (−) middle C. (A = 440 cps.) $f_{\pm n} = 220 \times 2^{(3\pm n)/12}$

    Exact frequency ratios between successive notes in the major diatonic scale are: 9/8, 10/9, 16/15, 9/8, 10/9, 9/8, 16/15.

12. Where l is the distance between nodes on Lecher wires or in a coaxial conductor: $f \doteq \dfrac{3 \times 10^{10}}{2l}$

The most accurate reference standards of frequency in use at present are vacuum-tube oscillators whose frequencies are controlled by mechanical vibrators made of quartz crystal. A special advantage of the oscillator type of standard is that its output of constant-frequency current can be sent over suitable communication channels and used anywhere as a reference standard of frequency. Such standards are maintained continuously by the laboratories of the National Bureau of Standards, the Bell System, and many others in America and abroad.

Oscillators of somewhat less accuracy have been built employing tuning forks or bars of metal for the frequency-controlling element. Usually these are coupled to the vacuum-tube circuit through electromagnetic means, but many such oscillators have been built using magnetostriction and electrostatic attraction for the coupling means. Prior to the general use of quartz for precise control, such oscillators were used in most frequency standard installations. Now they are used chiefly where the advantage of direct low-frequency control outweighs the requirement for extreme accuracy.

Although, for the greatest accuracy, frequency is defined and measured in terms of astronomical time, preferably by means of a combined time and frequency reference standard, there are many cases in which a good estimate of its value can be made from a knowledge of means controlling it or responding to it. Table 1 contains a number of formulas that may be used for the approximate determination of frequency under a variety of conditions.

Frequency measurements find their chief applications in electrical communication where they are used in the study and adjustment of various oscillators and electrical networks such as filters and equalizers. This applies in varying importance from the lowest frequencies employed in d-c telegraph to the highest used in ultra-short-wave radio.

They are involved in the control of power frequencies and in certain time systems. They are used in measuring linear and angular velocity and acceleration, for the study of vibration in mechanical systems, and for the most precise determinations of electrical-circuit constants.

They are of ever-increasing importance in basic physical studies involving relations between astronomical time, the velocity of light, and resonance phenomena in atoms and molecules.

2. USING A TIME STANDARD

COUNTING. Since frequency is defined as the number of recurrences of a cyclic phenomenon per unit of time, the most direct method of its measurement, and at the same time the most precise, is to count the total number of cycles during a known time interval and to divide by the number of elapsed seconds. The only inaccuracies in this method are in determining the time interval and in estimating the number of cycles. If the time error can be assumed to be negligible, and if the frequency is constant, the accuracy may be increased to any extent by increasing the duration of the measurement.

Depending on the nature and the frequency of the phenomena to be measured, and the accuracy required, the instrumentation may vary over a very wide range. For low frequencies, and with relatively low accuracy, a stop watch may be used to count recurrences over intervals of a few seconds. For greater accuracy, and for frequencies too high for direct perception, some automatic registering or totalizing means is required. By means of a chronograph or oscillograph, a recording can be made of the recurrences during a specified time interval which may be analyzed at leisure. By various counting means a continuous total may be produced from which the frequency may be determined with great accuracy in any desired time interval.

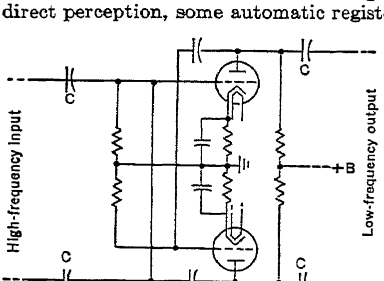

FIG. 1. Submultiple Generator of the Multivibrator Type. Capacitors C are for coupling only.

SYNCHRONOUS CLOCK. This in effect is the method used in calibrating the most accurate frequency standards of the quartz-controlled oscillator type. The actual method consists in operating a synchronous clock from the standard frequency source and in measuring the rate of the clock in terms of observatory time signals (astronomical time) by means of a chronograph. Since the accuracy of individual time signals may be somewhat better than 0.01 sec, the day-by-day accuracy of this method is of the order of 1 part in ten million. When the constancy of an oscillator justifies the use of a longer interval between checks, the accuracy of determination may be increased correspondingly. In this manner the rates of the best crystal oscillators may be determined in terms of astronomical time with an accuracy better than 1 part in a hundred million.

When accuracies of this order are involved, the variations in astronomical time itself should be taken into account, since changes in the rate of the earth in excess of 1 part in a hundred million have been observed from time to time. The largest such variation in recent years occurred in 1918 and amounted to about 1 part in thirty million.

Since the frequency of a crystal oscillator, best suited for use as a precise frequency standard, is too high to operate a synchronous motor directly, a circuit known as a submultiple generator is used to produce a frequency which is an exact submultiple of the original. Two or more stages may be required, depending on the ratio of the end frequencies. In one system that has operated continuously for over 10 years, the ratios 5 × 5 × 4 are used to operate 1000-cycle motors from a 100,000-cycle primary standard. Similar means may be used to obtain frequencies in any range convenient for distribution or for measurements which bear any exact rational relation to the primary control frequency. Two of the more important means for frequency subdivision are illustrated in Figs. 1 and 2. Although the former is most widely used, the latter has the advantage that no output is produced in the absence of an input.

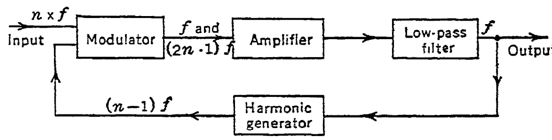

FIG. 2. Submultiple Generator of the Regenerative Modulator Type

3. USING A FREQUENCY STANDARD
(Frequency Comparison)

Methods for frequency comparison may be divided broadly into two main classes: those in which the actual number of cycles difference per unit of time may be determined between the unknown frequency and some simple exact fraction or multiple of the standard, and those in which some approximation is used that does not permit of actual counting. The first includes the various beat methods, the accuracy of which is limited only by the stability of the sources and the duration of observations. An accuracy of comparison of 1 part in 10^{10} may be obtained by some of these methods under good conditions. The latter includes (1) methods in which, for convenience and speed of operation, a calibrated interpolation oscillator is used to interpolate between standard frequency values, (2) methods in which circuit selectivity, or other non-synchronous means, are used to indicate frequency in some part of the system, and (3) methods in which the frequency of the source is in such a high range that the low-frequency beat contains irregularities and cannot be treated as a sine wave and used in any direct counting procedure. The accuracy of measurement in the last main class rarely exceeds 1 part in a million and may vary over a wide range, depending on the particular apparatus used and the skill of the observer.

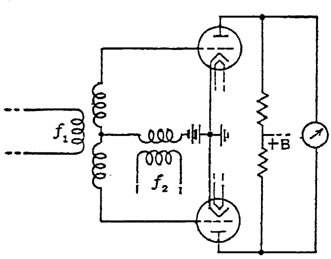

FIG. 3. Balanced Vacuum Tube Modulator for Observing Low-frequency Beats

ZERO BEAT. The simplest, most direct, and most accurate methods are those for comparing two frequencies which have nearly the same value. If the two sources are directed into a modulator so that the low-frequency second-order modulation produced goes through a d-c meter, the meter reading will vary periodically at a rate which is the difference between the two input frequencies. Thus the beats may be counted over a suitable interval and the number per second thus determined and added to or subtracted from the standard to obtain the unknown value. If the two frequencies are alike, there is no response, hence the term "zero beat." Figures 3 and 4 illustrate typical modulator circuits useful for this method.

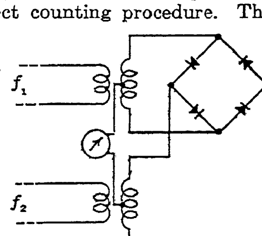

FIG. 4. Copper Oxide Modulator for Observing Low-frequency Beats

If a third-order modulator is used, such as silicon carbide, the greatest response is obtained with input frequencies near the ratio of 2 : 1. If higher-order modulation products are used, as by overloading vacuum tubes or other modulators, appreciable response can be obtained even when the input frequencies are related as $m : n$, provided that the product of the integers m and n is not too great. In this case beats are obtained between the nth harmonic of one input and the mth harmonic of the other. The numerical accuracy obtained is proportional to the ratio of the actual beat frequency observed to the frequency of the particular harmonic involved in the measurement. If the beat frequency obtained in this way is too high to observe directly, other means may be used to determine it.

The accuracy obtainable by this general method may be very high. For example, if the two frequencies, being in the ratio of nearly 1 : 1, are about 100,000 cycles, and if a beat of about 1 cycle in 10 seconds is obtained, an accuracy of only 10 per cent in the observed beat frequency corresponds to an accuracy of 1 part in ten million in the comparison of the two high frequencies. Highly stable sources may be compared readily by this means with an accuracy exceeding 1 part in 10^{10}.

OTHER BEAT METHODS. If the beat frequency obtained from a modulator is too high to observe directly, it may be measured by any other method suitable for the particular range encountered. For continuous comparisons the most precise method is to operate a synchronous clock from the beat frequency and to compute the frequency from its rate. A small percentage change in the rate of the undetermined high frequency will cause a much larger percentage change in the rate of the clock. For example, if the standard were 100,000 cycles and the undetermined frequency in the neighborhood of 100,100 cycles, the multiplying factor would be 1000.

If merely an indication of moderate accuracy is required, without integrating or recording, a commercial frequency meter, such as the vibrating-reed type, can be used giving a direct reading accurate to 1 cycle or a little better. The beat frequency must of course fall in the range of the particular instrument employed.

A very satisfactory direct-reading means for measuring the beat frequency in the range from one cycle to about 200 cycles per second is illustrated in Fig. 5. The modulator output operates a relay having a transfer contact combination. A condenser with capacitance C is charged to voltage E at the beat frequency f times per second. The meter then reads $f \times C \times E$, which is directly proportional to f. The factors C and E may be chosen in relation to the sensitivity of the meter so as to obtain a satisfactory scale reading. For very low frequencies, either a ballistic type of meter should be used, or a filter should be included in the meter circuit, in order to reduce meter fluctuation. Greater accuracy may be obtained, at the expense of the direct-reading feature, by balancing the voltage across a resistor, used instead of the meter, against a fraction of the voltage E, thus producing a null instrument. Both methods are suitable for continuous recording with commercial sensitive d-c recorders and are capable of high overall accuracy.

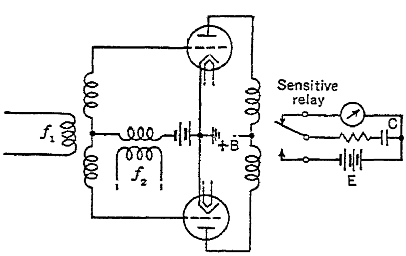

FIG. 5. Direct-reading Beat Frequency Indicator

Direct-reading instruments on the above principle have been built in which the relay is replaced by electron trigger tubes in order to extend the usable range of the beat frequency.

If the beat frequency is too high to measure accurately by any direct method, it can be determined in terms of a lower standard frequency by using a second modulating stage. This process can be carried out through a number of stages if desired so that, regardless of the value of the original undetermined frequency, the final beat is low enough to be measured accurately by some direct method. In one method that has been worked out in practice for measuring high frequencies, the frequency standard is made available in multiples of 1,000,000 cycles, 100,000 cycles, 10,000 cycles, etc., so that, by successive stages of modulation, a frequency determination is made in the range between 5000 and 30,000 kc in terms of a low-frequency beat and exact multiples of the several decade standards.

The frequency range over which this principle may be applied is limited only by the stability of the high-frequency oscillations. So long as the final beat frequency can be measured as a continuous sine wave, the limiting accuracy is about the same as for the zero-beat method. When, as is true at present of many ultra-high-frequency oscillators, the final beat signal contains such random variations that the cycles cannot be actually counted, some uncertainty enters even the best determinations of frequency. However, the accuracy may still be very high, because the beat frequency can be made such a very small part of the total range, thus reducing the necessity for great accuracy in its measurement.

STROBOSCOPIC METHODS. Stroboscopic methods are used for comparing the rate of one mechanical rotation or vibration with another or with the frequency of a fluctuating source of illumination. They are essentially low-frequency methods but have been used to measure speeds of rotation in excess of 10,000 rps. The accuracy of comparison is limited only by the constancy of the rates involved and the duration of a measurement, being in that respect like the beat methods just discussed.

In general a means is provided for permitting an observer to see an object periodically for very short intervals of time. If the object has a periodic structure like gear teeth or spokes, and if in the interval between glimpses it rotates a distance equal to one or any whole number of elements, it will appear to be stationary. If the glimpse frequency is not exactly equal to the apparent periodicity in the rotating structure, it will appear to move slowly, the amount and direction of motion corresponding to the relative rates. The time required for an apparent motion of the structure equal to one element space may be considered as the duration of one "beat" and treated as such in the comparison of rates. This method can be used in a large number of ways for measuring or comparing rotation speeds or for measuring frequency in terms of known rotation speeds, or vice versa.

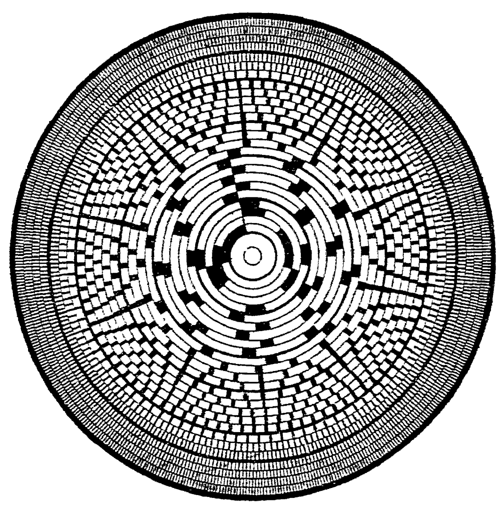

FIG. 6. Stroboscope Disk (Courtesy of General Radio Co.)

A simple apparatus for either case consists of a neon or other vapor lamp which can be flashed periodically by pulsating current, and a disk such as shown in Fig. 6 having concentric rows of black and white sectors of different periodicity, attached to a suitable rotating mechanism. If properly chosen, one row of sectors will appear stationary or nearly so in the intermittent illumination, and from the observation the ratio of the rotation speed to the flash frequency can be deduced readily and with great accuracy.

Similarly the frequency of any mechanical vibration of sufficient amplitude can be determined by observing the motion with a light flashed at a frequency that can be adjusted to the proper range. If the flash frequency is adjusted to the highest value that will give a single image of the vibrating part, that is the desired frequency, which can then be measured by electrical means or read from a calibrated dial.

CATHODE-RAY OSCILLOSCOPE. Probably the most useful of all laboratory apparatus for frequency comparison is the cathode-ray oscilloscope, now available in many compact and convenient forms. (See also Section 15, article 23.)

The oscilloscope, illustrated in Fig. 7, consists of a device for producing a stream of electrons which is directed toward a fluorescent screen within an evacuated tube, and of means for deflecting the electron beam in accordance with currents or voltages to be studied, thereby moving the luminous spot on the screen. At ordinary frequencies the motion of the spot is so rapid that its path is indicated by a continuous trace.

In the usual form of tube the deflections are obtained electrostatically by applying voltage to pairs of parallel electrodes between which the electron beam passes. When two voltage waves are to be compared they are connected to the two pairs of mutually perpendicular plates corresponding to the x and y axes in a cartesian coordinate system. The resulting motion of the spot on the screen is such that

$$x = ke_1 \sin (\omega_1 t + \varphi_1)$$
$$y = ke_2 \sin (\omega_2 t + \varphi_2)$$

where k is a constant for the tube and where e, ω, and φ are the voltage, angular velocity, and phase corresponding to the input waves.

The actual figure that is traced can be determined analytically in simple cases by eliminating t between the two equations. For example, if $e_1 = e_2$, $\omega_1 = \omega_2$, and $\varphi_2 - \varphi_1 = \pi/2$,

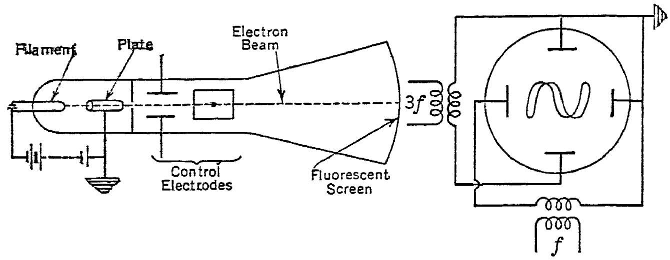

FIG. 7. Schematic of Cathode-ray Oscilloscope, Illustrating Electrostatic Method for Obtaining Lissajous Figures

we get $x^2 + y^2 = k^2e^2$, which is the equation of a circle. As the angle $(\varphi_2 - \varphi_1)$ changes we get various phases of an ellipse until, when it becomes 0 or π, it degenerates into a straight line inclined 45° to the axes. Thus when two waves are compared having equal amplitude and nearly equal frequencies, the pattern goes through a complete series of ellipses once for each cycle gained or lost by one frequency on the other. One such cycle

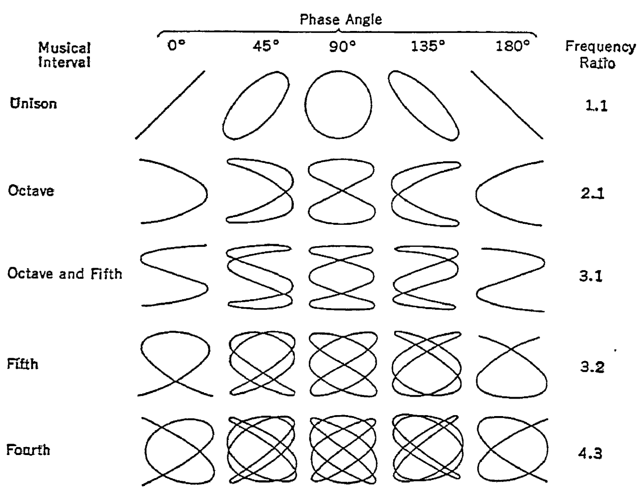

FIG. 8. Typical Lissajous Figures with Corresponding Frequency Ratios and Musical Intervals

of pattern changes corresponds to one "beat" between the input frequencies. Measuring the frequency of recurrence of such beats provides a convenient and extremely accurate comparison between the input frequencies.

Patterns formed in this way by frequencies that are equal or related as $m : n$, where m and n are integers, are known as Lissajous figures. Several such figures corresponding to simple frequency ratios and different phase angles are shown in Fig. 8.

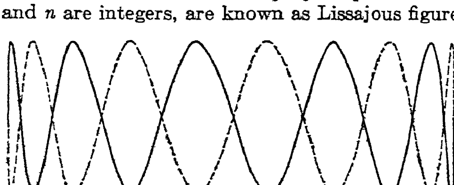

FIG. 9. Ten-to-one Lissajous Figure

When frequencies are to be compared which differ by a rather large ratio, say 10 : 1, a figure is obtained such as shown in Fig. 9. The figure looks like the projection of a sinusoidal trace of 10 cycles around a transparent cylinder. For illustration only, the drawing shows half of the figure solid, corresponding to the front side of the hypothetical cylinder, and the remaining half dotted. Actually, as viewed on the screen these two parts are indistinguishable in appearance. If the ratio departs very slightly from 10 : 1, the pattern moves as though the hypothetical cylinder rotated slowly at the rate of 1 complete revolution for every cycle gained or lost at the low frequency. Thus when the part shown solid in Fig. 9 moves to the right, the part shown dotted moves in the opposite direction.

In order to avoid the confusion of this double pattern, most cathode-ray oscilloscopes are now equipped with sawtooth wave sweep circuits, the frequency of which may be precisely controlled by an external standard. By this means the back pattern is eliminated and the whole visible pattern stands or moves as a unit.

Sometimes it is desirable to compare frequencies bearing a large ratio such as 100 : 1, or even 1000 : 1, in order to study small departures from such ratios, determined by other means, or to adjust the frequencies to those exact ratios. The patterns corresponding to such large ratios are too complex to be used in determining them directly, but by means of an auxiliary oscillator of intermediate frequency it is easy to obtain a nearly exact adjustment in two or three stages. For example, the 100 : 1 setting can be obtained by means of an auxiliary oscillator having 10 times the lower of the two frequencies concerned. As soon as the approximate adjustment is obtained between the end frequencies, the intermediate oscillator can be dispensed with and the final comparison carried out with the large ratio pattern. In such a procedure the horizontal gain of the oscilloscope may be made so large that only part of the complete figure appears on the screen. Because of the enlargement of the figure obtained in this way the accuracy of observation is materially improved. This is essentially a zero-beat method permitting extreme accuracy of comparison.

Frequencies over a very wide range may be compared by the cathode-ray-oscilloscope method, since many oscilloscope tubes will produce clear figures with inputs from the lowest frequencies up to many megacycles. The interpretation of multiline figures corresponding to fractional ratios and many special methods for using the oscilloscope are described in the references.

AUDIBLE METHODS. Audible methods are often useful, especially as a means for observing in one of the various beat methods. For example, if two frequencies which are nearly alike can be heard simultaneously, the beat frequency may be sensed as variations in loudness. The beats may be counted in order to determine the departure of one frequency from the other, or one of the frequencies can be adjusted to match the other by listening for zero beat. If one or both of the sound sources is rich in harmonics other ratios than 1 : 1 may be studied readily by this means.

When two audible frequencies are nearly alike and one source is movable in actual location, it is sometimes convenient to use the Doppler effect to determine which one is high. For example, if an observer holds a vibrating tuning fork in a stationary sound field of nearly the same frequency, slow beats will indicate the magnitude but not the sign of the frequency difference. However, if, while still vibrating, the fork is moved away from the observer and the beat frequency becomes lower (while moving), the fork frequency is higher than that of the sound field.

Often the musical pitch sense may be used to advantage in comparing the actual pitch of two tones one of which may be considered as standard. Since a musical semitone is approximately 6 per cent, it is evident that by this means alone the ratio of two tones in the musical range may be estimated to well within 5 per cent. As a direct measurement, this accuracy is insufficient for most purposes, but it is good enough to be very useful in making estimates of beat frequencies between two high-frequency sources. For example, a 5 per cent error in the 500-cycle beat between two frequencies, nominally 25 megacycles, corresponds to an error of only 1 part in a million in their comparison.

As an aid to this method it is convenient to keep in mind that the frequency ratios corresponding to the consecutive pairs of notes in the major diatonic scale are:

$$\frac{9}{8} \quad \frac{10}{9} \quad \frac{16}{15} \quad \frac{9}{8} \quad \frac{10}{9} \quad \frac{9}{8} \quad \frac{16}{15}$$

The product of all these together equals 2, that is, an *octave*. Also the product of the first four equals $^3/_2$, that is, the musical *fifth*, and similarly for the other recognized musical intervals.

Most keyboard musical instruments are tuned to the *equally tempered* scale in which the interval corresponding to all semitones is equal to $\sqrt[12]{2}$, and a whole tone equals two semitones. In Table 2 the actual frequencies are listed for a range including that of an 88 note piano with A above middle C equal to 440 vibrations per second. This is the most generally accepted standard of musical pitch. For the convenience of using round numbers, a pitch system is sometimes specified in which all the C's are powers of 2, middle C being 256 vibrations per second. The frequencies in this scale are about 2 per cent lower than in the accepted standard of musical pitch, corresponding to about a third of a semitone. The

Table 2. Equally Tempered Scale A = 440

C	32.70	65.41	130.81	261.63	523.25	1046.50	2093.0	4186.0

latter pitch is used chiefly in physics and sometimes is known as physical pitch. International pitch is based on A = 435.

INTERPOLATION METHODS. Most measurements of frequency, apart from the intercomparison of standards and similar studies, can be made most expediently, and with sufficient accuracy, by the use of a calibrated interpolating oscillator in combination with some means such as just described for indicating exact frequency relationships. The principle is illustrated in Fig. 10, which may be modified or extended in numerous ways depending on the application. It is evident that other types of indicator than oscilloscopes could be used, and that by means of suitable switches, S_1 and S_2, only one indicator is needed for the simple example described in the following.

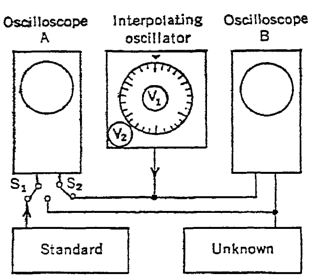

FIG. 10. Frequency Comparison with Interpolating Oscillator

The operation is best explained by an example. Let the standard be 100,000 cycles, and let us determine a frequency, say 3,564,000 cycles, by means of an interpolating oscillator stable in the range from 500,000 to 600,000 cycles and having a vernier dial, V_1, calibrated in this range. By a little experimenting one finds readily that an integral 6 : 1 pattern is observed on oscilloscope B when the interpolating oscillator is set a little below 600,000. That is the cue to calibrate the interpolating oscillator at 600,000 in terms of the standard by setting the dial to that exact value and adjusting vernier V_2 (which adjusts the frequency slightly, independently of V_1) until the ratio of the pattern on oscilloscope A is exactly 6 : 1. When the oscillator is again adjusted to give a 6 : 1 stationary pattern on oscilloscope B, the dial reading multiplied by 6 will be the frequency to be determined. In general it is best to so calibrate the interpolating oscillator that the two positions on the calibration dial are as near together as possible. When the oscilloscope is the indicator it is often desirable to use multiline figures in making one or both settings in order to accomplish this. For example, if the unknown frequency bore some simple ratio to 533,000 cycles, the three line pattern corresponding to the ratio $5\,{}^1/_3$ should be used in calibrating the interpolating oscillator. It is evident that the overall accuracy of the general method may be increased materially by this means especially if an auxiliary vernier dial is provided which is calibrated in a small percentage range and which can be used to interpolate between two close settings.

The method illustrated in Fig. 10 may be used in setting the "unknown" frequency at any value $P \times Q$ times the standard, where P and Q are integers or simple rational fractions. Using stationary figures on both oscilloscopes simultaneously, the accuracy of setting is very high. The "unknown" frequency can then be used as standard in a wide choice of frequencies to extend the range. Sometimes it is convenient to use more than one interpolating oscillator when it is necessary to cover a wide range of frequencies.

In particular this method can be used for extending the frequency of a standard upward for the purpose of measuring at ultra high frequencies in the decimeter and centimeter range. As yet, however, the oscilloscope cannot be used to obtain observable Lissajous figures at the highest frequencies because the stability of such oscillators is not yet good enough to produce stationary figures. This may be expected to come with time, however, and already cathode-ray tubes have been produced capable of resolving single traces at frequencies as high as 10,000 megacycles.

For ultra-high-frequency measurements in terms of a standard the usual method is to heterodyne a harmonic of a measurable source, such as the "unknown" of Fig. 10, with the high frequency by means of a crystal detector and either to estimate the frequency of the relatively low-frequency components obtained or to change the variable source until the detector output is as near to zero frequency as can be estimated. This does not have to be actually zero to be good; it should be remembered that, when measuring 10,000 megacycles, corresponding roughly to 3-cm waves, 10,000 cycles in the beat corresponds to only 1 part in a million in the overall measurement.

Standards of frequency of very great accuracy are made available by the National Bureau of Standards through continuous radio transmissions from station WWV. All the carrier frequencies, which are 2.5, 5, 10, 15, 20, 25, 30, and 35 megacycles, are regulated by the primary frequency standard of the bureau. Each carrier is modulated with seconds pulses and with the audio frequencies 440 and 4000 cycles, also of very high accuracy.

4. EMPLOYING CIRCUIT ELEMENT SELECTIVITY

When extreme accuracy is not a primary requirement, or when standard-frequency current is not available, it is often convenient to measure frequency in terms of the response of selective electrical networks or mechanical resonators.

METERS FOR POWER FREQUENCIES. Most of the commercial meters for indicating power frequency operate on one of three principles. Meters of the reed type employ a number of reeds tuned consecutively to slightly different values and loosely coupled to an electromagnet energized by the current to be measured. The reeds whose frequencies

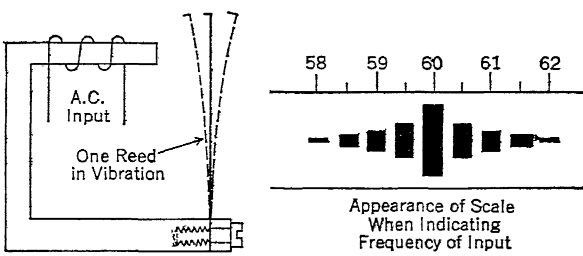

FIG. 11. Vibrating-reed Frequency Meter

correspond most nearly to the frequency of the input current vibrate at the largest amplitude. Usually the reeds are arranged in a row, as shown in Fig. 11, with the ends in line near a scale so that the frequency of the reed with greatest amplitude can be read off directly. Such meters are available in a considerable range of frequencies and are very useful for measuring low frequencies directly or for indicating beat frequencies in their range.

The Weston frequency meter, shown in Fig. 12, has a movable soft-iron armature free to move in the resultant field from two mutually perpendicular coils. When the frequency has some nominal value, the fields in the two coils are equal and the armature takes up a nominal position parallel to the resultant field. When the frequency changes, the ratio of currents in the coils changes, owing to the frequency selectivity of the input circuits, causing a shift in the resultant field and a corresponding movement of the armature.

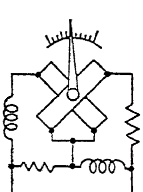

FIG. 12. Weston Frequency Meter

The induction frequency meter, shown in Fig. 13, consists essentially of two opposing induction voltmeter elements associated with one armature. The two motor elements are supplied through resistive and reactive circuits respectively so that the ratio of the effective currents varies with the applied frequency. In the type of meter shown, a circular disk is used and the indicating position is that for which a restoring spring just balances the resultant torque

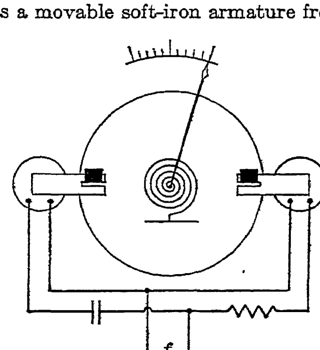

FIG. 13. Induction Frequency Meter

from the opposing drive elements. The deflection is therefore proportional to the frequency deviation from a nominal value.

In another type of this meter no restoring spring is used, but the armature is so shaped for one or both motor elements that the torque varies with angle of deflection as well as with input current. This permits an angular balance position to be obtained which does not depend upon the applied voltage or the reaction of a spring.

Some meters for power frequencies employ resonance to increase the sensitivity in a narrow frequency range. These and others are described in standard works on power meters.

BRIDGE METHODS. Various bridge methods may be used for measuring frequency. The one shown in Fig. 14 is typical. The bridge is balanced when

$$\left(R_2 + \frac{1}{j\omega C_2}\right)\left(\frac{1}{R_1} + j\omega C_1\right) = 1$$

With head phones, or other suitable null indicator, the frequency can be measured in terms of R_1, R_2, C_1, and C_2. As a frequency meter two of these elements can be made variable and calibrated to read input frequency at balance. For more detail about bridge measuring devices see below, article 12.

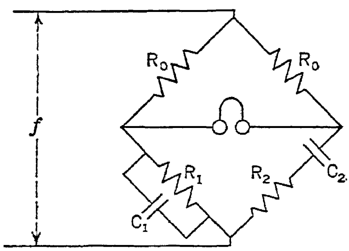

FIG. 14. Bridge for Measuring Frequency

THE MONOCHORD. This is a useful laboratory tool for the approximate determination of frequency in the lower and medium audible ranges. It consists of a steel wire under tension between movable bridges, the wire being coupled electromagnetically to the a-c input to be measured. The frequency of maximum response can be determined from the constants of the system, or a calibration can be made in terms of length or tension. Under some conditions an accuracy of 1 part in 1000 may be obtained with this means.

RADIO WAVEMETER. The tuned circuit wavemeter, Fig. 15, used extensively for radio-frequency measurements from 10 kc to 100,000 kc, consists primarily of a coil and condenser connected in a closed circuit and loosely coupled to a source to be measured. The circuit is tuned, usually by means of the condenser, until a resonance condition is indicated. From a scale on the condenser, previously calibrated by means of accurately known input frequencies, the frequency of any source in a limited range can be read off directly. In commercial wavemeters of this sort a set of coils is generally provided suitable for use in a number of adjacent and somewhat overlapping ranges.

The coupling from the source to be measured may be effected (1) through a low impedance, such as a low resistance, in series with the tuned circuit; (2) by loose magnetic coupling; or (3) by loose capacitance coupling as indicated in Fig. 15.

Resonance may be indicated (1) by a current-indicating instrument, such as a thermal galvanometer, in series with the tuned circuit; (2) by a voltage-indicating instrument, such as a crystal detector or diode in parallel with the reactive elements (if the source is modulated by audio frequency, head phones may provide the most convenient means for observing); (3) by the reaction on a power-indicating means associated with the source; (4) by a measure of power in a separate aperiodic circuit coupled to the tuned circuit but not directly to the source; and (5) by means of amplification followed by detection as in a simple radio receiver.

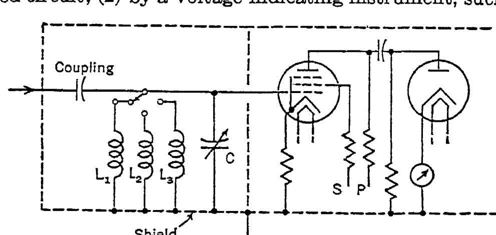

FIG. 15. Radio Wave Meter. Resonance type with high impedance resonance indicator.

Although all five methods are used, the fifth is preferable because of the vanishingly small effect of the indicating means on the Q of the tuned circuit and hence on the precision of observation. Used as indicated, an effective Q of 500 may be attained in a good part of the range, and with good equipment and careful procedure an accuracy of the order of 1 part in 10^4 may be achieved.

QUARTZ RESONATORS. Specific frequencies may be indicated with great accuracy by means of quartz resonators coupled loosely across the tuning elements of a resonant wavemeter. Owing to the relatively very much higher Q of the crystal, which is often in excess of 100,000, its response characteristic is confined to a correspondingly narrow and well-defined range of frequency. This response characteristic is superposed on the broader characteristic of the tuned circuit. Used in this way such resonators are valuable chiefly in fixing calibration points on the wavemeter. A variable input can be adjusted until the crystal response is indicated; then, with the same input frequency, the wavemeter condenser can be adjusted for maximum response to fix the calibration at the frequency of the crystal.

Quartz crystals may be used in a great variety of ways as single-frequency indicators. One interesting adaption, due to Giebe and Scheibe, consists of a series of resonators mounted in a gas at low pressure which may be coupled electrostatically to a circuit to be tested. If a frequency is applied which corresponds to that of one of the resonators, the large potential gradients in the neighborhood of that resonator due to its resonance will cause a luminous discharge which serves as indicator. This method is somewhat analogous to the reed indicator but is applicable to frequencies up to a million cycles per second or more and of course is inherently much more accurate.

CAVITY RESONATORS. The most convenient and generally satisfactory means for measuring frequencies in the region from 200 to 30,000 megacycles has been cavity resonators, which have been developed in a variety of forms for different frequency ranges and for different methods of use. A cavity is primarily an almost completely enclosed space in a rigid piece of metal, with openings only for coupling electromagnetic energy from wave guides or coaxial conductors, and usually also for the operation of a plunger for frequency adjustment.

The cavity itself in its lowest-frequency modes may be considered a familiar tuned circuit in which the *capacitance* is formed by opposite sides, sometimes the two flat ends of a cylinder, and connected by a continuous array of single-turn coils forming the cylinder wall. It is evident that for a moderate-sized cavity the effective capacitance and inductance are both very small and hence the frequency is very high. Since there are no radiation losses, and since the interior losses may be kept small, the Q factor may be very high. For silver-plated fixed cavities the Q may exceed 20,000; for adjustable cavities it is somewhat less.

Cavities are resonant elements and as such may be used as selective transmission devices indicating a *maximum* of transmitted energy into a detector, or as selective absorption devices indicating a *minimum* in a high-impedance source. In either case the actual detection is most easily accomplished by a crystal detector which may actuate a d-c meter, or, if the source is modulated, a set of head phones may be used, with amplification if necessary. The setting accuracy may be as high as 1 part in 10^5.

The design, construction, and use of cavity resonators are discussed at length in Section 7 and in references.

TRANSMISSION LINES. Very high frequencies can be measured with fair accuracy by a study of standing waves in transmission lines, the three usual types being Lecher wires, coaxial conductors, and wave guides. The simplest method involves a movable short-circuiting conductor which can be moved along the line by external control, and the observation of successive minima due to reaction on the source of high-frequency energy fed into the line. The actual distance between successive positions of the short-circuiting conductor which causes such minima determines a half wavelength for the particular line used. In the case of Lecher wires (parallel wires a few centimeters apart) and coaxial lines, the frequency is given approximately by

$$f = \frac{3 \times 10^{10}}{2l}$$

where l equals the distance between resonance positions. A calibrated instrument based on this method may be accurate to about 0.1 per cent.

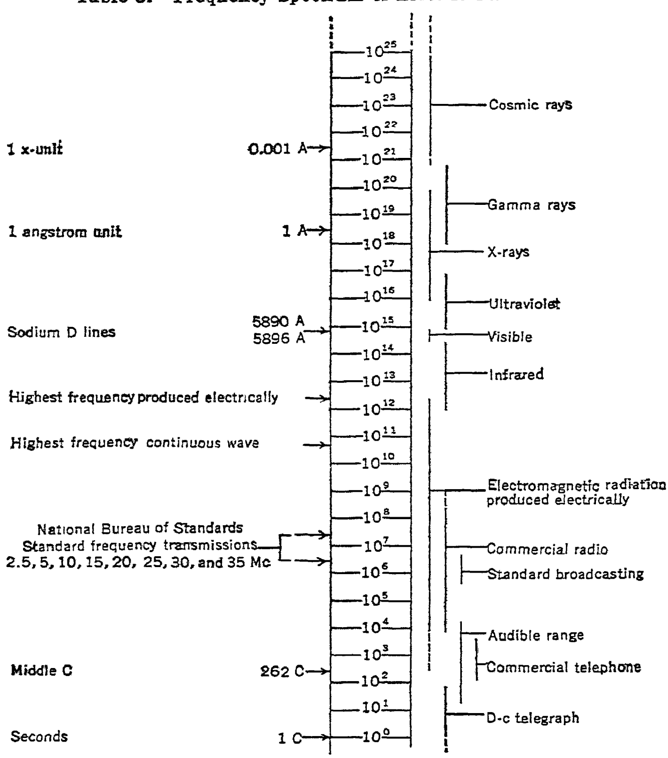
Although Lecher wires are convenient for purposes of demonstration, a low-resistance lamp on the short-circuiting rider being a suitable indicator of resonance, the attainable accuracy is limited by large radiation losses, especially at high frequencies. Wave guides are inconvenient for this purpose on account of the wide variety of modes that may give false indications unless special precautions are taken to suppress them. High-frequency transmission lines are discussed in Section 10, and some of the accompanying references deal with their use as frequency-measuring devices.

THE ECHELETTE GRATING. A method, closely analogous to the familiar optical grating, has been developed for establishing the frequency of the shortest electromagnetic radiations producable experimentally. The method consists in directing the radiation in question toward an array of stepped metal reflectors, like the slats in a venetian blind, and in observing the angle of reflection for which the greatest intensity of reflected energy is obtained. From the spacing of the reflectors, and the measured angles for maximum energy, the wavelength may be computed with considerable accuracy as with the optical grating. This method of measurement, in fact, was an important step in establishing the continuity of the electromagnetic spectrum between light produced by thermal excitation and electric waves produced by purely electrical means.

5. ELECTROMAGNETIC PHENOMENA

Table 3 shows in a graphical manner the relation between the frequencies of various observed electromagnetic phenomena. Where any considerable uncertainty exists as to the extent of a range due to ambiguity of definition or due to disagreement among sources, the uncertainty is indicated by dotted extensions.

Table 3. Frequency Spectrum of Electrical Phenomena



The lower end of the chart, and extending a little beyond 3×10^{10}, includes the entire range over which continuous alternating current can be produced at the present time. This is also the entire range over which frequencies can be measured or compared directly. Damped waves having frequencies up to 3×10^{12} have been produced by purely electrical methods. In this region, which overlaps the infrared spectrum, the frequencies can be determined by either electrical resonance methods or by optical interference methods.

From 10^{12} upwards the terms on the right refer to electromagnetic waves originating in hot or otherwise luminous bodies, in excited atoms, or in atom nuclei. Between 10^{12} and 10^{20} the frequencies are calculated from measured wavelengths; from 10^{20} upward they are calculated from measured photon energies. In certain ranges either of two names is applicable, as indicated by the overlapping grouping.

It is interesting to note that, by extending the frequency spectrum downward, frequencies of recurring astronomic phenomena are encountered that are about as far removed from one cycle as are the highest frequencies noted. Thus the frequency of rotation of the earth on its axis is 1.16×10^{-5}; the frequency of revolution of the earth around the sun is 3.17×10^{-8}. The frequency of rotation of the equinoxes around the ecliptic is

1.2×10^{-12}. The frequency of rotation of Andromeda Nebula is estimated (Jeans) to be 1.7×10^{-15}, and it is perhaps reasonable to suppose that frequencies of periodic phenomena involving interactions between the nebulae may be many orders smaller. Thus the frequencies to which the senses respond most readily are, on a logarithmic scale, about midway between the extremes of which we are aware.

MEASUREMENT OF PRIMARY ELECTRICAL QUANTITIES (CURRENT, VOLTAGE, RESISTANCE, CAPACITANCE, AND INDUCTANCE)

By J. G. Ferguson

The primary quantities of interest in the communications field may be divided into two classes: first, current and voltage; and second, the so-called circuit constants, resistance, capacitance, and inductance. Power is usually obtained from the measurement of voltage or current, and resistance. Frequency is covered under Frequency Measurements, pp. 11-1 to 11-15.

Values of current and voltage generally do not require very accurate measurement. On the other hand, very severe requirements are justified economically in the design and measurement of circuits and their component parts if they result in an increase in the number of channels which can be made available from a given physical circuit. These requirements are specified for the most part in terms of the three circuit constants, resistance, capacitance, and inductance.

The frequencies of interest in communication circuits range from a few cycles per second to the super high frequencies used in radio transmission, whereas the frequency range of major interest from the standpoint of the measurement of primary circuit constants is from about 30 cycles to about 100 megacycles.

6. MEASUREMENT OF CURRENT

The values of power of interest have a lower limit of about 10^{-16} watt determined by the necessity of keeping a level above resistance noise, and an upper limit of about 1 watt in wire transmission, determined by the necessity of avoiding excessive cross-talk to other circuits. The upper limit, of course, is considerably higher in certain applications such as radio transmitters. The currents corresponding to these power limits for the impedance ranges encountered range from about 0.1 amp down to fractions of a microampere. The three features most desired in an instrument to measure such currents are: an impedance practically non-reactive and independent of frequency and current level, a method of operation which furnishes effective values, and high ratio of response to input power.

TYPES OF INSTRUMENT. The dynamometer type and the magnetic-vane type measure effective values of current but require high input power. They are seldom used except at power frequencies. Practically all a-c measurements of current use as an indicator a d-c instrument of the moving coil-permanent magnet type. The problem then reduces to a means of transforming the alternating current to direct current.

THE THERMOCOUPLE TYPE. This has an impedance which is practically a pure resistance at all frequencies, and it measures effective values of current. It is the most accurate method for the measurement of small currents because it can be calibrated with reversed direct current. Its principal disadvantages are that, irrespective of the current measured, the output power is low, about 1 microwatt, and it will not stand heavy overloads. Enclosing the couple in a vacuum improves its speed and sensitivity and reduces temperature errors. The usual type has a heater in direct contact with the junction. This gives a maximum sensitivity and speed and is satisfactory for all but the highest frequencies. At very high frequencies the direct contact between the a-c and d-c circuits introduces objectionable couplings between the instrument and other parts of the circuit. A type having the couple insulated from the heater is to be preferred above about a million cycles in spite of a somewhat slower speed and slightly lower efficiency.

Typical vacuum couples of either the insulated or contact type have a couple resistance of about 10 ohms and are designed to work into a microammeter having a resistance of about the same value and a full-scale deflection of 200 to 300 μa. Table 1 gives essential information for instruments of this type having various ranges. Their accuracy is usually

Table 1. Typical Ranges and Resistances of Thermocouple Instruments

Range, milli-amperes	Input Resistance, ohms	Range, milli-amperes	Input Resistance, ohms	Range, milli-amperes	Input Resistance, ohms
250	0.5	25	10	5.0	100
100	2.0	10	35	2.0	600
50	4.0	7	50	1.5	1000

about 1 per cent of full-scale reading when used with the couple with which they have been calibrated.

Multirange milliammeters are made with self-contained shunts. The accuracy of such instruments at high frequencies is usually limited by the shunts.

Contact Rectifier Type. Contact rectifiers used in conjunction with d-c meters are the most rugged and efficient of the various low current instruments. The most common type uses the copper vs. copper-oxide disk. These instruments have the disadvantage, common to all rectifiers, that they introduce modulation due to instantaneous variation of the input resistance with current. This may be reduced considerably by the common arrangement of four units in bridge form, or an equivalent arrangement with two units and a center tapped transformer. They usually measure more nearly average than effective values, thus giving a wave-shape error. Their principal disadvantages lie in the variation of the rectification properties with time and temperature and the fact that the input impedance varies with current and has a large capacitive component which acts as a shunt across the rectifier and renders their use above about 10,000 cycles of little value, unless some compensation is provided. With proper compensation their frequency range may be extended considerably. For higher frequencies silicon or germanium crystal rectifiers may be used.

Since different ranges can be obtained by changing either the size of the disks or the sensitivity of the d-c meter, a very wide current range is available. It is possible to obtain meters with a full scale as low as 100 μa, but their resistance is high, about 3000 ohms. This makes them suitable for voltmeters, which can be obtained with ranges as low as 0.5 volt with a resistance of 3000 ohms per volt.

The accuracy of this type of instrument is usually limited to about 5 per cent of full scale, and errors in excess of this may occur with extremes of temperature and wave shape.

Two-element vacuum-tube rectifiers have characteristics somewhat similar to contact rectifiers. They are satisfactory up to much higher frequencies but have the disadvantage of requiring auxiliary power. They are discussed further under voltmeters.

MEASUREMENT OF HIGH CURRENT VALUES. These measurements may be made by means of low-range meters in conjunction with current transformers or shunts. Shunts are preferred for high frequencies. They should be designed to have impedance characteristics similar to those of the meter, particularly when used at high frequencies, so that the current will divide in the same proportion at all frequencies.

MEASUREMENT OF LOW CURRENT VALUES. Measurement of current values below the range of even the most sensitive instruments can be made after amplification by comparison with a known current obtained by attenuating a measured current a definite amount.

7. MEASUREMENT OF VOLTAGE

With the high impedances almost inevitable in an instrument for measuring low current values, there is no marked distinction between the measurement of current and voltage; thus all the methods discussed for current measurement will also measure voltage. However, care must be taken to avoid errors due to impedance change caused by series reactance in the leads at high frequencies. Static voltmeters are also common. They measure effective values, but their low sensitivity and high input capacitance limit their use to comparatively high voltages and low frequencies. In addition the following are available.

VACUUM-TUBE RECTIFIERS. This type provides the most satisfactory means of voltage measurement. Most vacuum-tube voltmeters employ diode rectifiers with high-resistance loads, rather than triodes, since the indication is less dependent on the tube characteristics, and because plate-voltage variations, which are a source of error in the triode, are eliminated.

To measure low voltages the rectifier is either preceded by an a-c amplifier or followed by a d-c amplifier. The frequency range and sensitivity of the former are limited by the problem of obtaining broad-band stabilized amplification. Instruments are available in multiple-range models with sensitivities in the order of 1 millivolt, covering the frequency range of 20 cycles to 5 megacycles. The input impedance is in the order of 0.5 megohm shunted by a few micro-microfarads. Indicated voltages are usually average values.

The sensitivity of diode voltmeters is limited by the diode characteristic, and the frequency is limited principally by lead inductance. To reduce this error, the diode is usually encased in a small probe connected to the set by a cable. Instruments are available in multiple-scale models with sensitivities of 0.1 volt covering the frequency range of 20 cycles to 100 megacycles. Input impedance is usually 1 megohm or more at low frequency but is limited at high frequency by the capacitance and conductance of the diode, which may be as high as 7 $\mu\mu$f and 10 micromhos at 10 megacycles. Indicated voltages are usually half wave peak values.

The accuracy of vacuum-tube voltmeters is 2 to 5 per cent, depending on wave shape and frequency.

For frequencies above the range of the diode, materials of high temperature coefficient of resistance are used in which the voltage is determined by the resistance change due to heating. Owing to their small size they may be made independent of frequency up to several thousand megacycles.

8. RESISTANCE STANDARDS

For the accurate measurement of circuit constants, precision standards are required. They form the most important part of the measuring circuits and therefore require full consideration. They consist of resistance, capacitance, and inductance. The following discussion is limited to their use as standards. Further general information can be found in Section 3.

Resistance standards are usually wire wound, but high resistances are also made by coating a thin film, usually of carbon, on an insulating form. These films have a high temperature coefficient of resistance, about -0.03 per cent per degree centigrade for carbon, and cannot be adjusted to very close limits. They are fairly stable with time if hermetically sealed, and the change with frequency is small for values below 10,000 ohms. They are cheaper than wire wound, especially for high resistance values.

The types of wire used most generally for resistance standards are the copper-nickel alloy Constantan and the copper-nickel-manganese alloy Manganin. Both materials have very low temperature coefficients, the variation in resistance over the temperature range of ordinary use being well below 0.005 per cent. Constantan is more easily soldered, and its resistance is more stable with time. Manganin is preferred for d-c standards on account of its lower thermoelectric power to copper, but this is a minor consideration for a-c use. Both alloys have a specific resistance of about 30 times that of copper. Other alloys containing chromium or iron have higher specific resistances but are not generally used on account of their higher permeabilities and larger temperature coefficients.

EFFECT OF HUMIDITY. Humidity affects the distributed capacitance of resistance windings unless they are sealed or impregnated. The impregnating material is usually a thin solution of shellac or a wax, such as paraffin. Impregnation also serves to prevent change in shape of the support or spool, but it is desirable to use as a support a material impervious to moisture, such as a suitable plastic, ceramic, or glass. The woven type of wire standard is the most independent of changes in the form.

PHASE ANGLE. The phase angle should be small. It is due to inductance, distributed capacitance, and capacitance between the terminals which is not due to the presence of the winding. Inductance can be reduced by reducing the size of wire and by winding the coil so that adjacent turns have opposite directions of winding and are spaced as close together as possible. Minimum spacing is determined by the thickness of insulation. Therefore, for a given type of wire and insulation there is a definite minimum obtainable ratio of inductance to resistance for any given wire size, this value being reduced as the wire size is reduced. Distributed capacitance can be reduced by winding so that turns which are adjacent physically are consecutive electrically. By this means the distributed capacitance can be reduced below the remaining capacitance between the terminals. Both types of capacitance can be decreased by reducing the physical size, that is, by reducing the wire size. Capacitance and inductance, when both are present in a resistance, have a compensating effect. For the small reactances present in resistance standards, the compensation will be almost perfect at all frequencies if the relation $L = Cr^2$ holds.

The reactance of carbon film type standards may be considered due entirely to capacitance between terminals. This may be held to about 1 $\mu\mu$f.

VARIATION WITH FREQUENCY. Resistance change with frequency is due principally to the presence of skin effect and of residual reactances. Skin effect may be reduced by using a small size of wire and reducing the inductance of the winding by suitable choice of winding type. For non-inductive windings, the increment due to skin effect may be taken as less than 0.1 per cent for No. 28 B.&S. gage wire at 1 megacycle, and less than 1 per cent for No. 30 wire at 10 megacycles. Where power considerations do not enter, sizes smaller than these are generally used in order to reduce the phase angle as already discussed, and skin effect is therefore usually negligible.

Reactance is a more serious cause of resistance variation with frequency. If a resistance has inductance in series with it, the effective resistance component of the combination considered as a parallel circuit will be increased to the value $r + (\omega^2L^2/r)$. If the resistance has capacitance in parallel with it, the effective resistance of the combination considered as a series circuit will be decreased to the value $r - \omega^2C^2r^3$. When both inductance and capacitance are present, the value of resistance is a function of both, and, if the inductance and capacitance are in such proportions as to give it a zero phase angle, its value will be increased to $r + (\omega^2 L^2/r)$. For high resistances at high frequencies, the dielectric loss of the associated capacitance affects the resistance value.

TYPES OF WINDINGS. The following windings are suitable for resistance standards having values above about 50 ohms, for which cases the reduction of both inductance and capacitance is important:

The Curtis winding made by winding one turn around a spool, then passing the wire through an axial slot and winding the next turn in the opposite direction. A flat slotted form or card is an improvement over a round spool.

The inductive winding on a thin flat card.

The woven type in which the warp consists of silk or cotton threads and the weft is the resistance wire.

The Ayrton-Perry type consisting of two parallel opposed windings either in a single layer, in which case they must cross at every turn, or one layer wound over the other. The single layer has a little more capacitance and a little less inductance than the two layers.

For resistance below 50 ohms where capacitance has less effect, windings having greater distributed capacitance such as the bifilar, and the reversed layer type may be used.

A well-made unit using No. 36 B.&S. gage wire may be wound to have a ratio of reactance to resistance, due to inductance, of about 0.1 at 1 megacycle, and, using No. 44 wire, to have a ratio of about 0.2 at 10 megacycles. If the capacitance is such as to give zero phase angle, which it may for windings of about 1000 ohms, the corresponding resistance increment will be about 1 and 4 per cent respectively. If the capacitance value is not such as to give zero phase angle, the effective shunt resistance will be different from the effective series resistance.

Table 2 gives representative values of inductance and capacitance for standards of several values wound with various sizes of wire.

Table 2. Representative Resistance Windings

Inductance and capacitance for various values and wire sizes

Resistance, ohms	Type of Winding	Insulation and Wire Size B.&S. Gage	Residuals		Net Residual	
			L, μh	C, $\mu\mu$f	L', μh	$C' = L'/r^2$, $\mu\mu$f

VARIABLE STANDARDS. Variable standards are used in precision measurements principally for covering the range between the smallest steps of the adjustable standards. They are usually wire wound and of low range. The simple series type has the objection that the contact resistance is usually an appreciable part of the total resistance of the standard. Preferred methods are to use the slide wire in a circuit as a potentiometer, in which case the contact resistance is not in the measuring circuit, or to use a shunted type of slide wire, in which case the resistance of the slide wire itself is higher than the range of the combination, thus reducing the effect of the contact resistance. Inductance constitutes the principal frequency limitation. The shunted type has lower inductance than the potentiometer type but does not have a linear scale unless used as a potentiometer. Compensation for inductance in single-turn slide wires may be made by substituting an equivalent length of copper wire for the resistance wire removed from the circuit. Compensation in the wound type is not generally made but can be effected in special cases by winding the slide wire non-inductively.

High-resistance variable standards are sometimes used in shunt connection as low-range conductance standards. These are commonly a composition type, particularly when used at high frequencies. They are not very stable standards.

ADJUSTABLE STANDARDS. Adjustable standards consist of a number of switch assemblies, usually 1 to 6, each containing resistance units arranged to give values in steps from 1 to 10. The switch and wiring add both inductance and capacitance. These may be reduced by reducing the switch size and the amount of dielectric material in it. These requirements are met very well by the wafer-type switch. The small size introduces some difficulties in obtaining satisfactory low and stable contact resistance, but the introduction of silver contacts reduces this difficulty. Their principal objection is their short life. They have considerable flexibility due to the availability of multiple decks. The usual arrangement is to connect 10 equal resistances in series and to short-circuit those not in use by means of the brush. The ground or low-potential side of the circuit should be connected to the brush to minimize the effect of capacitance. The inductance may be compensated for by using an additional 10 studs as shown in Fig. 1, to insert inductance equal to the inductance of the resistance and wiring which is removed, thus keeping the total circuit inductance constant for all switch settings at the cost of a slight increase of the zero inductance. This arrangement uses 2 decks of a wafer switch.

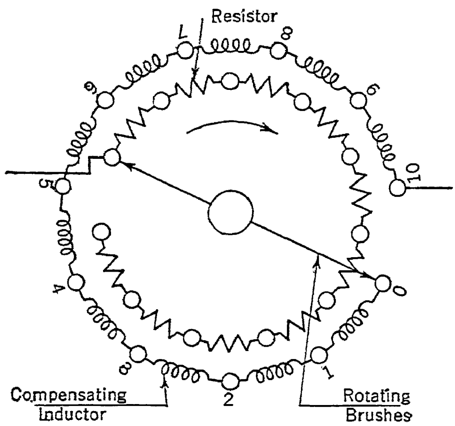

FIG. 1. Decade Resistance Standard, Compensated for Inductance

A method which reduces both capacitance and inductance to a minimum, and is therefore suitable for both high and low resistances, is shown in Fig. 2. A 20-stud switch is so arranged that the drum supporting the units and studs rotates, the brushes remaining stationary. Each unit in a decade has a resistance equal to the total value required for that particular setting. There is no switch wiring and there are no coils connected when not in use. The short-circuit connection for the zero setting may consist of a copper strap equal in inductance to the mean value of the units. The same arrangement with stationary studs and moving brushes is almost as satisfactory and allows the use of a 2-deck wafer switch. The principal disadvantage is the necessity for 10 different values for the resistance units.

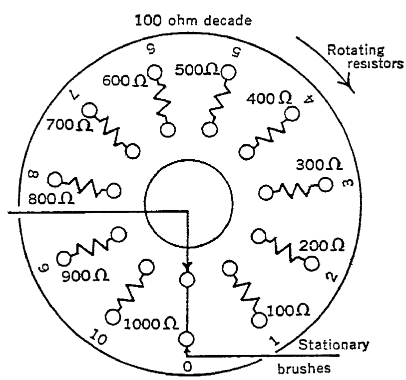

FIG. 2. Rotor Type Decade Resistance Standard

For high resistances there are advantages in arranging decades to read conductance. This means connecting them in parallel. Four units of value 1, 2, 3, 4 can be connected in various parallel combinations. The switching arrangement is the same as that for switching capacitors, shown in Fig. 5A.

9. CAPACITANCE STANDARDS

The principal requirements for a capacitance standard are a capacitance independent of time, humidity, temperature, voltage and frequency; a low power factor; and small size. The degree to which these requirements can be met depends principally on the choice of dielectric. All capacitors using solid or liquid dielectrics have losses when subjected to alternating voltages. The equivalent circuit of such a capacitor may be indicated as shown in Fig. 3 as a perfect capacitance C either with a resistance r_s in series with it, or with a conductance g in parallel with it. For these networks to be equivalent the two capacitances are not identical, but for the low power factors of standards, the difference is negligible.

Practically the only dielectrics used for capacitance standards are mica or air. Many other solid dielectrics are used for capacitors. None of them combines all the advantages of mica, although polystyrene is equal or superior to mica in practically all respects except temperature coefficient of capacitance.

Mica capacitors may be made of interleaved sheets of mica and foil such as copper, tin, or aluminum, or by depositing a film of metal, usually silver, directly on the mica. The last has the advantage of eliminating any air film between the dielectric and the metal, making the capacitance less dependent on the mechanical stability of the assembly.

Air capacitors require solid dielectric in their construction. Their performance depends considerably on their design as well as on the dielectric.

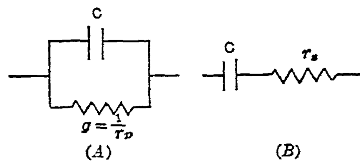

FIG. 3. Alternate Equivalents for an Imperfect Capacitor. *A*, parallel equivalent; *B*, series equivalent.

STABILITY WITH TIME AND HUMIDITY. All capacitors change slightly with age, owing to structural changes after assembly; good mica capacitors usually increase less than 0.05 per cent with age. Humidity has a serious effect unless the capacitors are protected. They are usually dried and hermetically sealed, either in molded plastic or in a can. In addition they may be vacuum-impregnated, usually with paraffin or Superla wax. Well-made air capacitors are less subject to these changes.

VARIATION WITH TEMPERATURE. The change in capacitance with temperature of mica capacitors is due partly to the dielectric material but is also affected considerably by the mechanical design. Unimpregnated capacitors usually have a positive linear change, which is due primarily to changes in the physical dimensions. In impregnated capacitors, additional changes occur owing to the effect of the wax, which has a negative temperature coefficient that increases with temperature. As a result, the temperature coefficient of the capacitor depends on the amount of wax and may be made extremely small over a limited temperature range. Standards can be obtained which vary less than 0.05 per cent from 10 deg cent to 35 deg cent. The shunt conductance of all mica capacitors increases with temperature. The amount varies considerably, but an average value may be taken as 2 per cent per deg cent. For air capacitors capacitance change is due partly to the insulating supports but principally to change in the plate area and spacing caused by changes in the dimensions of the parts. It may be reduced by the choice of materials of low temperature coefficient of expansion and by avoiding distortion due to unequal expansion of the parts.

VARIATION WITH FREQUENCY. Variations in capacitance with frequency of mica standards are caused by variations in the dielectric constant, and at high frequencies by the effect of inductance in the leads. The former causes a slight decrease in capacitance with increasing frequency, the change being approximately logarithmic with respect to frequency. The latter causes an increase in capacitance equal to ω^2LC^2. Lead inductance in a good standard may be held below 0.05 μh. Air capacitors change less, because of the smaller amount of dielectric material and because their comparatively low capacitance is affected by lead inductance only at higher frequencies.

An imperfect capacitor may be represented as shown in Fig. 3*A* or Fig. 3*B*. Metallic losses constitute a series resistance which is independent of frequency, except for skin effect. Leakage constitutes a shunt conductance independent of frequency. Dielectric loss is of such a nature that the loss per cycle is proportional to capacitance and approximately independent of frequency. In other words, this loss is proportional to ωC. If represented by Fig. 3*A*, g will be directly proportional to frequency, and if represented by Fig. 3*B*, r_s will be inversely proportional to frequency.

Table 3. Loss Variation with Frequency and Capacitance

Source of Loss	r	Q	P.F.	g
Series resistance r_s	r_s	$\frac{1}{r_s\omega C}$	$r_s\omega C$	$r_s\omega^2C^2$
Dielectric, D	$\frac{D}{\omega C}$	$\frac{1}{D}$	D	$D\omega C$
D-c leakage g_0	$\frac{g_0}{\omega^2C^2}$	$\frac{\omega C}{g_0}$	$\frac{g_0}{\omega C}$	g_0

In general, four different quantities are in common use for indicating the quality of a capacitor from the standpoint of loss. These are series resistance r, shunt conductance g, power factor which when small is equal to the dissipation factor ωCr or $g/\omega C$, and the reciprocal, which is commonly termed Q. Table 3 indicates how these quantities vary with frequency and capacitance.

In this table D is a fundamental property of the dielectric and is approximately independent of the frequency. For good mica it is as low as 0.0001 and decreases slightly with increasing frequency.

Low power factor or high Q in a standard is obtained by choice of mica of low dielectric loss, by keeping lead resistance low, and by eliminating moisture and impurities in assembly. Figure 4 shows curves of power factor and Q in terms of frequency for representative standards. The increase in Q with frequency is a characteristic of the dielectric. The decrease at high frequencies is due to effective series resistance. The larger the value of capacitance, the lower is the frequency at which the maximum occurs. Small capacitance values usually have greater dielectric loss because of the greater influence of the sealing material. They also have greater effective series resistance, owing, in part at least, to the smaller number of sheets in parallel.

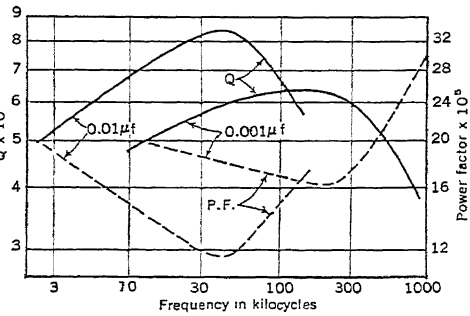

FIG. 4. Variation with Frequency of Q of Typical Mica Capacitor Standard

The Q of air standards is usually higher than that of mica on account of the reduced dielectric material and the reduced effect of series resistance due to the smaller capacitance.

VARIABLE STANDARDS. Variable standards are practically always air capacitors. They may be considered as two capacitances in parallel, one consisting of the minimum capacitance which includes the dielectric material, and the other consisting of the variable part. The former may be considered as a fixed capacitance shunted by a conductance representing the dielectric loss, which is not a function of setting. The latter may be considered as a loss-free variable capacitance in parallel with the former. They may be used, therefore, in measuring circuits, to obtain loss-free changes in capacitance. On the other hand, considering the standard as a whole, the power factor increases with decrease in setting and may be greater than that of a mica capacitor at minimum setting unless a very low loss dielectric is used.

ADJUSTABLE STANDARDS. These are usually in decade form, but, owing to the cost of good standards, only 4 units are generally used, the switch connecting them in the parallel combinations necessary to obtain steps from 1 to 10. Practically all such switches reduce to the principle of a brush for each unit contacting successively 10 studs which are wired so as to connect the unit in circuit at the positions required to give the desired combinations. This may be most readily done with minimum wiring by using cams. The method is indicated by the developed cam arrangement shown in Fig. 5*A*. By using 2 brushes on different diameters a single cam may be cut to connect 2 units. Wafer switches can be used requiring only 2 cams and 5 brushes mounted on a single deck to perform the whole switching sequence. A similar switch may be mounted on the same shaft with cams cut inversely as shown in Fig. 5*B* but parallel-connected to insert capacitances in place of those removed to compensate for the capacitance of the switch or for that of the units in excess of nominal values.

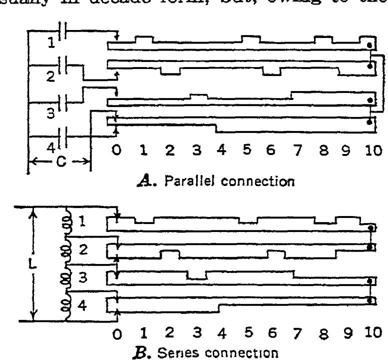

FIG. 5. Cam Type of Decade Switch for Series or Parallel Connection of 4 Standards. *A*, parallel connection; *B*, series connection.

10. INDUCTANCE STANDARDS

The requirements for inductance standards are similar to those for capacitance standards, namely, high stability of inductance under all operating conditions, low power factor or high Q, and small size. Coils cannot be built to meet these requirements as well as capacitors, and for this reason they are not used to the same extent as standards. For precise standards no magnetic material is sufficiently stable, and air-core coils are almost always used. They are wound either as toroids or as solenoids. The toroids have less external field but are larger for the same performance. External field is objectionable since it not only causes errors in measurement due to coupling to the rest of the circuit but the inductance of the standard itself is affected also. Shielding is generally used consisting of magnetic material at low frequencies and low-resistance material such as copper at high frequencies.

STABILITY WITH TIME AND HUMIDITY. Coils may be constructed to have negligible change in inductance and resistance with time. They are usually sealed and in addition may be impregnated to eliminate humidity effects.

VARIATION WITH TEMPERATURE. Change in inductance is determined principally by mechanical changes in the form and in the impregnating material when present. By choice of materials of low expansion these changes can be held to as low as 0.001 per cent per deg cent. A single-layer solenoid wound under tension on a ceramic form may be made with a temperature coefficient of less than 2 parts per million per deg cent. Change of resistance is due principally to change in the resistivity of the copper winding and to change in eddy-current loss which in turn is due to the change in resistivity. These changes are of opposite sign. The net change is a function of frequency but is usually positive.

VARIATION WITH FREQUENCY. Variations of inductance and effective resistance with frequency are due principally to eddy currents and distributed capacitance. The former results in an increment of resistance which is proportional to the square of the frequency. It can be reduced by using stranded wire and single-layer windings. The effect on the inductance is usually negligible compared with other effects. Distributed capacitance has the effect of increasing both inductance and effective resistance. It is a minimum for single-layer coils. Where this type is impractical, banked or sectionalized windings may be used. Capacitance to ground can be reduced appreciably only by reducing the size of the coil, which is at the cost of Q. For frequencies well below the resonant frequency of the coil, the increment in inductance due to capacitance C is ω^2L^2C, and the increment in the effective resistance is $2\omega^2LCr$. The dielectric conductance g associated with the distributed capacitance may also be appreciable. It increases the resistance of the coil by $g\omega^2L^2$. If the coil has no appreciable resistance or inductance variation with frequency, then the ratio of reactance to resistance or Q is proportional to the frequency. On the other hand the loss due only to capacitance and eddy currents results in a Q inversely proportional to the frequency. For the actual case, the Q usually increases to a maximum and then decreases. For low frequencies a high Q can be obtained only by means of a large size. This is the principal disadvantage of air-core standards. It is most evident when they must be used for measuring magnetic-core coils. As the frequency increases the comparison becomes more favorable to the air-core coils on account of the increase in core loss and decrease in effective permeability of magnetic core coils. Above 100 kc this disadvantage is negligible, and air-core coils can be built of small size to have values of Q as high as 100 to 200.

INDUCTOMETERS. All inductometers have an appreciable stray magnetic field which may cause error due to magnetic coupling to other parts of the circuit. They have characteristics similar to fixed standards but usually have relatively greater capacitance and greater resistance increment. The inductance and resistance increments are a function of the setting as well as of frequency.

One type consists of two coils arranged so that the position of the field of one may be varied so as to change their mutual inductance. They may be used as variable mutual inductors or, by connecting the two windings in series, as variable self-inductors. Another type consists of a single-layer rotating solenoid with spaced bare wire turns and a fixed brush riding on the turns. The former type has the advantage of no sliding contacts, but the latter has better performance in other respects.

ADJUSTABLE STANDARDS. Coils may be assembled to form adjustable standards similar to resistance and capacitance standards. Because of their large size, poorer characteristics, and difficulty in compensating for capacitances of switch and wiring with series connection, they are not used extensively. A typical method of connecting 4 units to form a decade is shown in Fig. 5B. Additional decks with cams cut inversely may be used to insert compensating resistances in place of inductances removed.

11. MEASUREMENT OF RESISTANCE

The method used almost exclusively for measuring circuit constants is the bridge method in which the unknown quantity is compared with a standard of known value. For the higher frequencies, say, above 10 megacycles, the errors caused by the presence of even very small stray inductance or capacitance limit the range and flexibility of the bridge method, and consequently at these frequencies other methods which involve less apparatus and simpler circuits are also used.

Resistance standards can be made so that their effective resistance does not differ from the d-c value appreciably compared with the errors of measurement up to the maximum frequencies used. Accordingly, the measurement of resistance is usually made by direct comparison with a standard on a bridge. The simplest type is the equal ratio-arm bridge. A modified equal ratio-arm bridge useful for the a-c measurement of both resistance and phase angle is shown in Fig. 6. It is adaptable only to the measurement of resistors having small phase angles, but, with a given air capacitor C_b of small range across one ratio arm, it will measure the reactance of resistors of any value over a wide frequency range. The equations of balance for this bridge for resistors of small phase angle are

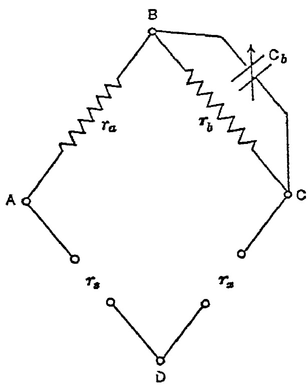

FIG. 6. Bridge Circuit for Measurement of Resistance and Phase Angle of Resistors

$$C_x = \frac{C_b r_b}{r_s} \quad \text{or} \quad L_x = -C_b r_b r_s$$

and

$$r_x = r_s$$

where r_s is the resistance of the standard.
r_x, C_x, and L_x are the values for the unknown.

Both positive and negative reactance can be measured by either transposing the standard and unknown in the bridge or by transferring the capacitance C_b from BC to AB. If the standard has appreciable reactance, correction for it is necessary. For maximum accuracy the bridge should be shielded. A method of shielding similar to that shown in Fig. 8 is satisfactory.

At very high frequencies a direct substitution in a resonant circuit as described under "Measurement of Inductance" may be used, or a voltmeter-ammeter method, with a vacuum tube voltmeter and a thermocouple.

Calibration of standards for phase angle may be made by substitution of one resistance by another having the same physical configuration but a different resistance value, thus obtaining a change in resistance without changing the associated inductance or capacitance. For low resistances this may be done by making identical standards of copper and of various resistance alloys. For high resistances, carbon of different thickness may be deposited on identical forms.

The measurement of effective resistance associated with inductance and capacitance is considered under those headings.

12. MEASUREMENT OF CAPACITANCE AND CONDUCTANCE

TYPES OF CAPACITANCE. In practice, a capacitor does not usually consist of a single capacitance between two terminals. There is, in addition, capacitance to ground or to other objects. The capacitor is usually equivalent to a three-terminal network of three capacitances even when reduced to its simplest form. As a result, different values of capacitance will be obtained, depending on the conditions of measurement. Referring to Fig. 7, C_1 is the capacitance to ground from A, and C_2 is the capacitance to ground from B. The direct capacitance between A and B is C; the mutual capacitance is $C + C_1C_2/(C_1 + C_2)$; and the grounded capacitance is $C + C_1$ or $C + C_2$, depending on whether B or A is grounded. Any or all of these capacitances may require measurement.

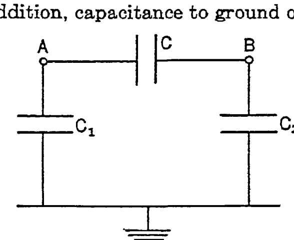

FIG. 7. Simplified Network of Capacitor Which Has Capacitance to Ground

In actual use, the capacitor is generally connected either from one side of the system to ground, in which event it is a grounded capacitance which is effective, or directly across the system which is balanced to ground, in which event it is the mutual capacitance that is effective. Direct capacitance is required, in general, only for special purposes or where the capacitor is so connected in service that the three direct capacitances are connected across different parts of the circuit and must be known individually.

BRIDGE METHODS OF MEASUREMENT. Owing to the satisfactory characteristics of capacitance standards, the measurement of capacitance is usually made by direct comparison with them. The simplest and most accurate method is the equal ratio-arm bridge. The advantages of this type of bridge over all other types are that the equality of the ratio arms may be tested in the bridge itself by means of simple reversal, and residual and lead impedances may be more readily balanced because of the symmetrical arrangement. The ratio arms are usually resistances. Capacitances have advantages for high voltages, and inductances, particularly when closely coupled, for high currents. For precise work, especially at the higher frequencies, some method of taking care of undesired capacitances between arms and from the arms to ground is necessary, the best method being to shield the bridge. This shielding should include at least one transformer. The shield should be complete enough to reduce the direct capacitance between windings below 1 $\mu\mu f$. In special cases it should be much better than this.

Capacitance. Figure 8 shows a shielded equal ratio-arm bridge which is satisfactory for the measurement of capacitance by direct comparison with a standard. This bridge will measure mutual, grounded, and direct capacitance. The requirement that must be met in order to measure mutual capacitance is that the bridge corners C and D be balanced to ground. Since there is no capacitance to ground from B, and since A and C are at the same potential when the bridge is balanced, this requirement is met when the total capacitance from A and C to ground equals the capacitance from D to ground. If at the same time these capacitances are proportioned to keep the bridge in balance, then the capacitances from A and C to ground will be equal, each being half the capacitance from D to ground. This adjustment may be made by means of auxiliary air capacitors. Grounded measurements are made by grounding the D corner by switch K_1. If the bridge is limited to grounded measurements, D may be permanently grounded, and the double shielding of the transformer T_1 and the ratio arms is unnecessary.

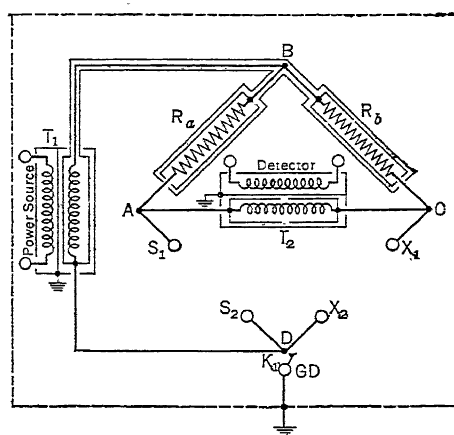

FIG. 8. Completely Shielded Equal Ratio-arm Bridge Suitable for Balanced-to-ground or Grounded Measurements

Conductance. The loss in a capacitor may be measured as a series resistance or as a shunt conductance. Using the bridge of Fig. 8 a standard resistance may be connected either in series or in parallel with the standard capacitor to balance this loss. For wide ranges of capacitance and power factor, however, the range of resistance required in either case is objectionable. The series method may require excessively small resistances, and the shunt method may require excessively high resistances. A modification which permits of a practical resistance range is to shunt both arms by a resistance of fairly high value and to reduce the resistance across the standard to balance any loss in the capacitor under test. Satisfactory values are 10,000 ohms for the fixed resistance across CD and a variable resistance range from 0.01 ohm to 10,000 ohms across AD. This allows the measurement of conductances from 0.0001 micromho up. If r_0 is the reading of r_{AD} in ohms for the zero balance and r_1 is the reading with the capacitor in circuit, then

$$g_x = \frac{r_0 - r_1}{r_0 r_1} \quad \text{mhos}$$

If r_0 is approximately 10,000 ohms, and the conductance is below 1 micromho, this reduces to

$$g_x = \frac{r_0 - r_1}{100} \quad \text{micromhos}$$

The bridge then becomes practically direct reading for conductance. This approximation holds for conductance values encountered in all good standards at moderate frequencies. These expressions are actually the difference in the loss between the standard and the capacitor under test. If the standard has conductance, it must be added to the difference obtained.

In order to calibrate standards for conductance, it is necessary to have a primary standard of zero or known conductance. This is usually obtained by means of an air capacitor specially designed to give a direct capacitance having no loss. If an air capacitor is built so that each set of plates is mounted by insulating supports on a third metal conductor or shield, we then have a system of three capacitors having three direct capacitances such as shown in Fig. 7, in which the dielectric loss is wholly in the direct capacitances from the plates to the support, the direct capacitance between the plates including no dielectric loss. This method, or the use of a variable air capacitor with conductance independent of setting, is the common method for obtaining standards of zero conductance.

Accuracy. The accuracy of a bridge of this type depends on the accuracy with which the capacitance standards are known. An overall accuracy of 0.1 to 0.25 per cent for capacitance is possible for frequencies up to 1 megacycle. The conductance accuracy stated in terms of power factor is in the order of $\pm(1$ per cent $+ 0.0001)$.

DIRECT CAPACITANCE. Direct capacitance may also be measured on the bridge of Fig. 8 as follows: Ground the point C of the bridge and all conductors of the apparatus under test except the two terminals between which the direct capacitance is desired. Connect one of these to C and one to D, and obtain a bridge balance. Then transfer the terminal connected at C to A, and rebalance the bridge. A little consideration will show that the only capacitance transferred in this operation is the direct capacitance required, and the difference between the balances is therefore equal to twice this capacitance.

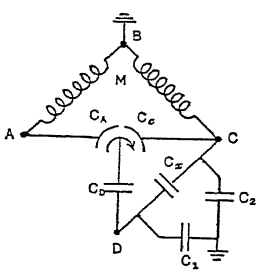

FIG. 9. Bridge for Measurement of Direct Capacitance

A second method which is satisfactory where all the capacitances involved are small, such as the interelectrode capacitances of a vacuum tube, is to connect the capacitance to be evaluated across CD, all other terminals including ground being connected to B. The capacitance thus placed across BC will affect the accuracy of conductance but not of capacitance measurement, and the direct capacitance may be measured directly.

The modified circuit shown in Fig. 9 has two advantages for the measurement of direct capacitance. By using a pair of closely coupled inductors for ratio arms, that is, parallel windings on a common core, the effect of the capacitance across BC will be very much reduced. If, in addition, the capacitance standard is such that capacitance is transferred from CD to AD, keeping the total value $C_A + C_C$ constant, and a fixed capacitance C_D is connected in series in the D lead, it may be shown that the bridge unbalance corresponding to an unbalance $C_A - C_C$ is equal to $\dfrac{(C_A - C_C)\, C_D}{C_A + C_C + C_D}$. If C_D is made small compared with $C_A + C_C + C_D$, very small values of direct capacitance, as low as 0.0001 $\mu\mu$f, may be measured.

A third method is by means of the Wagner ground.

The Wagner Ground. A common modification of the simple equal ratio-arm bridge and of other bridges involves the Wagner ground. This is a simple method of eliminating the effect of stray admittances, compared with complete shielding of the bridge. Referring to Fig. 8, but with power source and detector interchanged, it consists of a potentiometer connected across the input corners AC of the bridge, the adjustable contact being grounded and adjusted to bring the D corner of the bridge to ground potential. In some bridges, complex impedances are required instead of resistances for this balance. It has two disadvantages. First, it requires for any measurement two balances, namely, the adjustment of the Wagner ground and of the bridge itself, and these balances are not independent. This makes the balance procedure relatively slow and complicated. Second, the quantity measured is the direct capacitance. When the mutual or grounded capacitance is desired, it must be computed from the measured values of the individual direct capacitances. These limitations considerably restrict its usefulness.

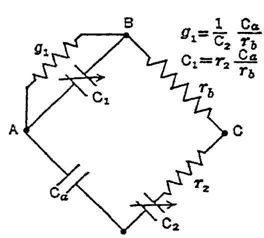

FIG. 10. Schering Bridge for Measurement of Capacitive Impedances

THE SCHERING BRIDGE. At high frequencies, adjustable resistance standards have serious limitations. Above about 1 megacycle, the Schering bridge is used to avoid them. In this bridge a fixed capacitance and a fixed resistance are in diagonally opposite arms, and the other arms may be arranged to allow both capacitance and conductance to be balanced by variable capacitors. The circuit and balance equations are given in Fig. 10. If the bridge is balanced and then the unknown is connected across C_1 and the bridge rebalanced by means of C_1 and C_2, the change in C_1 equals the capacitance of the unknown and the change in C_2 is inversely proportional to its conductance. If series components are desired the unknown may be connected either in series or in parallel with C_2. Then C_2

balances for capacitance and C_1 for series resistance but the bridge will not be direct reading for both components.

OTHER METHODS. Bridge methods have the advantage of a null balance. They do not have the advantage of both grounded input and grounded output unless transformers are used. Other methods are available, particularly at high frequencies, which have both these advantages. They consist essentially of two unbalanced transmission networks connected in parallel, the required relation between the arms for zero output being that their transfer constants be equal in magnitude but 180° out of phase (see Section 6). Commercial measuring circuits of this type are available, known as shunted T and twin T circuits.

The most popular method other than null methods is the simple tuned circuit, the condition sought being a maximum or minimum of either voltage or current with variation of inductance, capacitance, or frequency. A commercial circuit using this method known as a Q meter is described in article 13.

Practically all these special circuits substitute a capacitance standard for the unknown in measuring capacitance, the difference between them lying in the method of measuring the loss. Capacitance is seldom measured in terms of other quantities owing to the superiority of capacitance standards over all others.

13. MEASUREMENT OF INDUCTANCE AND EFFECTIVE RESISTANCE

As for capacitance, the simplest type of measurement is direct comparison, and the bridge of Fig. 8 is capable of the same accuracy for inductance measurements as for capacitance measurements, limited only by the standards. However, inductance standards are inherently less satisfactory than capacitance or resistance standards, particularly for wide inductance and frequency ranges. Accordingly, other less symmetrical bridges are common in order to take advantage of standards of capacitance and resistance. Of these the bridges most used are the resonance method with the equal ratio-arm bridge, the Owen bridge, the Maxwell bridge, and the Schering bridge.

COMPARISON METHOD. This measurement is made by comparing an inductance in the CD arm with an adjustable standard in the AD arm of an equal ratio-arm bridge such as shown in Fig. 8. In order to balance the effective resistance component and to measure it when required, it is necessary to add a series resistance in either the CD arm or the AD arm, depending on the relative resistance values of the unknown impedance and of the standard. The usual procedure is to connect a standard resistance by means of a switch at D to throw the resistance into either arm as required. The bridge permits balanced to ground and grounded measurements, as in capacitance measurements. When adjustable standard inductances are used, and when the series resistance required is large, the shielding of the standards becomes cumbersome and the bridge is commonly used grounded.

The inductance of the unknown is equal to the inductance of the standard at balance. The effective resistance is given by $r_x = r_L \pm r_s$ where r_L is the effective resistance of the standard inductance and r_s is the setting of the standard resistance, the sign depending on the position of the switch.

The accuracy of such a circuit depends on the frequency and on the accuracy of calibration of the inductance standards. An accuracy of about 0.25 per cent for inductance and 2 per cent for resistance is possible for frequencies as high as a megacycle.

Wagner Ground. This can be used with the above method to avoid shielding. However, the limitations of this method as outlined in article 12 apply equally to inductance measurements.

RESONANCE METHOD. Inductance can be compared with capacitance and frequency either by series or parallel resonance. The series method has the advantage of giving directly the series resistance and inductance of the coil which are the values usually desired. It is also inherently a low-impedance circuit, and this is often an advantage where the voltage available from the power source is limited. The parallel method gives the equivalent parallel values, which usually require subsequent transformation. It is inherently a high-impedance circuit.

The principle on which resonance measurements are based is the adjustment of the capacitor until the tuned circuit has zero or infinite reactance; that is, it is equivalent to a pure resistance. The measurement is usually made on an equal ratio-arm bridge, but any bridge that will determine when the impedance of the circuit is a pure resistance and that will measure the resistance is suitable. The principal objections to the method are that it is not direct reading and the accuracy is dependent on the frequency of the source.

Series Resonance. For the series measurement by the equal ratio-arm bridge of Fig. 8, an adjustable resistance is connected in the AD arm and the capacitance in series with the unknown in the CD arm. Since the unknown forms only part of the impedance in the CD arm, balanced-to-ground measurements are impractical and this measurement is usually made with D grounded. The capacitance is connected from C to the unknown in order that one terminal of the unknown may be connected to ground. The balance is obtained by adjusting the standard resistance and capacitance, and at balance the following relation holds:

$$\omega^2 L_x C_s = 1 \quad \text{or} \quad L_x = \frac{1}{\omega^2 C_s}$$

r_x is equal to r_s less the equivalent series resistance of C_s. If the conductance of C_s is used, as it generally is, since when multiple standards are used their conductances add directly, then

$$r_x = r_s - \frac{g_s}{\omega^2 C_s^2} = r_s - \frac{L_x g_s}{C_s}$$

where r_x, L_x are the values of the unknown.
g_s is the conductance of the standard C_s.

Parallel Resonance. For this measurement the capacitance and the unknown inductance are connected in parallel in the CD arm of the bridge. Either balanced-to-ground or grounded measurement may be made. Since the resistance required for the balance may be very high, an arrangement similar to that for a capacitance bridge is customary; that is, a fixed resistance, usually 10,000 ohms, is connected across CD and the loss is read as conductance by means of a variable resistance across the AD arm of the bridge. The balance is then obtained in the same way as for series resonance. Then

$$L_p = \frac{1}{\omega^2 C_s} \quad \text{and} \quad g_p = \frac{r_0 - r_1}{r_0 r_1} - g_s$$

where g_s is the conductance of the condenser C_s.
r_0 and r_1 are the open-circuit and final readings of r_s.
L_p is the parallel inductance of the unknown impedance.
g_p is its conductance.

The series equivalents may be obtained by transformation.

Accuracy. The accuracy of resonance bridges depends on the accuracy of both the capacitance standards and the frequency. Accuracies as high as 0.1 per cent are possible without extreme precautions. They are probably the most accurate circuits for measuring effective resistance, accuracies of the order of 2 per cent being readily obtainable, even for high-Q coils.

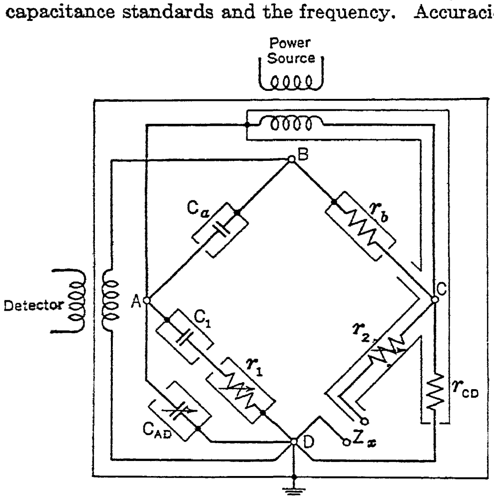

Fig. 11. Shielded Owen Bridge for Measurement of Inductance and Effective Resistance

THE OWEN BRIDGE. This bridge in common with the Maxwell bridge has the advantage that inductance is measured in terms of capacitance and resistance. It is not frequency sensitive and can be made direct reading for both L and r. A shielded circuit for the Owen bridge is shown in Fig. 11. The equations of this circuit at balance are

$$L = C_a r_b r_1 \quad \text{and} \quad r_2 = \frac{C_a r_b}{C_1}$$

where r_2 includes the effective resistance of the unknown. Two methods of operation are possible. Both C_1 and r_1 may be adjustable, and then the inductance of the unknown is proportional to r_1 and the total effective resistance in the CD arm is proportional to $1/C_1$. It is usually more convenient to have C_1 fixed or adjustable in a few steps and to have r_2 adjustable. Then by taking a short-circuit reading r_0 for r_2 it follows that $L = C_a r_b r_1$ and $r_x = r_0 - r_2$. Since the unknown is not connected directly across the arm CD, balanced-to-ground measurements are impractical. Since the resistances are capable of adjustment to their nominal values with a high degree of precision, the bridge is direct reading for both inductance and resistance without the need for calibration. Also, the range of inductance may be made very wide since r_1 may be designed to have as many as six or seven dials. The bridge is not so suitable for the measurement of effective resistance on account of residual reactances in the various bridge arms and difficulties in shielding always encountered in arms having series impedances.

The shielding is made only partially complete in the interest of simplicity. The resistance r_{CD} is used to compensate the shield capacitance across AD, a resistance being required because of the 90° phase relation of the ratio arms. With this circuit inductance accuracies as high as 0.1 per cent are usual at audio frequencies. It is not as satisfactory at higher frequencies as the following bridges.

THE MAXWELL BRIDGE. In this bridge fixed resistors are used in diagonally opposite arms. The inductance and effective series resistance of the unknown are then balanced by capacitance and conductance respectively in the standard arm. The circuit and balance equations are shown in Fig. 12. If r_a and r_b are not pure resistances, the balance equations still hold if their phase angles are equal but of opposite sign. If g_s is designed to read directly in conductance (see article 8) the bridge may be made direct reading for both L and r. This feature makes the bridge as attractive as the Owen bridge. In addition, since it has no series connections in the arms, stray admittances may be compensated more readily and the bridge is satisfactory at higher frequencies.

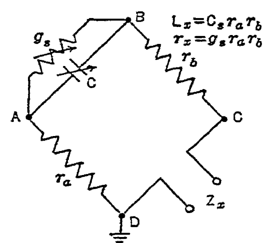

FIG. 12. Maxwell Bridge for Measurement of Inductance and Effective Resistance

THE SCHERING BRIDGE. This is described in article 12. It is essentially a capacitance bridge but will measure inductance as a negative capacitance and is particularly adapted to high-frequency measurements of low-Q impedances which may have either positive or negative reactance.

METERING. The values of inductance and resistance of magnetic-core coils are usually a function of the saturation. It is therefore desirable to know the current through, or the voltage across, the coil when measured. In any so-called ratio-arm bridge, where two adjacent arms are invariable, the current through the unknown, or the voltage across it, will have a definite relation to the total bridge current or voltage, determined only by the ratio arms and the choice of input and output corners. Thus in Fig. 8, which uses a current connection, the current input divides at balance in proportion to the admittances of the ratio arms, and a meter in the input circuit can be calibrated to read directly the current through the unknown. In Fig. 11, which shows a voltage connection, the input voltage divides at balance in proportion to the impedances of C_a and r_b, and a meter across the input can be calibrated to read directly the voltage across the unknown. Here the calibration will be a function of frequency but is independent of the value of the unknown.

Bridges of the so-called product-arm type, having the fixed impedances diagonally opposite, such as the Maxwell and the Schering bridges, do not have this feature, and the metering is usually done by connecting a vacuum-tube voltmeter directly across the unknown.

SUPERIMPOSED MEASUREMENTS. Measurement of inductance is sometimes required for magnetic-core coils, with direct current flowing through the winding. Such measurements may be made on an equal ratio-arm bridge such as that of Fig. 8, applying the direct current across the BD corners and separating the direct current from the alternating current where necessary by stopping condensers and a choke coil. A more convenient bridge is the Owen bridge of Fig. 11. If direct current is applied across BD and alternating current across AC, the only additional apparatus required is a stopping condenser in the detector circuit. The Maxwell bridge is also well adapted to making these measurements.

OTHER METHODS. At very high frequencies where extreme circuit simplicity is desirable, the simple tuned circuit is commonly used. The method of measurement is as follows.

If a voltage is applied to an inductance in series with a capacitance as shown in Fig. 13 and either L, C, or ω is varied to give maximum voltage across C, then

$$\omega L = \frac{1}{\omega C}$$

and

$$\frac{E_2}{E_1} = \frac{\omega L}{r} = \frac{1}{\omega C r}$$

where E_1 is the voltage across the tuned circuit.

E_2 is the voltage across L or C.

r is total resistance of the circuit.

Thus, if the values of E_1, E_2, and ω are measured, the inductance and resistance of a coil can be determined if the capacitance and resistance of the capacitor are known, and vice versa. A refinement of this circuit consists of adjusting the input voltage to a definite value either directly by a voltmeter or by adjusting the current into the known resistance r_c. Then the voltmeter across C may be calibrated in terms of Q. If the capacitor C has negligible loss, this will be the Q of the coil. Commercial measuring sets called Q-meters are available with self-contained oscillator, low-loss variable-capacitance standard, and vacuum-tube voltmeter, which are direct reading for Q. They are satisfactory up to 200 megacycles or higher.

There are a number of errors in the Q reading that may be corrected for when known. The resistance r of the circuit includes the equivalent series resistance of the capacitor, which includes its dielectric loss and the admittance of V_2. The frequency response of the voltmeters may not be flat. If the input current is controlled, E_1 is affected by change in impedance of r_c due to reactance or skin effect, and by the shunting effect of r. These errors vary independently with Q, X, and ω so much that no average figure for accuracy applies. For values of Q about 100, and values of X about 100 ohms, accuracies of 5 per cent can be expected up to 25 megacycles.

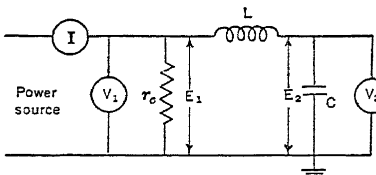

FIG. 13. Q Meter Circuit

MUTUAL INDUCTANCE. Mutual inductance between two coils can be determined by measuring the self-inductance of the two windings by any suitable method, with the windings connected first series aiding and then series opposing. The difference between the two values is four times the mutual inductance. The ground conditions are usually different for the two measurements from the actual operating conditions. This may be a source of error, particularly where the coupling is low. The ratio of secondary voltage to primary current may be determined directly by thermocouple and vacuum-tube voltmeter.

14. SIGNAL GENERATORS AND DETECTORS

The following discussion is limited to the special requirements which apply to use with measuring circuits such as those described. More complete information may be found in articles 36 to 40.

SIGNAL GENERATORS. Many single-frequency generators are available in the audio-frequency range provided the requirements are not severe. However, the tuning fork operated by a microphone or vacuum tube, and the rotating generator, represent practically the only types, other than vacuum-tube oscillators, with satisfactory characteristics for precise work. Where a range of frequencies is necessary and particularly for frequencies above the audio range, vacuum-tube oscillators are used almost exclusively.

VACUUM-TUBE OSCILLATORS. The principal requirements for an oscillator for measurement purposes are adequate output level, low level of harmonics and other spurious frequencies, and high stability of frequency and output level with respect to time and temperature. The emphasis on these requirements depends on the type of measurement. The output level should be high enough to insure that the input level to the detector is above thermal noise for the most precise balance. An output of 0.1 watt is usually adequate. Level stability requirements are more lenient for null measurements. Harmonic requirements are more lenient for null measurements which are not frequency dependent. In general, when untuned detectors are used, harmonics should be held below 3 per cent of the fundamental, and for null resonant measurements, below 1 per cent. Harmonics may be suppressed by filtering external to the oscillator, either before or after the measuring circuit. The former is preferable in so far as it prevents production of false signal by modulation in the measuring circuit, but it places severe modulation requirements on the filter.

Oscillators are in general of three types, according to the type of frequency-selecting network used, namely, crystal, LC, and rC oscillators. The crystal oscillator is the most stable and is the preferred type for fixed frequency applications over the frequency range for which crystals are applicable, about 10 kc to 10 mc. The LC oscillator is the most versatile and can be used over the whole frequency range up to the maximum frequency at which lumped constants are practical. At low frequencies, the necessity of using coils of large physical size to obtain a high Q makes it cumbersome, and the rC oscillator is preferred. This oscillator has the advantages that the components are small even at very low frequencies, and it may be made direct reading more readily. It is suitable for frequencies lower than 1 cycle up to about 100 kc, where, in spite of lower stability, it competes with the LC oscillator because of the direct-reading feature.

HETERODYNE OSCILLATORS. These oscillators, having an output frequency which is the difference between the frequencies of a fixed and a variable oscillator, can be made to cover a wide frequency range with a single continuous control. This has two advantages: it allows them to be made direct reading over wider ranges than the conventional *LC* oscillator, and the broad continuous range makes them suitable for sweep frequency measurements required in recording, and in cathode-ray visual indication, of frequency characteristics.

DETECTORS. Detectors, as distinct from actual measuring instruments, are limited to the detection of null balances and equality of output from different circuits or from different arrangements of the same circuit.

The principal requirements are adequate sensitivity for the accuracy required, sufficient discrimination against harmonics, and stability of gain with time and temperature. Sensitivity can usually be obtained by amplification. The limit is determined by thermal noise, which depends on the band width. This limit is approximately 10^{-20} watt per cycle band width. For instance, using a detector with a 1000-cycle band width working out of a bridge of 1000 ohms impedance, minimum signal to exceed thermal noise will be 10^{-17} watt or 0.1 μvolt.

The harmonic suppression required depends on the oscillator harmonics, the method of measurement, and the characteristics of the unknown. Gain stability requirements are least severe for null measurements. They are most severe in adjusting two outputs to equality using some form of suppression.

The telephone receiver with or without preceding amplification is the simplest and most sensitive detector within the audio-frequency range. Owing to the frequency characteristic of the ear and of the receiver, considerable discrimination against harmonics can be obtained in the frequency range where they are most sensitive. At higher frequencies, the heterodyne type of detector giving an audio output may be used with the receiver. It has the advantage of giving considerable discrimination. In all detectors care must be taken that the harmonics do not overload the input sufficiently to cause a false signal due to modulation.

In addition to the telephone receiver, a rectifier, such as copper oxide or a vacuum tube, may be used with a d-c instrument or cathode-ray-tube indicator. These require greater amplification and more discrimination.

WIRE LINE MEASUREMENT

By H. J. Fisher

15. TRANSMISSION MEASUREMENTS

Transmission measurements evaluate a circuit or facility (wire line, cable, radio circuit, three- or four-terminal network, etc.) in regard to its ability to transmit telegraph, voice, modulated carrier, television, or other communication signals. This evaluation usually involves two criteria, (1) effect on signal amplitude and (2) effect on signal shape. It has been found convenient to express the criteria in terms of steady-state measurements of loss or gain, phase shift, and envelope delay distortion vs. frequency, and, in addition, non-linear distortion (compression, expansion, interchannel modulation cross-talk) as a function of signal amplitude. Usually the device or circuit to be measured is one of many connected in tandem between the original signal source and the final receiver, and it is desired to know the effect on overall transmission caused by inserting the portion in question. Since the individual portions of a system are usually designed to have a nominally constant impedance (vs. frequency) of a standardized value (e.g., 600 ω, 135 ω, 75 ω) the insertion transmission can be measured directly with test equipment having the same nominal impedance. Impedance variations with frequency of the unit to be measured, of the connected circuits, or of the testing equipment, will produce errors in the insertion transmission measurement which must be considered. If all impedances are designed to have less than 5 per cent reflection coefficient these errors usually can be neglected.

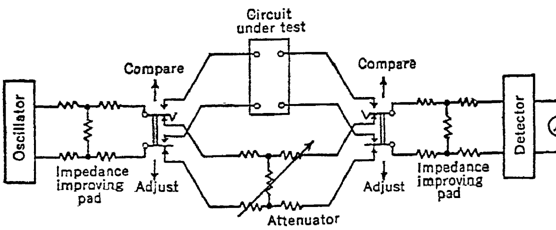

FIG. 1. Comparison Method for Measuring Insertion Loss

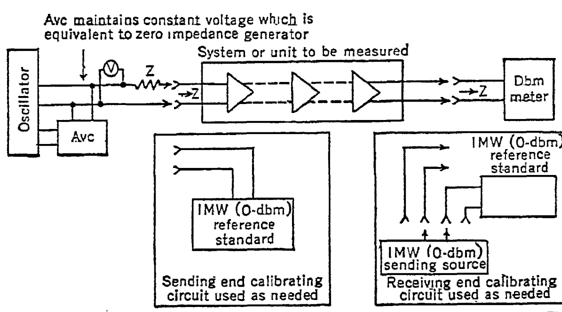

FIG. 2A. Straightaway Method for Measuring Insertion Gain or Loss

INSERTION LOSS OR GAIN. Comparison Method. Figure 1 shows a commonly used setup for measuring insertion loss. The attenuator is adjusted until equal readings are obtained on the meter for the two positions of the key. When measuring gain the attenuator is connected in tandem with the unknown. Systems or units having input frequencies that differ from the output frequencies such as modulators or mixers can be measured with this setup provided that the detector and attenuator characteristics do not change over the frequency range of interest.

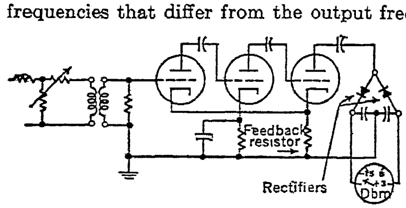

FIG. 2B. DBM Meter

Straightaway Method. Figure 2A shows a setup for making this type of measurement. A circuit of this type is required when the input and output terminals are not available at the same location. The circuit is self-explanatory except for the following items.

Dbm Meter. This is usually a broad-band amplifier having adjustable gain in 10-db steps followed by a linear rectifier (diode or varistor) with a meter calibrated in dbm over about a 13-db range. See Fig. 2B.

1 Milliwatt (0 Dbm) Reference Standard. This is usually a thermocouple circuit of the correct impedance arranged to be calibrated by standard d-c power as determined by a d-c milliammeter.

Voltage Method. For making measurements on working systems without causing disturbance to the working signals, a frequency selective voltmeter is used (see reference 3). This is a high-impedance selective heterodyne detector of adjustable sensitivity in, say, 10-db steps followed by a linear detector and dbm meter. The measurements are usually made at the pilot frequencies or other frequencies not in the signal channels. Since the working signals may be at higher levels than the pilots, it is important that the first modulator and input amplifier be operated at levels low enough to reduce the error due to intermodulation products falling at the measuring frequency. Frequency discrimination, at intermediate and final frequency stages, sufficient to eliminate all other unwanted frequencies is obtained by means of quartz crystal filters and selective interstage circuits. The required discrimination can be reduced by about 26 db by the use of a linear rectifier rather than a peak detector and about 23 db with square-law or thermal-type indicators.

MEASUREMENT OF INSERTION TRANSMISSION (LOSS OR GAIN) OF CIRCUITS AND UNITS HAVING MISMATCHED IMPEDANCES. As stated above, when the reflection coefficient of the circuit or unit being measured and the test equipment are less than 5 per cent when referred to the nominal impedance the measured insertion transmission is usually negligibly different from the true insertion transmission. In some broad-band systems the impedances of the tandem components vary considerably with frequency from the nominal, and the reflection losses incurred are sometimes employed in overall equalization of the system. When measuring components of such a system with nominal impedance test equipment there is a discrepancy between the measured and actual insertion transmission. When measuring with a voltmeter type of circuit the discrepancy is different and usually larger. This in itself causes no great complication in the maintenance of these systems since the operating limits are specified having in mind the type of test equipment which is used. Difficulty does arise when attempts are made to correlate measurements made by the two methods. A calculation using complete impedance information and rigorous insertion transmission equations is necessary.

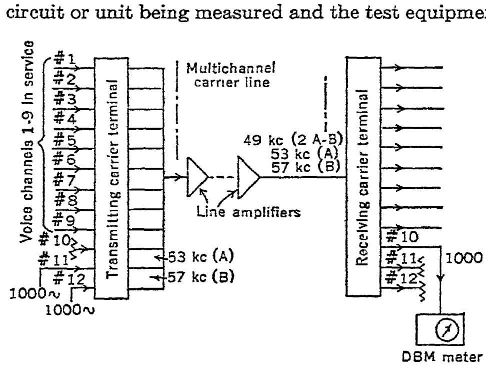

FIG. 3A. Modulation Measurements on Overall Carrier Telephone System

INTERMODULATION DISTORTION MEASUREMENT. As a result of non-linear distortion (such as occurs in vacuum-tube amplifiers) in a transmission system, frequencies other than those applied to the input of the system are produced. For example, if two tones are applied to the system, say (a) and (b), new components having frequencies such as $2a$, $2b$, $a \pm b$, $2a \pm b$, $2b \pm a$, $3a$, $3b$., etc. are produced. In some cases, these new frequencies fall outside the band of interest and need not be considered, but in wide-band systems many of these products fall within the transmitted band. In multichannel systems these new frequencies may result in interchannel interference. To prevent this interference from exceeding allowable amounts, measurement of intermodulation distortion is a necessary part of the maintenance of multichannel systems.

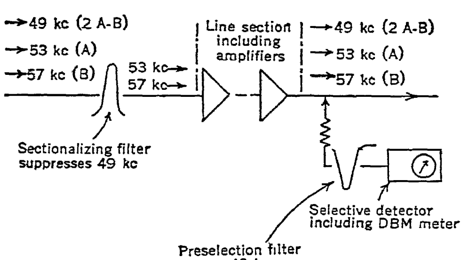

FIG. 3B. Modulation Measurements on Line Section

There are two types of test: (1) an over-all test to check whether the circuit as a whole meets specified requirements; (2) a test on a portion of the circuit or on individual repeaters to locate the defective tubes or other component or a maladjustment.

Figure 3A shows how the over-all test is made on a typical 12-channel carrier system. Channels 1 to 9 are continued in operation, channels 10, 11, and 12 being turned down. Channels 11 and 12 are energized with 1000-cycle power of specified level, and after passing through the terminal modulating equipment they appear on the line as 53 and 57 kc.

As a result of third-order intermodulation in succeeding amplifiers, 49 kc ($2a - b$) is produced. At the receiving end this product appears in voice channel 10 as 1000 cycles, where it is measured with a sensitive dbm meter. The $2a - b$ product is used for this test because it is the product most likely to be excessive. The reason for this is that the modulation component produced at each repeater tends to add in phase with the components produced by other repeaters whereas most other products add on a random basis.

To localize sources of excessive intermodulation the line may be sectionalized as shown in Fig. 3*B*. In this case, the three channels are turned down as before, the 53 and 57 kc originating as 1000 cycles at the transmitting terminal. Any 49 kc produced between the terminal and the suppression filter is suppressed and the test is essentially originated at that point. The selective detector and preselection filter are portable and can be moved as near to the suppression filter as desired, for example close enough to include only one repeater.

In other multichannel systems the modulating test tones are applied directly to working lines by means of high-frequency oscillators. They are allocated in spaces between working channels and are also chosen so that the product being measured, which may be $2a$, $3a$, $2a - b$, etc., also falls in an idle part of the spectrum.

See references 1 to 3.

INSERTION PHASE MEASUREMENT. This measurement is almost entirely restricted to the laboratory, where it is particularly useful in connection with the measurement of the feedback factor ($\mu\beta$) loop of a feedback amplifier (see references 4 and 5) and

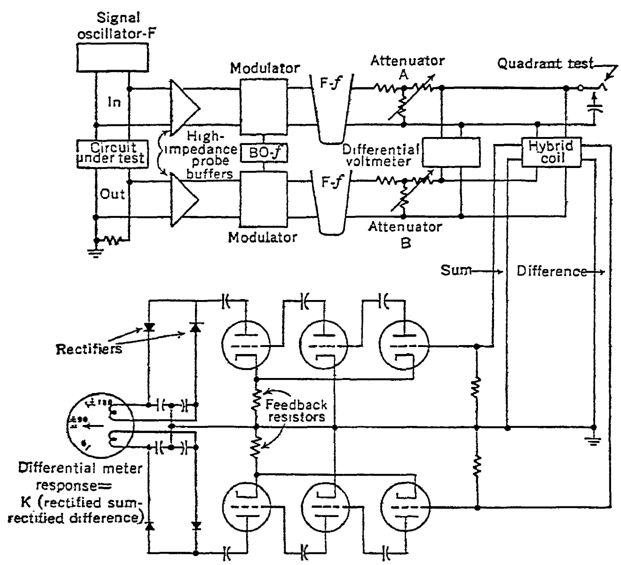

FIG. 4*A*. Direct-reading Phase-measuring Circuit

the insertion phase of networks (see reference 6). In connection with transmission of television signals over coaxial cables phase data are obtained indirectly by the integration of the envelope delay characteristic.

Figure 4*A* shows a direct-indicating type of circuit by means of which the $\mu\beta$ characteristic can be quickly obtained. Attenuators *A* and *B* are adjusted so that the input and output vectors are equal in magnitude. The loss or gain of the circuit under test can be obtained from these attenuator readings. By an alternative arrangement, using avc amplifiers this can be accomplished automatically. Assuming that vectors of equal magnitude are applied to the hybrid coil the meter reading will indicate the phase difference directly. Figure 4*B* shows the characteristics of the direct-indicating phase indicator. The difference of the rectified sum and difference outputs is used because it permits the use of a more linear portion of a cosine function $\left[\text{response} = k' \cos\left(\frac{\pi}{4} + \frac{\alpha}{2}\right)\right]$. By this means a quite linear indication of phase difference can be obtained over a 180° range and within the range of 90° ± 45° the deviation is usually negligible. This range of good linearity may be shifted to any other desired portion of the range by means of a calibrated phase shifter in one of the branches. In Fig. 4A a modulation method is shown to provide selectivity to reduce the effect of noise and to permit the use of fixed-frequency circuits, but successful broad-band sets have also been constructed. This type of set is also easily adapted to the automatic recording of $\mu\beta$.

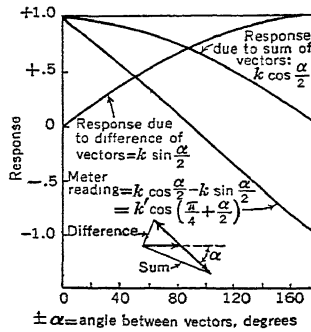

FIG. 4B. D-c Response vs. Difference in Phase of Two Equal-frequency Sine Waves

Other types of phase-measuring circuits have been devised. Generally they require the adjustment of the reference and unknown vectors to equal magnitude. Phase may then be computed from the difference in magnitude of their sum and difference, or, by means of an adjustable calibrated phase shifter (of any of several well-known types) placed in either branch, the sum or difference may be adjusted to a null and then the phase shift may be read directly from the calibrated phase shifter, due allowance being made for quadrant determination. In a variation of this method suggested by S. T. Meyers and used extensively, the sum or difference is adjusted by means of a calibrated phase shifter to equality with the reference and unknown vector. This indicates a 120° phase difference between the two applied vectors which when added to or subtracted from the indicated phase shift depending on the quadrant gives the actual phase difference.

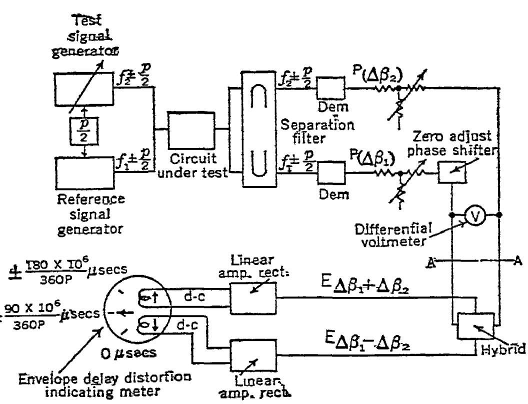

FIG. 5. Envelope Delay Distortion Measuring Circuit

Another widely used phase-measuring circuit is described in W. P. Mason's patent U. S. 1,684,403. This is known as the sum-and-difference method and requires only commonly available equipment such as an oscillator, a detector, and attenuators (see reference 6).

INSERTION ENVELOPE DELAY DISTORTION MEASUREMENT. In some types of communication, such as television, telephoto, and telegraph, distortion of signal shape is more important than for ordinary telephone communication (see references 7–12). Equally as important as attenuation distortion (vs. frequency) as a criterion for distortion of signal shape is envelope delay distortion. Envelope delay is expressed as $d\beta/d\omega$, and in an ideal system it is independent of frequency in the range of interest. Envelope delay distortion is corrected by means of phase-shift networks, the objective being to obtain a phase shift vs. frequency characteristic in the frequency range of interest having a slope $d\beta/d\omega$ which is constant. For networks and amplifiers the necessary phase data are usually obtained directly from phase measurement. For long lines it is difficult to make accurate straightaway phase measurements on account of the instability of the loss and phase of the line which may include many repeaters, and the usual practice is to measure envelope delay distortion. From these data the phase requirements for the equalizer can be computed.

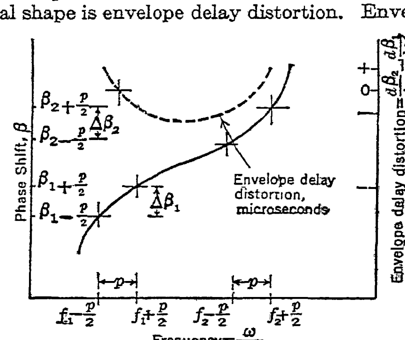

FIG. 6. Typical Phase Characteristic of a Transmission Line

Figure 5 shows a circuit for making straightaway measurements of the envelope delay distortion of long coaxial circuits. At the sending end four frequencies of equal amplitude are transmitted: $f_1 + p/2$ and $f_1 - p/2$, representing the reference signal; and $f_2 + p/2$ and $f_2 - p/2$, representing the test signal. Referring to Fig. 6, assume that the line under test has a phase vs. frequency characteristic as shown. At the distant end of the line each of the four frequencies will have been shifted in phase by different amounts $\beta_{(1-p/2)}$, $\beta_{(1+p/2)}$, $\beta_{(2-p/2)}$, and $\beta_{(2+p/2)}$. Now we can say that

$$\Delta\beta_1 = \beta_{(1+p/2)} - \beta_{(1-p/2)}, \qquad \Delta\beta_2 = \beta_{(2+p/2)} - \beta_{(2-p/2)}$$

and if p is chosen small enough then for all practical purposes

$$\frac{\Delta\beta_1}{2\pi p} = \frac{d\beta_1}{d\omega} \quad \text{and} \quad \frac{\Delta\beta_2}{2\pi p} = \frac{d\beta_2}{d\omega}$$

The envelope delay distortion $\left(\frac{d\beta_2}{d\omega} - \frac{d\beta_1}{d\omega}\right)$ is equal to $\frac{(\Delta\beta_2{}^\circ - \Delta\beta_1{}^\circ)_{10^6}}{360p}$ microseconds.

If f_2 is varied over the band of interest the measurement of $\Delta\beta_2 - \Delta\beta_1$ will represent envelope delay distortion referred to the envelope delay at the reference frequency f_1. If the set is given a "zero" adjustment by means of the "zero adjust" phase shifter so that with a distortionless line or resistance pad in place of the line under test the indicated envelope delay distortion is zero then the equipment at the receiving end will provide an indication proportional to $(\Delta\beta_2 - \Delta\beta_1)$ and therefore also to $\left(\frac{d\beta_2}{d\omega} - \frac{d\beta_1}{d\omega}\right)$, the envelope delay distortion. The receiving circuit functions as follows: the reference signal and the test signal are separated by filters as shown and then demodulated to obtain the difference products. The outputs of the two demodulators are of the same frequency p but have a phase difference equal to $\Delta\beta_2 - \Delta\beta_1$, assuming that the zero adjustment has been made. The amplitudes of the two vectors are made equal by means of the attenuators (which incidentally provides a measure of attenuation distortion) and combined in the hybrid coil from which two new vectors are obtained, one whose amplitude is a function of the sum of the two vectors $(E_{\Delta\beta_2} + E_{\Delta\beta_1})$ and the other whose amplitude is a function of the difference $(E_{\Delta\beta_2} - E_{\Delta\beta_1})$. These new vectors are rectified separately in linear amplifier rectifiers, and the difference of the d-c outputs is indicated on the two-winding zero center meter. By the use of the difference of the sum and difference d-c outputs the indication obtained is very closely proportional to $\Delta\beta_2 - \Delta\beta_1$ from 0 to $\pm180°$ and, as shown above, is therefore also proportional to $\left(\frac{d\beta_2}{d\omega} - \frac{d\beta_1}{d\omega}\right)$, the envelope delay distortion in microseconds. If the area under the plotted curve is integrated step by step by means of a planimeter or graphical methods, the phase vs. frequency characteristic can also be obtained which is the form of data required for use in designing phase-correcting networks.

By the introduction of a motor-driven signal generator and interlocking arrangements at the sending end and avc amplifiers in place of the attenuators and a recording meter at the receiving end, this circuit can be adapted to automatic recording of both the attenuation and envelope delay distortion vs. frequency characteristics.

After the initial phase correction is made by means of phase correctors in the line, the residual delay distortion is considerably reduced and it is necessary to increase the delay sensitivity of the measuring circuit to obtain data for more accurate phase equalization; this is accomplished by insertion of harmonic multipliers at A. Similarly the phase sensitivity may also be increased by increasing the frequency interval, p. The objection to this is that it does not catch the narrow interval variations.

16. NOISE MEASUREMENTS

Telephone circuit currents other than those produced by acoustic pressures on the transmitters (e.g., currents produced by electromagnetic or electrostatic induction from power circuits or from other telephone circuits, currents produced by thermal noise, vacuum-tube noise, defective components, etc.) produce noise in a telephone receiver connected to the circuit, these currents being called noise currents. Not all frequency components of noise have the same interfering effect on a telephone conversation, since the human ear and the telephone system do not respond equally to all frequencies. (See also Coordination of Communication and Power Systems, Section 10.) A measurement of the total noise power on a telephone circuit would, therefore, not be a true indication of its interfering effect.

For many years noise currents were measured by comparing the actual noise as heard in a receiver to an adjustable standard noise produced by a buzzer, the ear weighting the different frequency components of the noise. Difficulty in comparing the noise with the standard when it did not have the same frequency components, and variations between different observers when measuring the same noise, resulted in the development of meter methods, the device for measuring telephone circuit noise being known as a circuit noise meter or noise-measuring set (see references 13 and 14). This consists of a high-gain amplifier a weighting-network, a rectifier, and a d-c meter as shown in Fig. 7.

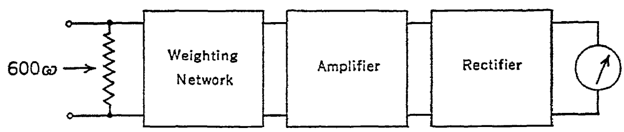

FIG. 7. Circuit Noise Meter

A typical weighting network and amplifier together have the response characteristic as shown in Fig. 8. This curve is based on a large amount of experimental data and takes into account the typical receiver-ear sensitivity and terminal trunk transmission characteristics. For lines carrying program, the weighting characteristic would be different, giving more weight to the upper and lower frequencies.

The rectifier circuit has been designed so that the d-c output for a steady-state complex input to the rectifier is proportional to the square root of the sum of the squares of the individual single-frequency voltages in the complex input. The output is a function of the average power impressed on the rectifier and not of wave shape.

A limited db scale on the meter and a gain control calibrated in decibels are provided for indicating the noise level in decibels above "reference noise," which is the term given to any circuit noise which would produce a meter reading of zero, the same reading as would be produced by sending 10^{-12} watt of 1000-cycle power into the circuit noise meter (600 ohm input).

Reference noise is defined in this manner so as to facilitate calibration and measurement. For a single type of telephone instrument and corresponding weighting network the definition is sufficient. However, there are several instruments with different frequency-response characteristics, and each requires a separate weighting network. The method of calibration makes these networks all give the same reading for a 1000-cycle input, but noise measured as equal with different networks may not be equal in interfering effect when heard with the corresponding instruments. In practice, it is customary to express noise magnitudes in dba (decibels adjusted) by adjusting the reading in db above reference noise so that equal magnitudes (in dba) represent equal interfering effects for different types of instruments. A different adjustment is required for each type of telephone instrument.

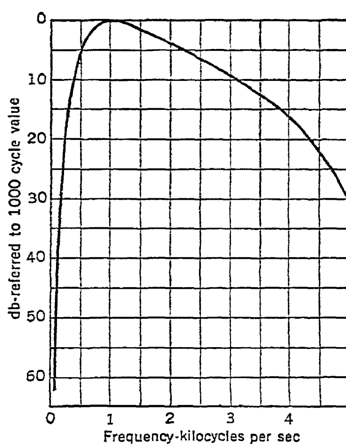

FIG. 8. Frequency Characteristic of Typical Weighting Network

The meter and associated circuits have a dynamic characteristic such that the response to sounds of short duration approximately simulates that of the ear.

17. CROSS-TALK MEASUREMENT

Transmission between separate communication circuits is called cross-talk. When the cross-talk comes principally from one other circuit, it is measured in the same way as a transmission loss by sending testing power into the disturbing circuit and measuring the cross-talk power received in the other, the ratio between the powers being expressed in decibels, since, if a circuit is not overloaded, the ratio is substantially independent of the actual power. This type of measurement is called a cross-talk coupling measurement.

In measuring the cross-talk coupling between two coterminous two-wire circuits, the generator which supplies the testing power and the receiving device which measures the received power are connected at the same ends of the circuit as in Fig. 9, the measurement being called a near-end measurement. Four-wire and carrier circuits have separate transmitting and receiving paths. For these types of circuits, it is, therefore, often desirable to connect the disturbing generator and the receiving device at opposite ends of the circuits, as shown in Fig. 10, this type of cross-talk coupling measurement being called a far-end measurement.

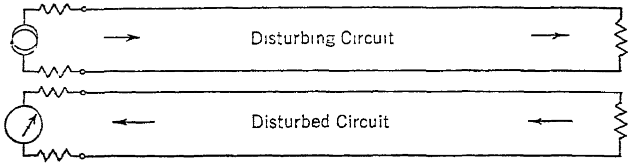

FIG. 9. Near-end Cross-talk Coupling Measurement

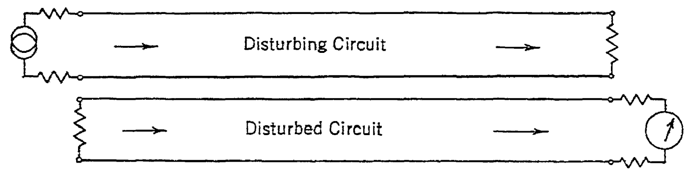

FIG. 10. Far-end Cross-talk Coupling Measurement

As the frequency of the disturbing power is changed, the cross-talk coupling between two circuits varies over a wide range. Single-frequency cross-talk measurements are therefore of little value, and generators of complex wave shape are used to obtain results approximating actual talking conditions. Either warbler oscillators or tube noise generators whose energy-frequency spectra are shaped to simulate the human voice are used as power sources. The warbler oscillator contains a frequency-changing device that causes the frequency to sweep over a wide range several times per second. The meter in the receiving or measuring device averages the results over the range.

Except when there is trouble, the cross-talk between any two circuits is generally very small. However, when there are many circuits in a group, as in telephone cables, each may produce a small amount of cross-talk in any one circuit so that the total cross-talk in that circuit may be noticeable. Coming from so many sources, it is usually unintelligible and is commonly known as "babble." The amount of babble varies with the actual volume of speech on the other circuits, being greatest at periods when the greatest number of circuits are in use.

Since the sources of babble are numerous, and since the volume on the disturbing circuits cannot be controlled, the babble noise on a circuit must be measured in some such manner as speech volume, or noise, the measurement being one of power, rather than a power ratio measurement as in cross-talk coupling.

Tests are made by connecting a high-impedance vacuum-tube measuring device across an idle circuit. This receiving device is similar to that used in transmission level or volume tests with the exception that the amplifier does not have a uniform frequency response, the characteristic of the amplifier being similar to that used in noise measurements. If observations with this device for short periods during several successive days show no abnormal conditions, the circuit is considered satisfactory. A high-impedance device is employed so that it will not interfere with normal use of the circuit.

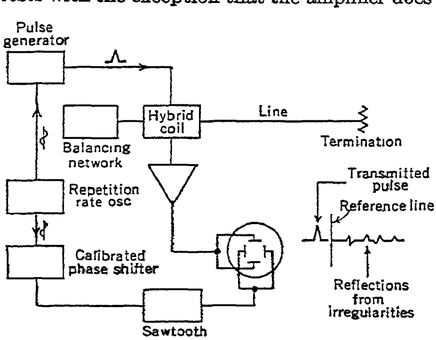

FIG. 11. Echo Indicator

18. ECHO TESTING OF LINES

This method of test is an adaptation of radar methods and has been used in two principal applications: (1) location of gross faults in cable and open-wire circuits, and (2) detection of irregularities of coaxial cable circuits used for television.

Figure 11 shows a circuit applicable to this test. The fundamental circuit is similar for both applications, the differences being in the shape and length of the transmitted pulses, the repetition rates, and the sweep speeds (see references 12, 15, and 16).

resistance and reactance curves are no longer smooth but change periodically, curve B showing the effect of an irregularity on the effective resistance. The reactance changes in a similar manner. This effect is utilized in locating the irregularity, as there is a relation between the separation of peaks on the curve and the distance to the irregularity.

When an alternating current strikes a circuit irregularity such as a sudden change in impedance, some of the current is reflected towards the sending end, the amount so reflected depending upon the size of the irregularity. Sometimes this reflected current aids the current entering the line and sometimes it reduces it, depending upon the distance to the irregularity and the frequency. When the distance from the sending end of the line to the irregularity is great a larger number of wavelengths is included between the two points than when the line is short; consequently a smaller change in frequency is necessary to add an extra wavelength. Each wavelength, half of which adds to and half of which subtracts from the original current, thereby decreasing or increasing, respectively, the impedance of the circuit, causes a peak or hump in the curve.

As an example of the manner in which the distance to an irregularity can be determined (see Fig. 12), let d be the distance to an irregularity. The reflected current must travel from the sending end to the irregularity and back again to the starting point, so that it really travels twice the distance or $2d$. If the length of one wave is W_1, the total number of wavelengths in the reflected current equals twice the distance divided by the wavelength. Let the number of waves be designated by N; then $N = 2d/W_1$ at some particular frequency which can be called f_1. Assume that f_1 is the frequency corresponding to one of the peaks on the impedance curve.

As brought out in the foregoing, when the frequency has been increased so that one more wavelength is included in the double length of line, another peak will be produced in the impedance curve. Let this frequency be designated as f_2. There are now $N + 1$ wavelengths at a frequency f_2, or $N + 1 = 2d/W_2$. The distance d to the irregularity has not changed, but the length of one wave has changed to some value W_2.

As the wave travels along a telephone line at practically the same velocity at all frequencies, the wavelength can be expressed in terms of velocity and frequency. If an alternating current flows over a circuit at some velocity V miles per second, the length in miles of any one wave, W, is equal to the velocity divided by the number of waves per second, or the frequency. In other words, $W = V/f$.

As shown above, the number of waves in the double path of the reflected current is equal to N for frequency f_1 and $N + 1$ for frequency f_2. In turn $N = 2d/W_1$ and $N + 1 = 2d/W_2$. Since the wavelength equals the velocity in miles divided by the frequency, the wavelength for any particular frequency such as f equals the velocity divided by that frequency. Therefore,

$$W_1 = \frac{V}{f_1}$$

and

$$W_2 = \frac{V}{f_2}$$

Substituting these values of W_1 and W_2 in the equations

$$N = \frac{2d}{W_1}$$

and

$$N + 1 = \frac{2d}{W_2}$$

respectively. Then

$$N = \frac{2d/V}{f_1} = \frac{2df_1}{V}$$

and

$$N + 1 = \frac{2d/V}{f_2} = \frac{2df_2}{V}$$

The frequency f_1 represents one peak on the curve, and f_2 represents the next peak as the frequency increases. From the curve can be determined the number of cycles difference in the two frequencies representing adjacent peaks, this difference, of course, being equal to $f_2 - f_1$. Combining the two equations above so that the term $f_2 - f_1$ will be present, subtract N from $N + 1$. Then

$$N + 1 - N = \frac{2df_2}{V} - \frac{2df_1}{V}$$

This gives

$$1 = \frac{2df_2}{V} - \frac{2df_1}{V}$$

or

$$V = 2d(f_2 - f_1)$$

From this the distance to any irregularity may be determined provided the difference in frequency between two adjacent humps and the velocity with which an alternating current flows along the line are known. The above equation may be written as

$$d = \frac{V}{2(f_2 - f_1)}$$

Expressed in words this means that the distance to any irregularity equals the velocity with which an alternating current flows along the line in question divided by twice the difference in frequency between adjacent humps.

The velocity of transmission for all types of circuits is determined experimentally by introducing a known irregularity and solving the equation for V. In practice it is usual to take the difference in frequency between several adjacent peaks, between approximately 700 and 1500 cycles, and use the average difference in velocity at different frequencies which causes the interval between peaks to change slightly with frequency.

Measurements are usually made with the simple form of impedance bridge shown schematically in Fig. 12.

21. D-C AND LOW-FREQUENCY LINE TESTING

Telegraph and telephone line test boards are generally equipped with special types of voltmeters and Wheatstone bridges for making periodic tests of the line wires and for the location of faults. These faults are of three general types: grounds, crosses, and opens; and they may have any value of resistance from zero to several megohms. The voltmeter provides a simple method of determining the type and magnitude of a fault, as shown in Figs. 13, 14, 15, and 16.

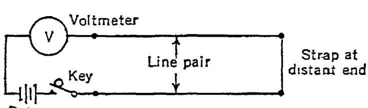

FIG. 13. Continuity Test

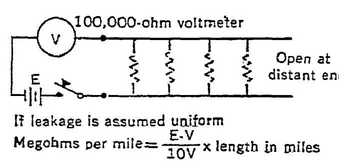

FIG. 14. Insulation Test

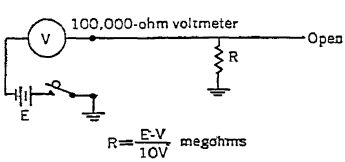

FIG. 15. High-resistance Leak to Ground

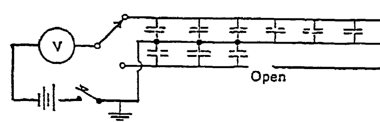

When key is closed the charging current will cause a momentary deflection. The duration is proportional to the capacitance. Thus by comparing the deflection obtained with the defective wire with that obtained with a good conductor of known length the distance to the fault can be estimated.

FIG. 16. Voltmeter Test for Open

For the actual location of faults the Wheatstone bridge is used as illustrated in Figs. 17, 18, 19, 20, and 21. In these figures L is the length of the line and d is the distance

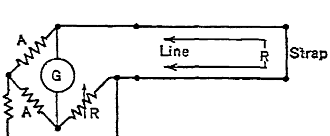

FIG. 17. Simple Bridge to Measure Loop Resistance. At Balance $R_L = R$.

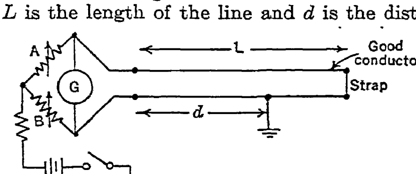

FIG. 18. Simple Murray Loop Test for Grounded Conductor. When A and B are adjusted for balance

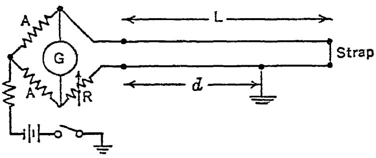
$$d = 2L\frac{B}{A+B}$$

from the testing end to the fault. It is assumed in the illustrations that the good and faulty conductors used in the bridge measurement have the same resistances per unit length in the case of grounds and crosses, and the same capacitances per unit length in the case of opens.

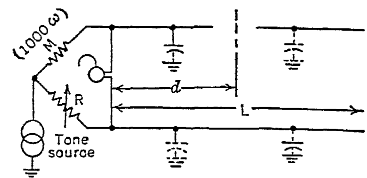


Note: The conductor unit resistance will not usually be accurately known. For this reason a fault is ordinarily located on a percentage basis by making both simple loop and Varley measurements.

FIG. 19. Simple Varley Loop Test for Grounded Conductor

$$d = L - \frac{R}{2K}$$

(K = ohms per conductor unit length.)



When R is adjusted to give minimum response in telephone receiver

$$d = \frac{R}{M} L$$

FIG. 20. Simple Murray Loop Test for Opens. [Suitable only for short lines (1/2 mi cable). For longer lines use Fig. 21.

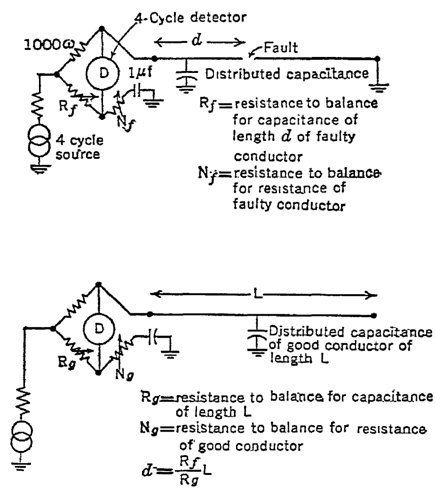


FIG. 21. To Locate an Open, a Bridge Reading Is Taken on the Open Conductor and Compared with the Reading Obtained on a Good Conductor of Known Length

If the fault is a cross between wires, the second crossed wire is substituted for the ground connection to the battery key.

It is important that the location be as accurate as possible to lessen the overall fault clearing time, and to this end variations of the simple bridge tests are used to minimize errors (see references 22–29).

ROUTINE MEASUREMENTS ON A-M AND F-M BROADCAST RECEIVERS

By W. O. Swinyard

In receiver measurements it is sometimes convenient to use the logarithm of the stage gain so that gains can be added, instead of multiplied, to determine the overall non-regenerative gain, and to express these in terms of decibels. It is also convenient to discuss overall sensitivities in terms of decibels below 1 volt, in which case the microvolt sensitivity is used to determine a voltage ratio. Though this is strictly a misuse of the term, it is convenient and will lead to no serious difficulty as long as the user is aware of the limitations of these practices.

22. OVERALL A-M RECEIVER MEASUREMENTS

REQUIRED TEST EQUIPMENT. Standard-signal generator, standard dummy antenna, standard test loop, output wattmeter, audio-frequency generator, distortion meter or wave analyzer, and an auxiliary 1000-kc signal generator.

STANDARD TEST CONDITIONS. Standard line voltage is 117 volts for a-c, d-c, and a-c/d-c receivers. Receivers designed for a-c and d-c operation are usually tested on alternating current and check measurements are made on direct current.

Measurements on automobile receivers should be made using a battery which provides 6.6 volts at the receiver battery terminals.

The normal test voltage for receivers designed for farm lighting systems is 36 volts.

Battery-operated receivers should be tested using new batteries of the type and voltage specified by the receiver manufacturer.

The volume control and the tone control or controls should be set to provide maximum 400-cycle output. If a selectivity control is provided, it should be set, for the initial tests, to provide greatest selectivity. The effect of the tone and selectivity controls on the performance should be determined by special tests.

RECEIVER ALIGNMENT CONDITIONS. The overall sensitivity, selectivity, and range coverage of the receiver are first measured without disturbing the receiver alignment. These measurements are followed by the single-stage measurements, after which the receiver is aligned, in accordance with the manufacturer's service instructions if available, and complete overall measurements are made. Normally, no overall measurements are made with the receiver aligned at each test frequency. However, in certain cases such measurements might be desirable since they would show the effect of circuit misalignment on the overall sensitivity, assuming no regeneration. In all cases, however, the frequencies at which the circuits are in exact alignment should be noted.

Figure 1 shows the equipment as it is set up for overall measurements.

RANGE COVERAGE. The maximum and minimum frequencies to which the receiver can be tuned in each band are recorded for the "as received" and later for the aligned conditions.

OVERALL SENSITIVITY (SENSITIVITY-TEST INPUT). This test normally consists of determining the sensitivity-test input at three to six points in each wave band. The output of the standard-signal generator is fed into the input terminals of the receiver through the standard dummy antenna. The output meter is connected to the secondary of the output transformer, and the load is adjusted to the proper value. The receiver is then turned on and the voltage of the power source set to the correct value. After it has throughly warmed up it is tuned to the modulated signal-generator output and the controls are adjusted to provide maximum 400-cycle output. The 400-cycle filter is then switched in to remove the noise, and the sensitivity-test input is determined. It may be measured in decibels below 1 volt or in microvolts.

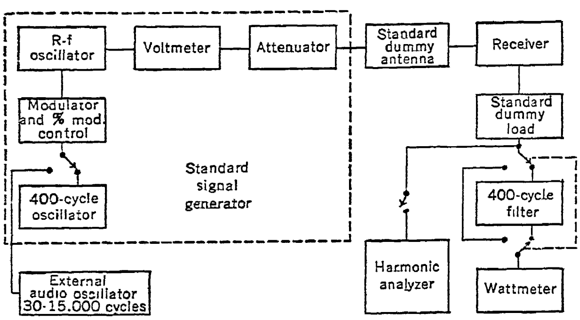

FIG. 1. Arrangement of Apparatus Used for Overall Measurements

If the receiver employs a selectivity control its effect on the sensitivity is determined by additional measurements which are usually made at 600 kc, 1000 kc, and 1400 kc.

The sensitivity of battery-operated receivers is measured in the normal way and with A and B batteries whose terminal voltage has dropped to 1.1 volts for the A and to 60 per cent of the nominal value for the B battery.

A 400-cycle filter used with the output wattmeter usually will reduce the noise voltage in the output to a negligible level. However, there may be cases where noisy or extremely sensitive receivers are being measured when allowance must be made for residual noise.

EQUIVALENT-NOISE-SIDE-BAND INPUT. The equivalent-noise-side-band input is taken equal to the input of a single side band of 400-cycle modulation which will produce an output from the receiver equal to the noise output, other conditions being the same. The reason noise of both side bands has to be identified with a single-side-band component of modulation is that there is a random-phase relation between the noise side bands as distinguished from the specific phase relations existing between the carrier and each pair of side-band components of modulation. The equation for *ENSI* is:

$$E_n = 0.3E_s \frac{E_n'}{E_s'}$$

where E_n is the desired *ENSI* in microvolts, E_s is the carrier level in microvolts, E_n' is the rms output voltage of the noise alone with an unmodulated carrier applied to the antenna, and E_s' is the output voltage due to modulating this carrier 30 per cent at 400 cycles. The coefficient 0.3 is required because the test input is modulated 30 per cent, and only one side band is considered.

To obtain *ENSI*, the sensitivity is first determined making due allowance for noise. This gives a convenient value for E_s in microvolts. The corresponding 400-cycle output voltage gives the value of E_s'. The modulation is then removed, the 400-cycle filter switched out, and the rms voltage due to the noise is noted. This gives the value of E_n' if a thermocouple meter is used or if the proper correction is applied for the particular meter used. The corresponding *ENSI* may then be computed from the equation given above.

The value of E_s' and E_n' may be observed at a higher signal input level since only their ratio enters. A good practice is to increase the carrier input at which *ENSI* measurements are made, whenever the ratio E_n'/E_s' exceeds 1. This makes the effective increase in noise power due to beats between noise side bands negligible relative to the power due to beats between the noise side bands and the carrier.

It should be noted that it is possible to determine *ENSI* without using a 400-cycle filter. Where this procedure is followed, it is convenient to set the attenuator to the point which makes the noise-output power equal to the signal-output power. *ENSI* is then the signal input multiplied by the per cent modulation.

SELECTANCE RATIOS. It is of interest to know how well the receiver discriminates against signals located 10 kc away on either side of the desired channel. The regular overall sensitivity setup is used. The selectance ratio in decibels is the difference between the signal input in decibels below 1 volt required for normal test output on the channel to which the receiver is tuned and that required for normal test output on the adjacent channel. The selectance ratios are usually measured at 600 kc, 800 kc, 1000 kc, and 1400 kc in the broadcast band and at corresponding points in the long-wave band if one is used.

IMAGE RATIOS. The setup for these measurements is the same as that for overall sensitivity. After measuring the sensitivity, the receiver tuning is left undisturbed and the signal generator is set to the image frequency. The least signal-input voltage with the signal modulated 30 per cent at 400 cycles required for normal test output is the image sensitivity. The image ratio in decibels is the difference between the overall and image sensitivities, when both are expressed in decibels below 1 volt.

There are other spurious responses such as the half i-f image which are due to oscillator harmonics beating against either the fundamental of an interfering signal or harmonics of that signal which may be generated in the receiver. However, these are not usually measured in a routine receiver analysis.

I-F REJECTION RATIOS. The sensitivity of the receiver to the intermediate frequency is determined with the regular setup used for overall-sensitivity measurements (including the standard "all-wave" dummy antenna). The i-f rejection ratio in decibels is the difference between overall and i-f sensitivities in decibels below 1 volt. Measurements are usually made at three points in each wave band. In the broadcast band these points are usually the two lowest and the highest frequency test points.

OVERALL SELECTIVITY. The overall selectivity is measured at the center of the band (1000 kc in broadcast receivers). The setup is the same as that used for overall-sensitivity measurements, and the measurement can conveniently be made after the measurement of sensitivity and *ENSI* at 1000 kc. The total widths of the selectivity curve at points 6, 20, 40, 60, and 80 db down from the resonant voltage peak are recorded in kilocycles as W_6, W_{20}, W_{40}, W_{60}, and W_{80}. The procedure is as follows: the receiver is tuned to resonance at 1000 kc and the attenuator set to the sensitivity-test input; the signal generator is then tuned off resonance and the output voltage is increased 6 db; the generator is tuned toward resonance until normal test output is secured and the frequency is noted; the generator is then tuned through resonance to the point on the other side where normal test output is secured and the frequency is again noted. The difference in kilocycles between these two readings is W_6. For W_{20}, W_{40}, etc., the process is repeated. At this point it should be pointed out that the modulation should be removed while the generator is tuned through resonance to avoid damage to the output meter and that care should be taken to avoid errors in the measurement due to possible back-lash in the signal generator frequency-dial mechanism.

Where variable i-f selectivity is employed, selectivity measurements are usually made at each position of the selectivity control switch, or at three positions, in the case of continuously variable selectivity, at the extremes and middle settings of the control.

An additional measurement of selectivity is made in the case of battery-operated receivers, namely, under the "dead battery" conditions previously described.

For a receiver employing a long-wave band, it is desirable to measure the selectivity at the midpoint of this band since the normal selectivity of low-frequency preselector circuits may result in appreciable narrowing of the skirt selectivity.

In the case of a receiver incorporating a double avc system normal selectivity measurements will indicate sharper selectivity than is actually provided by the selectivity of the resonant circuits. This is true to some extent in any receiver which has less selectivity to the avc detector than to the signal-frequency detector. In some cases it may be advisable to disable the avc before making selectivity measurements.

WHISTLE MODULATION. When a signal having a frequency close to twice the intermediate frequency is being received it is often accompanied by an audible whistle or tweet. This is measured at several values of signal-input level and compared with the corresponding 400-cycle modulated signal by expressing the whistle in terms of the per cent modulation at 400 cycles required to give an output voltage equal to that resulting from the whistle.

Measurement of the equivalent whistle modulation is made with the regular setup for overall-sensitivity measurements. The signal generator with the output set to the appropriate value and with zero modulation is tuned to approximately twice the intermediate frequency. The exact setting is chosen by slowly turning the generator from about 30 kc below to 30 kc above the frequency that is twice the intermediate frequency while the receiver tuning control is rocked. The generator is set at the point providing the greatest whistle output. The receiver, not the generator, is detuned to produce a whistle of maximum intensity to the ear, the volume control being set so that the output voltage at this point is well below the overload level. The 400-cycle filter is then switched in; the modulation is applied to the signal generator and adjusted until the output approaches as closely as possible the output previously noted. The ratio of the 400-cycle output voltage to the whistle voltage multiplied by the per cent modulation gives the whistle modulation in per cent. This procedure is followed for inputs of 0, 20, 40, and 60 db below 1 volt.

The above procedure must be modified when measuring the whistle modulation at input levels of 80 db below 1 volt and less, since the noise tends to mask the whistle when the filter is not used. Therefore, the 400-cycle filter is switched in and the whistle carefully adjusted to give maximum output. Then the receiver is tuned slightly to one side of the carrier, the modulation applied, and the whistle modulation determined as before. The equivalent whistle modulation measured at 400 cycles is usually substantially less than that of higher frequency whistles, when appreciable avc voltage is developed. However, these low-level measurements are usually only important qualitatively, and they indicate the need for work on the receiver to remove their causes. In thoroughly shielded receivers of correct design the whistle is usually not measurable with inputs below 80 db below 1 volt.

OUTPUT AND AVC CHARACTERISTICS. These measurements are made in the middle of the band (1000 kc for broadcast receivers) using the setup and test conditions for overall sensitivity. The signal is modulated successively at 0, 10, and 30 per cent for each value of signal input. The signal input is varied from 120 db to 0 db below 1 volt, and the audio output for each of the three modulation percentages is plotted against the corresponding signal input. The 400-cycle filter is switched in to remove the noise from that portion of the 30 per cent curve which is below the overload level, and the data are recorded with and without the filter for this portion of the curve. The 0 per cent output curve indicates the noise output of the receiver at full sensitivity. It also indicates the presence of hum modulation and motorboating at high signal-input levels.

The avc characteristic is taken in the same manner as the 30 per cent modulation curve except that the volume is reduced sufficiently to prevent overloading the output amplifier. Usually a reduction in the output voltage of 6 db with a 0 db below 1 volt signal input is sufficient. The 400-cycle filter should be used where a measurable amount of noise is present.

AVC FIGURE OF MERIT. The avc figure of merit can be obtained from the avc characteristic. It is the number of decibels decrease in signal input necessary to reduce by 10 db the output obtained at a signal input level of 20 db below 1 volt.

TWO-SIGNAL SELECTIVITY (CROSS-TALK INTERFERENCE). For these measurements the generators may be coupled to the receiver under test in either a series or parallel arrangement. The measurement is made at 1000 kc for two values of desired signal input: 46 db and 0 db below 1 volt for home receivers and 46 db and 14 db below 1 volt for automobile receivers. The 1000-kc signal is tuned in with the volume control set to provide a medium-strength a-f output from a 1 per cent modulated signal. Modulation is then removed; the two generators are connected together with the interfering signal modulated 30 per cent and introduced at amplitudes which result in the output previously noted for the 1 per cent modulated desired signal. The interfering signal measurements are taken at every channel on both sides of 1000 kc up to a 100-kc difference unless the necessary signal input reaches the maximum output of the generator before the plus and minus 100-kc points have been reached.

If an auxiliary 1000-kc generator is used, the necessary output adjustments can be made using the standard-signal generator modulation for both desired and interfering signals. When the two are connected in series for the test the auxiliary 1000-kc generator, having no modulation, serves as the desired signal.

It should be noted that the impedances of the two standard dummy antennas which are necessary if the signal generators are connected in parallel should be double the normal values. If the two generators have equal output impedances independent of the attenuator settings, the effective output voltage produced by either one is only half the indicated output.

In making the two-signal selectivity tests two whistles will usually be encountered on the low-frequency side of 1000 kc. If the intermediate frequency is 455 kc, the first occurs at approximately 955 kc and is due to the beat between the fundamental of the receiver oscillator, 1455 kc, and the second harmonic of the input signal. The second occurs at approximately 910 kc and is the regular twice-i-f whistle to which previous reference has been made.

HARMONIC DISTORTION. A distortion analysis is made at 1000 kc using the setup for overall sensitivity in conjunction with a distortion meter or a wave analyzer. Three sets of measurements of per cent harmonics are made. For the first the signal input is maintained constant at 46 db below 1 volt, with 30 per cent modulation at 400 cycles. Harmonics are measured at several output levels up to and including the maximum obtainable. It is desirable to choose one output level so that 10 per cent total distortion results since this is usually chosen as representing the maximum undistorted output. For the second set of measurements the signal input is maintained constant at 46 db below 1 volt and the receiver volume control is adjusted for normal test output. The modulation is then set to 10 per cent, 50 per cent, and 80 or 100 per cent, and the harmonics are measured for each value of modulation percentage. The final measurements are made keeping the modulation at 30 per cent, the output at normal test output, setting the signal-input level to 60 db, 40 db, 20 db, and 0 db below 1 volt and measuring the harmonics at each value of signal input. These values of signal input may have to be modified for receivers of special types. If a wave analyzer is used the total per cent harmonic distortion is calculated as the square root of the sum of the squares of the individual per cent harmonics.

OVERALL ELECTRICAL FIDELITY. The regular overall-sensitivity-measurement setup is used for this measurement except that the signal generator is modulated 30 per cent by an a-f signal generator of variable frequency and the 400-cycle filter is switched out. The receiver is first tuned to 1000 kc using a weak signal. The signal input is then set to 46 db below 1 volt, and the receiver volume control is set to provide an output well below overload. The modulation frequency is then increased until the output is reduced by about 14 db, and the tuning control is finally adjusted for minimum output at this frequency. The modulation is then set back to 400 cycles and a final adjustment of the output voltage is made. The output is then measured at a sufficient number of modulation frequencies to permit plotting a curve showing the relative response, in decibels, versus modulation frequency using the 400-cycle output voltage as a reference. Curves are made showing the maximum overall fidelity and the effect of the tone control on the fidelity. Usually two curves are recorded: (1) with the tone control set for maximum highs, and (2) with the tone control set for minimum highs. In the case of 1.4-volt battery-operated receivers the fidelity is also measured using "dead batteries." If a bass-compensated volume control is used, measurements should be made with the arm set both above and below the tap to show the effect of the bass compensation. It may be better to disconnect the network from the tap in order to avoid overload.

TESTS ON PUSH-BUTTON TUNERS. Receivers provided with a mechanical push-button tuning mechanism are subjected to tests devised to show how accurately the push buttons can be set and how well they return to the frequency to which they are set. For these tests the buttons are all set up to tune a signal near the high-frequency end of the band to zero beat with a signal from another generator which is set to the intermediate frequency. For each push button the gang is opened, the button actuated, and the resultant beat recorded as a frequency error. This is repeated several times, usually eight, and similar tests are made from the closed position of the gang. Finally tests are made with the gang alternately opened and closed before the button is pushed. All measurements for each button (24) are then averaged taking account of the sign, and the result is recorded as a setting error. The setting errors for each button are averaged without regard to sign to secure the average setting error. The deviations of all the errors for each button from the figure representing the setting error for that button averaged without regard to sign give the mean tuning deviation. The average mean tuning deviation is the average of the mean tuning deviations.

MEASUREMENTS USING STANDARD TEST LOOP. The following measurements which employ the standard test loop (Fig. 2) are made on loop receivers: sensitivity,

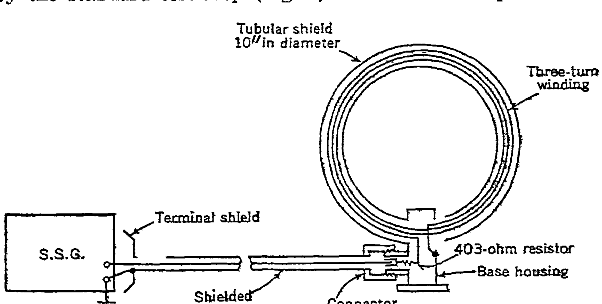

FIG. 2. Test Loop

ENSI image, i-f and selectance ratios, and loop figure of merit. The test loop is connected to the output of the signal generator and set up 24 in. away from the receiver loop with the loops arranged coaxially. The overall sensitivity in decibels below 1 volt per meter is 20 db below the signal generator attenuator reading when the input is adjusted for normal test output. The loop figure of merit is the difference between the sensitivity in decibels below 1 volt per meter and the sensitivity at the first grid measured in decibels. It is recorded as minus when the absolute magnitude of the overall sensitivity in decibels below 1 volt per meter is less than the first grid sensitivity in decibels. Where no external antenna connection is provided other measurements than these must of necessity be made using the loop input. In all cases the same procedure is followed as has been previously outlined except that the input is specified in decibels below 1 volt per meter. Many signal generators operated with the standard test loop will not provide an input to the receiver loop of more than 20 db below 1 volt per meter when the test loop is operated under normal conditions.

AUDIO FEEDBACK FACTOR. If the audio amplifier of the receiver employs negative feedback a measurement of overall a-f gain is made with the feedback removed, and the increase in gain measured in decibels at 400 cycles is expressed as the audio feedback factor.

OSCILLATOR DRIFT. This test may be carried out as follows: The receiver is tuned to a secondary frequency standard or to a signal generator of known stability characteristics. The resultant beat produced as the oscillator drifts is measured by zero beating it against an audio signal from an amplifier fed by an a-f generator. Oscillator drift measurements are made at some point near the high-frequency end of each band. The receiver is tuned to about the right point and then turned on and as quickly as possible tuned to zero beat against the frequency standard or signal generator. Measurements are made every 5 minutes for a half hour and then every 15 minutes for 2 hours or until the oscillator frequency has become stabilized. If the oscillator drift is such that the beat note goes above the range of audibility the drift can be determined directly by zero beating with the signal generator for each measurement. The direction of drift can be determined by noting the effect on the beat note of a small change in the capacitance in the oscillator tank circuit—a change such as is produced by bringing a finger up close to the tuning condenser stator.

23. SINGLE-STAGE MEASUREMENTS

REQUIRED TEST EQUIPMENT. Standard-signal generator, standard dummy antenna, output wattmeter, vacuum-tube voltmeter, tuning wand, reactance meter or *Q* meter, high-resistance voltmeter, and a wattmeter.

HIGH-FREQUENCY MEASUREMENT PRECAUTIONS. In many cases measurements cannot be made properly by substituting a vacuum-tube voltmeter for a tube or by placing it in parallel with a tube. The inherent capacitance of the stage may be so low that a change in its value may decidedly influence the shape of the selectivity curve. In such cases it is suggested that the procedure to be described later for use in making single-stage measurements on f-m receivers be followed.

ANTENNA GAIN AND BAND WIDTH. The voltage gain from the antenna to the first grid is measured at all the test frequencies used for sensitivity measurements. The width of the resonance curve 6 db down is measured at three points in each wave band. For these measurements the signal generator output voltage unmodulated is fed into the receiver antenna circuit through the standard dummy antenna. The voltage developed across the output of the antenna circuit is measured by means of a vacuum-tube voltmeter to which the lead normally connected to the grid of the first tube is connected. The signal generator output voltage is increased by 6 db and the generator is then detuned on each side of resonance until the output drops to the reference value. If there are two tunable circuits ahead of the first tube the gain and band widths are also measured on the first circuit alone. Where measurements are made at high frequencies, the precautions previously noted must be observed.

COIL MISALIGNMENT. When there are two tunable circuits ahead of the first tube or an antenna and an r-f stage, the misalignment of these circuits can be measured by means of a reactance meter or a *Q* meter. For a receiver with a tuned r-f stage, the receiver tuning condenser is set at a minimum capacitance and the standard dummy antenna is connected across the antenna-ground terminals of the receiver. The r-f circuit is used as a standard and connected across the condenser terminals of the *Q* meter, with a standard coil covering the desired range plugged into the coil terminals. The frequency of the *Q* meter is set to the high-frequency alignment point and the *Q* meter condenser adjusted for maximum *Q* indication. The antenna circuit is then substituted for the r-f circuit and the antenna trimmer adjusted to bring the antenna circuit into exact alignment with the r-f circuit as indicated by a maximum reading on the *Q* indicator.

After the antenna and r-f circuits have been aligned, the Q meter is set to each of the test frequencies and at each point the r-f circuit is connected to the condenser terminals and the Q meter tuning condenser is adjusted for maximum Q indication. The antenna circuit is then substituted for the r-f circuit and the Q meter condenser is readjusted for maximum Q indication. The difference between the two condenser settings is the misalignment correction in micromicrofarads between the two circuits.

Another measurement is made using the Q meter to determine the effect changing the antenna capacitance has on the broadcast or long-wave band tuned antenna circuit. For these measurements the receiver tuning condenser is set to minimum capacitance and the condenser terminals of the Q meter are shunted across the tuned antenna circuit. A dummy antenna, identical to the standard dummy antenna except that the series capacitance element is adjustable, is set to the standard value of 200 $\mu\mu$f and connected across the antenna input circuit. The Q meter is set to 500 kc, and the Q meter condenser is adjusted for maximum Q indication. The antenna capacitance is then set to 60 $\mu\mu$f, 100 $\mu\mu$f, 300 $\mu\mu$f, 500 $\mu\mu$f, and short circuit (infinite capacitance), and the alignment corrections are noted for each value of antenna capacitance. These measurements are usually made at 500 kc, 600 kc, 700 kc, 1000 kc, and 1400 kc for the broadcast band in cases where a high-inductance antenna primary is used. The 700-kc and 1000-kc points may be omitted if the alignment is good. If the antenna circuit employs a low-inductance primary, resonant above 1500 kc, the test points are usually 600 kc, 1000 kc, 1200 kc, 1400 kc, and 1500 kc. In this case the 1000-kc and 1200-kc points may be omitted if the alignment is good at 1400 kc. Corresponding values are used in the long-wave band if one is provided. In the case of receivers intended to operate with antennas having characteristics substantially different from normal, values of antenna capacitance appropriate to the case are chosen instead of the above-mentioned values.

ALTERNATIVE METHOD OF MEASURING ALIGNMENT OF PRESELECTOR CIRCUITS. To remove the possibility of error due to regeneration the avc line is biased by means of a battery, 4 1/2–9 volts will usually be sufficient. All circuits are then aligned in accordance with manufacturer's service instructions. At each test frequency the misalignment of the preselector circuits can be determined by means of a "tuning wand," which consists of a length of insulating rod, such as hard rubber or Bakelite, to which an iron-dust slug and a brass slug are attached, one at each end. This is held inside or near each preselector coil. If the output of the receiver decreases when either the brass or the iron is brought near the coil, no misalignment exists. However, if either end causes an increase in output the misalignment is equal to the decibel increase in sensitivity. If the increase is caused by the brass, the coil inductance is too high; if it is caused by the iron, the inductance is too low.

R-F STAGE MEASUREMENTS. The voltage gain from the grid of each r-f amplifier stage to the grid of the following stage is measured at all the regular test frequencies, and the 6-db band width is measured at three points in each band as discussed in the section covering antenna circuits. The output of the signal generator is fed into the grid of the tube incorporated in the stage being measured, and a suitable vacuum-tube voltmeter is connected to the lead which normally is connected to the following grid. When the signal generator is connected so as to replace a grid circuit which normally returns to the avc string it should be connected through a condenser, with a grid leak returning to the avc circuit so as to maintain normal bias on the tube. The grid leak is returned to the avc circuit even though the avc may eventually return to ground, since otherwise the measurements may be in error owing to the initial avc voltage caused by space current due to the emission velocity of electrons from the diode cathode.

I-F MEASUREMENTS. Diode Stage. The diode stage gain is measured by connecting the vacuum-tube voltmeter from the diode plate to ground, thus not appreciably disturbing the loading on the diode transformer. The signal generator output is connected through the previously mentioned condenser-grid leak combination, to the last i-f grid, and the stage is aligned for maximum output. A measurement of the voltage gain of the stage is then made, and the bandwidths 6 db and 20 db down are determined.

I-F AMPLIFIER STAGE GAIN AND BANDWIDTHS. Measurements of gain and bandwidths of i-f stages are made as described above except that the vacuum-tube voltmeter is not shunted across the grid circuit of the following tube; it replaces it. It often is advisable to isolate the vacuum-tube voltmeter by means of a high-resistance grid leak and condenser if these elements are not incorporated in the instrument.

MODULATOR STAGE GAIN AND BANDWIDTHS. This measurement is made in the manner described in the above paragraph. The signal-frequency circuits should be set to the middle of the band and the oscillator should be operating for this measurement.

CONVERSION GAIN. The connections for the signal generator and vacuum-tube voltmeter used in measuring the gain of the modulator stage are employed to measure conversion gain, the only difference being that the signal generator is set to the standard test frequencies in each band, conversion gain being defined as the ratio of rms voltage of intermediate frequency at the grid circuit terminals of the first i-f transformer to the rms voltage of signal frequency applied at the grid of the modulator tube. The avc system should be disabled for these measurements.

SENSITIVITY ON MODULATOR AND ON I-F GRIDS. The least signal input to the last i-f grid required to produce normal test output with the signal modulated 30 per cent at 400 cycles is called the i-f sensitivity. A corresponding measurement made from the modulator grid is called the modulator-grid sensitivity. The i-f circuits should be aligned in both cases.

DETECTOR SENSITIVITY. The detector sensitivity is defined as the amplitude of the 30 per cent modulated rms voltage which must be applied to the detector tube to produce normal test output. It is of course an indication of the total a-f gain. It is usually determined indirectly from the measured diode stage gain and the sensitivity on the last i-f grid, the difference between these two quantities being the detector sensitivity in decibels below 1 volt.

OSCILLATOR VOLTAGE. The oscillator voltage usually measured is the d-c voltage across the oscillator grid leak, as calculated from the measured resistance value of the grid leak and the measured current flowing through it when the oscillator is working. The voltage is measured at each test frequency throughout the range of the receiver. If the oscillator circuit necessitates some other method of measuring oscillator voltage, the procedure followed should be noted.

24. MISCELLANEOUS MEASUREMENTS ON A-M RECEIVERS

HUM VOLTAGE. The rms value of the hum in the output of the receiver can be determined by means of the output meter, provided sufficient sensitivity is available, or by connecting the primary of a voltage step-up transformer across the primary of the output transformer. The voltage measured across the secondary of this transformer by means of a vacuum-tube voltmeter is divided by the transformer voltage ratio to get the required value of hum in the output circuit. The voice coil should be connected for this measurement. The hum should be measured for both the maximum and the minimum settings of the volume control. To prevent receiver noise from interfering with the measurement a large condenser should be connected from the plate of the last i-f tube to the $B+$ line.

MINIMUM OUTPUT SIGNAL. This measurement is made to determine how close to zero output the volume control can reduce the signal. The receiver is tuned to a 1000-kc 46-db below 1 volt signal 30 per cent modulated, and the power across the standard dummy load is measured. The 400-cycle filter should be used to remove hum and noise.

CONDENSER GANG ALIGNMENT. In the case of gangs having uniform sections the corrections in micromicrofarads required to bring the antenna and/or r-f sections into alignment with the oscillator section are measured for several settings of the condenser gang. If these measurements exceed normal tolerances the gang can be knifed to make the necessary changes.

D-C VOLTAGES. The principal d-c potentials existing at the tube elements should be measured using a high-impedance voltmeter, preferably an electronic voltmeter, and tabulated. These measurements are made directly after the "as received" measurements and at standard line or test voltage.

POWER CONSUMPTION. The power consumed by the receiver at standard line or test voltage is measured by means of a suitable wattmeter. In the case of battery-operated receivers the A and B drains should be measured.

25. F-M RECEIVER MEASUREMENTS

Measurement of such characteristics as antenna and r-f gain and selectivity, i-f gain and selectivity, etc., is independent of the type of modulation which the receiver is designed to receive, hence the methods described above are applicable. In the case of f-m receivers, higher frequencies are involved; hence, the high-frequency measurement precautions to be described later must be observed.

EQUIPMENT. The equipment required for routine measurements on a-m receivers is usually required for f-m receivers, since relatively few are designed solely for frequency modulation. Generally, frequency modulation is one of several frequency bands incorporated in a receiver. Only measurements such as quieting and deviation sensitivity, etc., where f-m modulation of the signal generator is required, necessitate the use of an f-m signal generator.

DEFINITIONS OF TERMS. See also *Standards on Radio Receivers*, 1947, I.R.E., Methods of Testing Frequency Modulation Broadcast Receivers.

Standard Very-high-frequency Dummy Antenna. The very-high-frequency dummy antenna is a pair of resistors, one connected in series with each terminal of the signal generator, of such value that the total impedance between terminals, including the signal generator, is 300 ohms balanced to ground.

Standard De-emphasis Characteristic. The standard de-emphasis characteristic has a falling response with modulation frequency, the inverse of the standard pre-emphasis characteristic, equivalent to that provided by a simple circuit having a time constant of 75 microseconds. The characteristic may be obtained by taking the voltage across a condenser and resistor connected in parallel and fed with constant current. The resistance in ohms is equal to 0.000075 divided by the capacitance in farads. The standard de-emphasis characteristic is incorporated in the detector and/or audio circuits of the receiver.

Standard Test Frequencies. The standard test frequencies used in testing f-m receivers are 88, 98, and 108 megacycles. If more than three frequencies are required, it is suggested that 93 and 103 megacycles be included. If only one test frequency is needed, 98 megacycles should be used.

Standard Test Modulation. This term refers to a signal that is frequency modulated at 400 cycles with a deviation of 30 per cent of the maximum system deviation of 75 kc. The deviation due to standard test modulation is therefore 22 $^1/_2$ kc.

Maximum-sensitivity Test Input. The maximum-sensitivity test input is the least input signal of a specified carrier frequency having standard test modulation which, when applied through the very-high-frequency dummy antenna, results in standard test output when all controls are adjusted for greatest sensitivity. It may be expressed in terms of power in decibels below 1 watt, in decibels below 1 volt, or in microvolts. Generally it is advisable to use a 400-cycle filter to remove the noise from the output.

Maximum-deviation-sensitivity Test Input. The maximum-deviation-sensitivity test input is the least input signal of a specified carrier frequency having full rated system deviation which, when applied to the receiver through the very-high-frequency dummy antenna, results in 10 per cent distortion in the output when the volume control is adjusted to standard output. It is expressed in decibels below 1 watt, in decibels below 1 volt, or in microvolts.

Deviation-sensitivity Test Input. The deviation sensitivity test input is the minimum deviation at 400 cycles of a carrier of 60 db below 1 volt required to give maximum undistorted output when all controls are adjusted for greatest sensitivity. The deviation sensitivity is expressed in kilocycles or as a percentage of maximum full system deviation.

Quieting-signal-sensitivity Test Input. The quieting-signal-sensitivity test input is the least unmodulated signal input which, when applied to the receiver through the very-high-frequency dummy antenna, reduces the internal receiver noise to the point where the test output rises 30 db when standard test modulation is applied to the input signal, the volume control being adjusted to avoid audio overload. It is expressed in decibels below 1 watt, in decibels below 1 volt, or in microvolts.

26. OVERALL PERFORMANCE TESTS

The setup for overall performance tests is the same for f-m receivers as for a-m receivers, assuming that in each case an appropriate signal generator and standard dummy antenna provide the test signal. For measurements on f-m receivers a resistor having a value equal to the input impedance for which the receiver was designed may be used as a dummy antenna. If the receiver employs a balanced input, half the resistance is used in each side. The conditions set down on p. 11-43 regarding receiver alignment apply here also.

OVERALL SENSITIVITY. The sensitivity-test input for the maximum sensitivity, the maximum deviation sensitivity, the quieting-signal sensitivity, and the deviation sensitivity should be measured at 3 to 6 frequencies.

IMAGE AND I-F RATIOS. The procedure for determining these characteristics is the same as for a-m receivers. The maximum-sensitivity test input should be used in determining the image and i-f sensitivity.

OUTPUT AND AVC CHARACTERISTICS (LIMITER CHARACTERISTICS). This measurement corresponds to the output and avc characteristics of a-m receivers, and the same procedure is followed in obtaining the data. In the case of f-m receivers, the modulation percentages used are 30 per cent (22 $^1/_2$ kc) and 10 per cent (7.5 kc). The output power versus signal-input voltage is determined at 98 megacycles for maximum setting of the volume control. The limiter or avc characteristic is measured with 30 per cent modulation at a volume control setting which gives 6 db less than the maximum output. The output versus input for zero modulation is also determined.

HARMONIC DISTORTION. The measurements of harmonic distortion required for an f-m receiver are as follows: per cent harmonics versus per cent modulation and per cent harmonics versus signal-input level and per cent harmonics versus output.

OVERALL ELECTRICAL FIDELITY. The overall electrical fidelity is measured at 98 megacycles using a signal input 60 db below 1 volt, 30 per cent modulated. The curve thus obtained should normally be a close approximation to the standard de-emphasis curve for f-m receivers assuming no pre-emphasis in the signal generator. If the receiver is multi-band, the effects of the tone controls will be shown by the fidelity measurements on the a-m bands; otherwise, additional data should be taken to show these effects on the fidelity.

I-F AMPLIFIER CHARACTERISTICS. The overall selectivity of the i-f amplifier from the modulator grid to the first limiter grid or, if limiters are not employed, to the plate of the detector driver tube, is measured after the individual stage gain and selectivity have been measured. The level at the limiter grid should be that required for quieting the receiver. Where avc voltage is applied to i-f amplifier stages, the overall i-f amplifier selectivity characteristics should be measured for different levels of signal input to the modulator grid in order to show the detuning effect due to the change in tube input capacitance with a change in grid bias. Typical input levels are 80 db, 60 db, and 40 db below 1 volt. The avc voltage in the circuit should be held at the center frequency level by means of a battery supply.

27. SINGLE-STAGE MEASUREMENTS

REQUIRED TEST EQUIPMENT. Standard-signal generator, standard dummy antenna, output wattmeter, vacuum-tube voltmeter, tuning wand, high-resistance voltmeter, and wattmeter.

HIGH-FREQUENCY MEASUREMENT PRECAUTIONS. It will usually be found impracticable in making stage gain measurements on f-m receivers to substitute a vacuum-tube voltmeter for a tube or to place it in parallel with a tube. The inherent capacitance of the stage is usually so low that accurate measurements cannot be made if the measurement setup appreciably changes its value. A preferred method is as follows (Fig. 3): A resistor of approximately 500 ohms is substituted for the normal plate load of the tube which the vacuum-tube voltmeter would replace at lower frequencies. Under most conditions it is inadvisable to shunt this resistor across the normal plate load. The low-potential end of the resistor is bypassed directly to ground, keeping lead lengths as short as possible. The signal generator is then connected to the grid of the tube, the normal grid load being disconnected, and a vacuum-tube voltmeter is connected across the resistor in the plate circuit. The input-output voltage characteristic can then be checked and a suitable operating point chosen on the linear portion of the gain characteristic. With the suggested value of load resistance and the usual high-transconductance tube, a gain of 0–6 db will be secured.

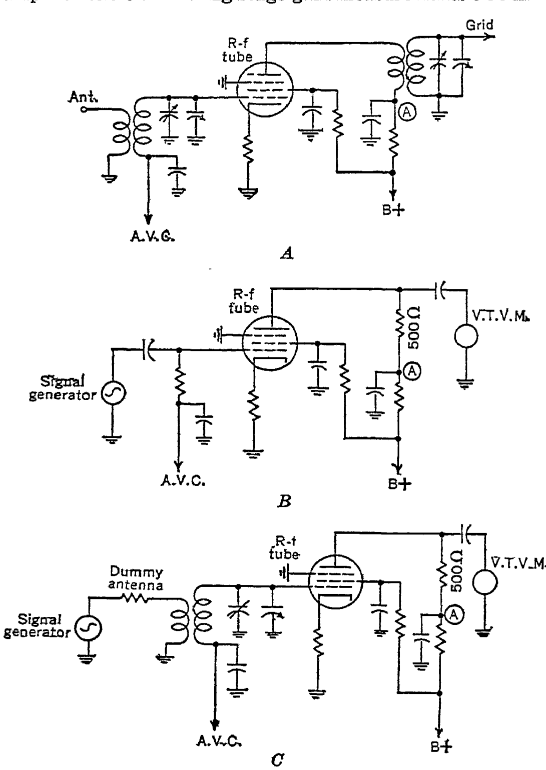

FIG. 3. Single-stage Measurement Set-up. *A*, normal circuit; *B*, calibrating rf tube; *C*, set-up for measurement of antenna gain and bandwidths.

Under these conditions it will be convenient to select as a reference output voltage that value which corresponds to a signal on the grid of 10 db below 1 volt. It is important that the voltmeter have sufficient sensitivity to make possible the selection of an operating point which can be obtained without danger of grid current due to high signal levels on the grid. After the operating point has been chosen, the grid of the tube can be connected back in the circuit, the signal generator connected to the grid of the preceding tube, and performance measurements made without upsetting the grid loading in the stage being measured.

ANTENNA GAIN AND BANDWIDTHS. The measurement of antenna gain and band width to provide data representative of those secured under actual operating conditions requires considerable care. If the first tube is a pentode r-f amplifier, antenna gain and band widths may be measured by placing the voltmeter across a resistive plate load of a few hundred ohms and then calibrating the tube as previously described. The data may then be secured without upsetting actual operating conditions.

If the antenna secondary feeds into the grid of the converter tube, it may not be possible to measure antenna gain separately. In such cases, it is usually possible to measure the gain from the antenna terminals to a resistive load in the plate circuit of the i-f amplifier tube. In this way the sum of the antenna gain and conversion gain can be obtained. If it is possible to measure the conversion gain separately, the antenna gain can be obtained indirectly by subtraction of the conversion gain.

R-F GAIN AND BANDWIDTH. The method of measurement of r-f gain, like that of the measurement of antenna gain, depends to a great extent on the type of circuit. In some cases, the voltmeter can be shunted across the grid of the modulator tube to enable a measurement of r-f gain to be made. In others, it is necessary to measure the r-f gain plus the conversion gain as has been discussed under the immediately preceding heading. It is always necessary to exercise care to make sure that the loading on the r-f tuned circuit under measurement conditions is the same as that under actual operating conditions.

CONVERSION GAIN. Conversion gain measurements where a pentagrid converter is used can generally be made by placing the vacuum-tube voltmeter across a resistive load in the i-f plate circuit as has previously been discussed for antenna and r-f gain measurements. Where a pentode modulator is used with both oscillator and signal voltages on the same grid, it is necessary to measure conversion gain indirectly. The antenna gain plus conversion gain or r-f gain plus conversion gain can be measured. The antenna gain or r-f gain, as the case may be, can then be measured and subtracted to give the conversion gain. As usual, in making measurements at these frequencies, care must be exercised so as not to allow the measurement setup to change the loading on the antenna coil.

I-F GAIN AND BANDWIDTH. The measurement of i-f gain and band width at the standard intermediate frequency of 10.7 megacycles can best be made by placing the vacuum-tube voltmeter across a resistive load in the plate circuit of the tube following the stage on which measurements are being made. The tube can then be calibrated and the measurements made without upsetting actual operating conditions.

REJECTION OF A-M BY F-M DETECTOR. No measurement has yet been standardized for this test. However, Fig. 4 shows one method for setting up equipment in a way which will provide useful information regarding the ability of an f-m detector to reject amplitude modulation. Imperfect a-m rejection at any signal input level will result in the "bow-tie" pattern. For this test the f-m signal generator must be capable of being simultaneously amplitude- and frequency-modulated. The a-m and f-m frequencies should be asynchronous. It is suggested that the f-m frequency be approximately 100 cycles and that the a-m frequency be approximately 400 cycles.

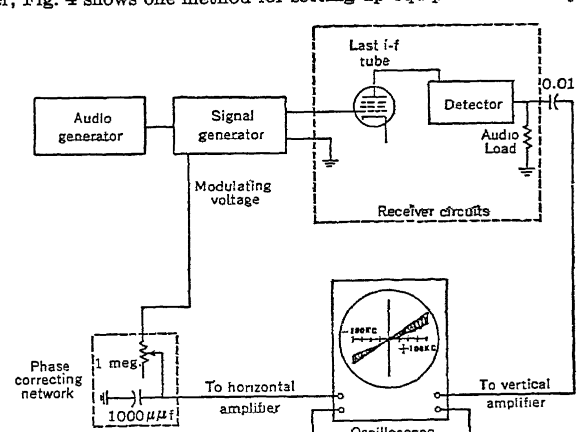

FIG. 4. Equipment Set-up for Test of A-m Rejection in F-m Detectors

OSCILLATOR DRIFT. The frequency drift of an f-m receiver oscillator circuit may be determined by employing the equipment setup shown in Fig. 5. The procedure is as follows:

1. Tune the receiver to the 100-megacycle signal from the crystal oscillator.

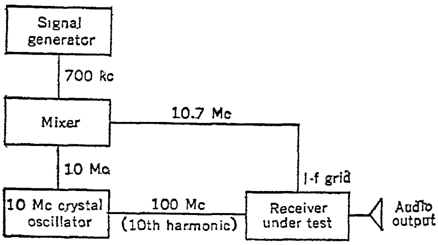

Fig. 5. Oscillator Drift Measurement Set-up

2. Adjust the frequency and level to produce zero beat in the output.
3. Maintain zero beat by adjusting the frequency of the signal generator. Note frequency drift versus time until the receiver has stabilized.

MISCELLANEOUS MEASUREMENTS. There are several characteristics for which measurement procedures have not yet been standardized. These include oscillator radiation, effect of detuning, two-signal interference tests, tests on built-in antennas, tests for the effects of downward modulation, and others. The measurement of such characteristics is important, but a lack of standardized procedures precludes the possibility of discussion at this time.

WAVE ANALYSIS

By E. Peterson

Some of the terms applied to devices which isolate, measure, and display the component amplitudes of complex electric waves include wave, harmonic, and spectrum analyzers; distortion and intermodulation meters and analyzers; and spectrographs.

28. WAVE CHARACTERISTICS

Waves to be analyzed may have components located at discrete frequencies or distributed more or less generally throughout frequency bands. Discrete components are encountered in studies of the response of a non-linear circuit or circuit element to the action of periodic waves. The resultant modulation products can be localized and measured individually or, in some cases, collectively. Band distributions on the other hand are found in speech and music and sometimes in noise. There, where the spectral distribution changes with time, it is difficult to keep track of individual components, and measurements are conveniently made of energies within bands of definite extent.

DISCRETE FREQUENCY DISTRIBUTIONS. Discrete or single frequency analysis is used in a variety of fields such as noise reduction, machinery noise, power interference, and modulation studies. Of these the last mentioned is the most important and the most demanding. Modulation studies are of interest throughout the frequency range occupied by the various communication services, and the amounts of power associated with them vary greatly in the different applications. Considering extreme cases, the power associated with modulation products in long loaded cables and in multichannel carrier amplifiers may be comparable with resistance noise in an audio band, while modulation products in high-power radio transmitters may amount to kilowatts.

The frequency of any modulation product is expressible in terms of the fundamental frequencies which produce it. If as example there are two fundamental frequencies f_1 and f_2, the frequencies of all products are included within the expression $|mf_1 \pm nf_2|$. Here m and n are positive integers, or zero. Products may be distinguished by their order, which is the sum of m and n. Thus the components $2f_1$, $2f_2$, $|f_1 \pm f_2|$ are all of the second order; $3f_1$, $3f_2$, $|2f_1 \pm f_2|$, $|f_1 \pm 2f_2|$ are all of the third order.

Modulation product amplitudes may be expressed in terms of the impressed waves or fundamentals producing the modulation, or in terms of a significant component, using arithmetic or logarithmic (decibel) scales for the ratios. Whereas in many detailed studies each modulation product of importance is specified individually, in others, in which an idea of the total modulation is required, the rms value of all unwanted products within a certain frequency band is specified. Thus, in one method of testing distortion in a radio link, a sine-wave signal, preferably at a low audio frequency, is impressed upon the transmitter. At the receiver output this component is removed by a filter or bridge type of suppression network. The rms value of all remaining products in the audio band is measured by means of a thermocouple or suitable rectifier. When expressed as a percentage of the rms fundamental in the normally terminated circuit, the ratio is termed the distortion factor.

When the modulation of a particular circuit element is under consideration, and is to be expressed in a way which would be applicable with the element connected in any given circuit, it is customary to specify the equivalent (modulation) generator emf. This is the voltage which, when inserted in the circuit made up of linear elements, gives rise to the observed distortion products. It is used ordinarily of elements only slightly non-linear.

The ratios of modulation products to their fundamentals which analyzers are used to evaluate fall into two ranges of values. One applies to products falling within the frequency range constituting quality impairment of the originating channel. The other characterizes products which fall outside the transmitted frequency range, constituting interference with other channels. Examples may be drawn from the audio, carrier, and radio broadcast fields. Thus the requirements on a system transmitting speech are usually that the distortion products be at least 20 to 40 db down on the wanted components in the normal channel (10 to 1 per cent in amplitude, or 1 to 0.01 per cent in power). Interfering products in other channels are restricted to smaller amplitudes. In multichannel carrier telephone amplifiers the figures range from 40 to 80 db down; in multichannel carrier grouping filters which serve to separate transmitted and received currents the figures range from 70 to 120 db down. In certain radio transmitters the products appearing in other channels are restricted to something of the order of 70 db down on the fundamentals. Corresponding figures for elements or units which make up a system may be more stringent than those specified for the system as a whole, especially where the modulations in several elements or units contribute to the total.

TEST WAVES. In the analysis of speech, music, or noise, or of the output waves of such devices as oscillators and harmonic producers, the questions involved are those of isolating and measuring the components. In establishing the performance of circuits or of circuit elements, however, the additional problem arises of specifying and of supplying the wave to be used for test purposes.

Generally speaking, the input wave should permit an indication of the performance of the apparatus to be tested, approximating as closely as possible the conditions of actual use. Where the apparatus is subjected in use to an impressed wave of simple form, comparatively little difficulty arises since the wave can be readily reproduced by oscillators and filter networks. On the other hand, the apparatus may be subjected to signal waves which are highly complex in nature, such as those of speech. Such waves may require comparatively elaborate and cumbersome setups for the measurement of modulation products, especially where the fundamentals and the various products overlap in the frequency spectrum.

To facilitate analysis, the complex signal waves are replaced by comparatively simple ones. At the present time one of two types is ordinarily used according to the problem encountered—a pure sine wave, or a complex wave consisting of two sine-wave components. To prevent interaction of the two components before reaching the circuit under test, tuned circuits, filter networks, or bridge networks may be employed. The amplitude of the testing wave is chosen so as to traverse much the same region of the non-linear characteristic as does the complex signal wave for which it is substituted. In some cases the test wave is made to have the same rms value, and in others the same peak value, as the normal signal. The test frequencies are so selected that, together with their important modulation products, they fall in a frequency region of interest.

To illustrate the use of single- and two-frequency test waves consider the investigation of a narrow band amplifier passing frequencies, let us say, from 100 to 110 kc. If a sine wave of frequency 105 kc is impressed for test purposes then the harmonics are 210 kc, 315 kc, and so on, all harmonics falling outside the transmitted band and being greatly attenuated. A measurement of distortion within the pass band would yield nothing. If, on the other hand, instead of applying a single frequency, we impressed two frequencies at 105 and 106 kc, say, the harmonics would fall outside the band and be attenuated as before, but the third-order products at 104 and 107 kc would lie within the band, as indicated in the spectrum (Fig. 1). These would furnish a useful indication of the non-linear distortion which a single-frequency test wave could not provide. Another example may be drawn from the same vacuum-tube amplifier. It may be shown that the amplitudes of the above-mentioned third-order products depend upon the impedance offered to second orders, one of which is the difference frequency (1 kc in the above example). This impedance may vary widely in different designs without affecting the normal transmission or

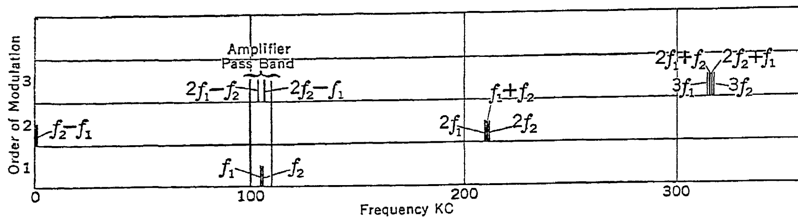

FIG. 1. Output Wave Spectrum of Narrow-band Amplifier with Frequencies of 105 and 106 kc Impressed

harmonic production. Figure 2 shows the results of measurement of third-order modulation as a function of the frequency difference between the two input components. No indication of this significant effect would be revealed by a single-frequency testing wave.

Another instance in which the two-frequency test wave is used is in the measurement of distortion produced by ferromagnetic-core coils. There only the main hysteresis loops are called into play when a sinusoidal magnetizing force is applied, but with complex waves of magnetizing force a different characteristic is involved since subsidiary loops appear.

To exemplify the use of the single-frequency test wave, consider a vacuum-tube amplifier supplied with power obtained from the 60-cycle line. There exists a certain amount of modulation of each signal component with the 60 cycles and its harmonics in the amplifier. To measure this effect a single-frequency test wave will serve.

BAND FREQUENCY DISTRIBUTIONS. Band frequency analysis involves measurement of energies or amplitudes in the sub-bands into which the main band is divided. It is usually employed for waves such as room noise or windage noise from certain types of machinery, which contain no prominent discrete frequency components, and for waves which contain discrete frequency components varying rapidly in both frequency and amplitude, such as speech and music. Band frequency analyses have also been used for waves consisting largely of discrete frequency components when it is unnecessary to know the precise frequencies of the individual components. Examples come up in studying the effect of vibration-absorbing mountings and of the acoustical treatment of rooms for the reduction of machinery noise. In the communications field, band frequency analyses of program material and of circuit noise are useful in determining requirements to be placed on systems for reproduction of the input waves with the desired fidelity and freedom from interference. For testing multichannel carrier systems, the loading effect of many talkers has been simulated by introducing bands of resistance noise.

FIG. 2. Third Order Modulation at Amplifier Output as Function of Frequency Difference between the Two Impressed Fundamentals

29. GENERAL ANALYZER REQUIREMENTS

The requirements which an analyzer is called upon to satisfy in general are those ordinarily imposed upon any piece of measuring apparatus: that it furnish an indication of the quantity sought, within certain limits of accuracy and of precision, without disturbing the essential performance of the circuit to which it is applied.

INPUT COUPLING. Connection of the analyzer to the circuit under test without altering the essential circuit performance is accomplished by assigning a suitable impedance to the input circuit of the analyzer. Three circuit arrangements have been used for this purpose. These are the high-impedance or voltage-analyzer connection, the low-impedance or current-analyzer connection, and the termination. In the first the analyzer is made to have an impedance much higher than that of the circuit across which it is shunted. In the second, the analyzer is made to have an impedance much smaller than that of the circuit in series with which it is connected. In the third, the analyzer is made to have a definite resistance to replace a resistance of the same value in the circuit studied. It will be observed that, under these conditions, insertion of the analyzer will normally have but little influence upon the normal functioning of the circuit studied, since all three may be made balanced or unbalanced to ground as desired. Figure 3 shows connections to a resonance type of analyzer as an example. For current analysis, connection is made to point a and for voltage analysis to point b when the resistor R is made large. For use as a termination R is given a suitable fixed value to fit the circuit or line to which it is connected, usually 600 or 72 ohms. The resistance r is usually made less than the effective resistance of the tuned circuit to avoid reducing selectivity and may be adjusted for the required gain.

A preferable connection for voltage analysis, shown in Fig. 3b, usually permits a greater fraction of the desired input voltage component to be transmitted while maintaining a high input impedance. Another connection suitable for voltage analysis, particularly useful over wide frequency bands, employs a probe including a condenser-resistance divider (Fig. 3c). Its input impedance is that of a 1- or 2-$\mu\mu$f capacitance shunted by a resistance of the order of 1 megohm. To make transmission flat with frequency, the two time constants C_1R_1 and C_2R_2 must be made equal.

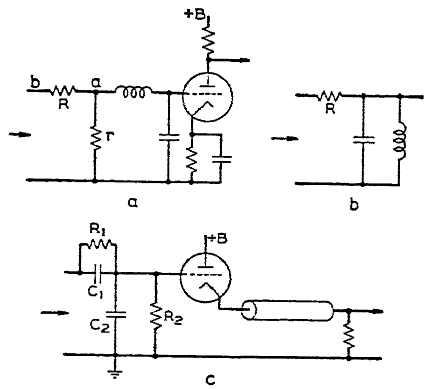

FIG. 3. Analyzer Input Circuits Illustrating High-input Impedance and Low-input Impedance Connections

RESOLUTION OF COMPONENTS. The analyzer band should be wide enough to permit easy tuning-in of the desired component, including an allowance for variations in frequency of the selected component. At the same time it must be narrow enough to select a specific product. The equivalent band width of a selective circuit may be defined as the band width of an idealized filter having a constant loss in the pass band equal to the minimum loss of the circuit in question, infinite loss outside the pass band, and passing the same amount of energy from a continuous constant-energy spectrum applied to the input. Analyzers for the study of low-frequency machine noise require a band width from 3 to 5 cycles. Those for telephone circuit noise caused by induction from neighboring power circuits require an equivalent band width of 20 to 30 cycles at least. For speech and for general types of noise, band widths of 45 to 300 cycles are appropriate. For intermodulation studies of discrete components, the bands used range from a cycle or so at low frequencies to several kilocycles and more at high frequencies.

Similarly the frequency discriminations required vary widely in different cases. In fixed-band analyzers used for speech, discriminations of 20 db or so against components located at the centers of neighboring bands are sufficient to provide useful information. Other a-f analyzers usually require discriminations of the order of 25 to 50 db against components 60 cycles from the tuned frequency.

The wide divergence in requirements has led to the development of a number of different forms of analyzers, each suited to a limited class of work.

MEASUREMENT AND DISPLAY OF SELECTED COMPONENTS. With the simpler manually operated forms of frequency analyzers, the point-by-point method of analysis is employed. Here, for the discrete frequency analysis of a steady wave, the frequency spectrum is explored point by point over the range of interest, and whenever a component of importance is located its frequency and amplitude are observed. For band frequency analysis of a periodic wave, measurements of the energy in each of a number of adjacent sub-bands are made successively without reference to the distribution within the sub-band. In analyzing waves of short duration which can be repeated a large number of times during the exploration of the frequency spectrum, a similar procedure is followed.

The net result of an analysis in which the several components are examined individually is usually presented as a meter deflection. To permit the use of simple d-c meters the selected wave feeds a thermocouple or a rectifier of the vacuum-tube or copper oxide type. The thermocouple is somewhat sluggish in operation, and the process of tuning accordingly must be slowed sufficiently to permit the products to produce an observable deflection. The slow response is advantageous where the smoothing out of rapid fluctuations in the selected wave is desired. Deflections are closely proportional to the square of the heater current. This is a valuable property in estimating energies in band analysis. Tube and varistor circuits may be made much more rapid in operation and may be given a wide range of desired relations between input amplitude and deflection by suitable choice of operating potentials and circuit parameters. For high rectifying gain a small negative bias may be used. For greater precision a large negative bias may be used since then a small input change may be made to yield a large change in rectified output. By the same token, however, an interfering component produces a correspondingly large change in rectified output.

Where a graphical record of wave analysis is to be had in a short period of time, one of several types of recording frequency analyzers is employed. These recording analyzers are designed to perform automatically the same operations performed manually with the simpler devices, including the plotting of wave component values. Recording analyzers of this type may be used as well for the analysis of non-periodic waves of short duration which can be repeated so that the effect of a steady wave is obtained.

Thus in the analysis of speech sounds and of single tones from musical instruments, or of other non-steady waves which are not readily reproducible, with devices employing the point-by-point method, the wave may be recorded and repeatedly reproduced. Finally, non-steady waves may be analyzed directly without the necessity of recording them by means of devices giving a visual indication of the complete energy spectrum of the wave and capable of showing the rapid changes in spectrum which are characteristic of speech sounds and some musical tones. A photograph of cathode-ray patterns or a recording on electrically sensitive paper of the indications of such an analyzer can be made for a permanent record of the analysis. These arrangements are discussed in article 31, p. 11-65.

30. METHODS OF WAVE ANALYSIS

The earliest methods used for wave analysis were based upon observed wave forms—observed directly by means of an oscillograph, or synthesized point by point from synchronous contactor measurements. Wave components are deducible from the wave form by application of Fourier series, which expresses the amplitude of any component as an integral. Evaluation of the integrals is customarily handled by a time-consuming point-by-point calculation, for which tables and schedules have been formulated to facilitate the work. This method is useful when only harmonics of a single frequency are present in the wave to be analyzed; when the wave has more than one fundamental, the computation ordinarily becomes too involved to be useful, since a multiple Fourier series must be employed. For harmonics of a single frequency which are not too small in amplitude, the accuracy of the determination depends largely upon the accuracy with which the oscillogram is read, the number of points included in the analysis, and the order of the harmonic. Because of its limitations, the computational method has been superseded by methods of direct measurement, wherever possible.

The first direct method of analysis was that of Pupin, in which a series-resonant circuit was used to select a component of interest, and amplitude was deduced from the indication of an electrostatic voltmeter connected across the condenser of the tuned circuit. Discrimination by means of simple tuned circuits is employed in certain types of analyzers of the present day, their sensitivity and flexibility being greatly increased by means of vacuum-tube amplifiers. Selectivity and sensitivity are improved by having several tuned circuit and amplifier units in cascade, and by substituting filter networks for the simple resonant circuit. A different way to improve selectivity involves the use of a negative resistance circuit to reduce tuned circuit losses.

RESONANCE ANALYZERS. Variable Tuned Circuit. The simple form of current analyzer shown in Fig. 4 is useful where a high degree of frequency selectivity is not required. It is made up of four units: coupling unit, frequency-discriminating network, amplifier, and indicator. The tuning unit precedes the amplifier to discriminate against other components of the input wave. This procedure reduces modulation in the amplifier, which may introduce components of the same frequencies as those to be measured.

The tuning unit consists of a simple series-resonant circuit with the input wave introduced through a small resistor. The amplifier input is taken across the condenser when the input fundamentals are of frequencies higher than the frequency of the component being measured. When the fundamentals or other possible interfering components are at lower frequencies the amplifier input is connected across the coil for greater discrimination. The amplifier is made responsive over the frequency range of interest; it is usually of the resistance-capacitance coupled type.

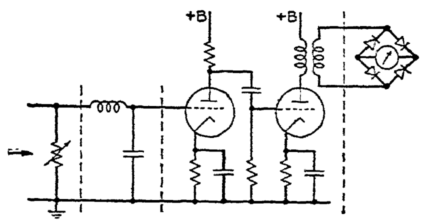

FIG. 4. Resonance Analyzer Circuit with Input Arranged for Current Analysis.

To increase the selectivity over that available in the simple tuned circuit, several discriminator-amplifier units are used in cascade. Efficient coupling between units is provided by step-down transformers. Here the signal level must be kept low enough to avoid appreciable modulation of the fundamentals in the early amplifier stages. A preferable arrangement from this standpoint would be to locate as much of the necessary frequency discrimination as possible ahead of the amplifiers. For greater discrimination than simple tuned circuits can conveniently afford, use is made of filter networks, which, being much more cumbersome and less flexible in adjustment, are usually employed where only a small number of fixed frequencies are to be measured.

The substitution method is currently used for evaluating component amplitudes since the loss of the tuned circuit, and therefore the analyzer response, varies with frequency. The connections are shown in Fig. 5, the switch being used to connect the analyzer to either the test or the standard circuits. The standard circuit includes an oscillator adjustable in frequency, a vacuum-tube voltmeter or thermocouple and associated meter to indicate the standard input, and a calibrated attenuator to vary the input amplitude to the analyzer. The analyzer input impedance is fixed at a value at which the attenuator is properly terminated.

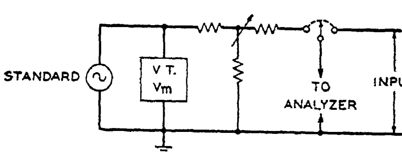

FIG. 5. Substitution Method for Evaluating Component Amplitudes

The test procedure consists in connecting the analyzer to the unknown, tuning in the desired product, and adjusting the analyzer gain until a suitable deflection is obtained on the output meter. The switch is then thrown to the standard side, and the standard oscillator frequency is varied until it coincides with the analyzer tuning. The attenuator is then varied until the same deflection is obtained as before. The frequency of the unknown component may then be found from the frequency calibration of the standard oscillator or of the analyzer, and the amplitude is computed from the voltmeter reading and attenuator setting.

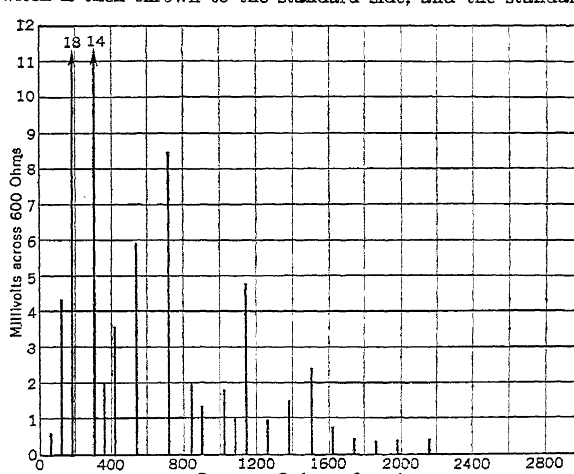

FIG. 6. Spectrum of Noise on an Open-wire Telephone Circuit

Another form of resonance analyzer with shunt tuning in the plate circuits of two amplifier stages has been used extensively in the analysis of power-frequency harmonics and of induction from power circuits. Voltages from 5×10^{-6} to 50 are measurable in the range up to 3 kc with an accuracy of ± 5 per cent. The discrimination of such an analyzer varies with frequency, being about 40 db at 60 cycles from the tuned frequency when tuned to 180 cycles, and from 24 to 32 db 60 cycles away when tuned to 3000 cycles. Figure 6 gives an example of an analysis of telephone-circuit noise caused by induction from power circuits. Approximately 1 hour is required to obtain with this apparatus the amount of data shown in the figure.

The speed and ease of operation of the more modern analyzers have resulted in supplanting the resonance type for all but special purposes.

Fixed Bands. A decidedly different form of analyzer using direct frequency selection avoids the need for manual tuning to each frequency of interest by means of a bank of fixed contiguous band-pass filters. Fourteen filters are used in one particular model to

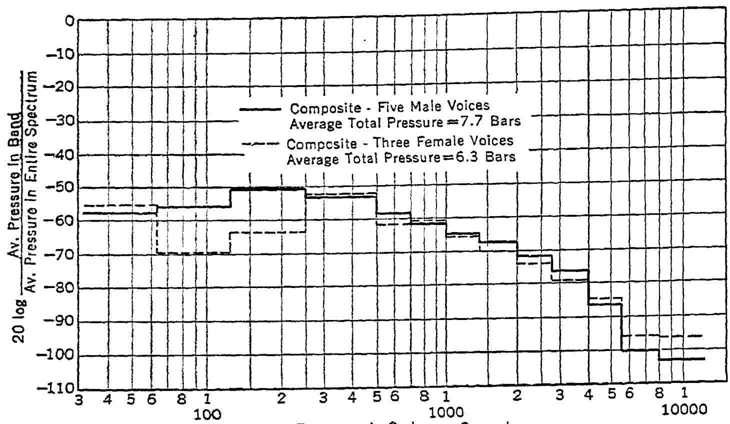

FIG. 7. Average Speech Pressures per Frequency Interval of 1 cycle per second—normal conversational voice. Distance 2″.

cover the frequency range from 30 to 12,000 cycles in approximately logarithmic steps. The filters are connected in parallel at the input side and introduce a loss of about 8 db at the crossover points and greater than 70 db over most of the frequency range beyond the transmission band. A flux meter is used to integrate the sub-band output over a 15-second interval for the measurement of average amplitudes, while a series of gas-filled discharge tubes with associated relays and electrical counters measures peak magnitudes over a 54-db range in steps of 6 db. These measurements are made in one band at a time although both average and peak measurements of the total spectrum may be made simultaneously with the band measurements. Peak measurements in $^1/_8$-second intervals are made over as long a time as desired. Figure 7 shows amplitude-frequency distributions for conversational speech for male and female voices.

Another type of fixed band analyzer has been used to measure distortion generated in non-linear circuits by complex input waves. Here the input wave is made to pass through a narrow band-elimination filter before it enters the circuit to be tested. A narrower band-pass filter is used for the analysis, with its pass band located within the band eliminated at the input. By this procedure the band-pass filter output has had the fundamental components eliminated, so that it constitutes a measure of distortion.

Feedback Type. A third means of providing frequency discrimination is particularly useful for the analysis of discrete components in sub-audio- and audio-frequency ranges. It consists of a negative feedback amplifier incorporating a bridge type of network in its feedback path. One form shown in Fig. 8 uses a parallel T network made up of capacitances and resistances which provides high suppression at a single frequency. At this frequency therefore the full amplifier gain is effective. At frequencies removed from the balance point, transmission through the feedback network acts degeneratively to reduce the amplifier gain. By insertion in the feedback path, therefore, the null of the network is transformed into a transmission maximum through the amplifier circuit. The network null may be conveniently varied in frequency by ganging the three resistors. Its selectivity remains constant on a percentage basis throughout the band, independent of frequency.

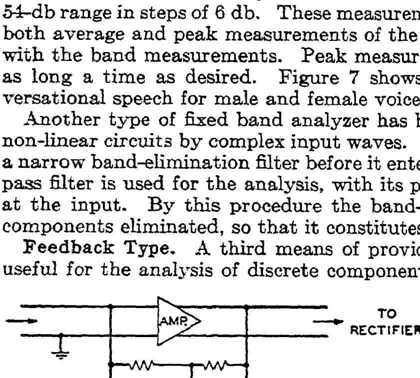

FIG. 8. Feedback Analyzer Using Twin-T Capacitance-resistance Network to Provide Frequency Discrimination

The following figures on frequency discrimination apply to a two-stage amplifier with a null set at 25 cycles. Roughly 12 per cent away from the null, the discrimination is 10 db; 20 per cent away it is 16 db, and in the limit approaches 45 db down on the maximum transmission.

Transmission of the amplifier proper is made substantially flat over the maximum range of analysis. Beyond that, the gain and phase around the feedback loop are arranged to avoid regeneration and oscillation, as in feedback amplifiers generally.

SUPPRESSION AND INTERMODULATION ANALYZERS. Although these two analyzer forms are not related in general, it will be convenient here to take them together.

A simple type of suppression analyzer previously mentioned evaluates the rms sum of the harmonics generated with usually a sinusoidal signal impressed. The fundamental may be suppressed through the action of a resonant bridge, or a suppression filter, or a twin-T network. The output includes any noise and interfering components which may be present. If the harmonics are comparable in amplitude to these components, the harmonic distortion proper cannot be found directly by this method.

Another form of suppression analyzer uses special procedures which are applicable to the detection of a carrier and its two sidebands, as practiced in radio broadcast reception. These procedures form the basis for a method of measuring intermodulation between two frequencies in the audio band, one low (40 to 100~) and the other comparatively high (1 to 12 kc). The two tones are supplied to the system under test, and the output is filtered to suppress the low-frequency tone. The residual wave is then treated as a carrier accompanied by the two sidebands to determine the extent to which the higher-frequency component is modulated by the lower, as described below.

Measurement of Percentage Modulation. The special procedures referred to may involve the cathode-ray oscillograph or the linear rectifier. If the modulating signal is applied to the horizontal deflection plates of the oscillograph, and the r-f output consisting of the carrier and its two second-order side frequencies is applied to the vertical deflection plates, then patterns like those shown in Figs. 9*a* and 9*b* are obtained on the oscillograph screen, according to the phase shifts in the system. These patterns yield the percentage modulation from the lengths of the minimum and maximum ordinates indicated. One hundred per cent modulation is obtained when the wave envelopes go to zero, and greater modulations are indicated by intersection of the envelopes. When a linear sweep circuit controlled by the modulating signal is connected to the horizontal deflection plates, rather than the modulating signal itself, then Fig. 9*c* is obtained.

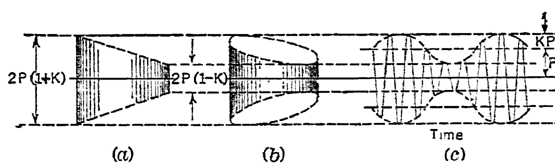

FIG. 9. Modulated Wave Patterns

Knowledge of the percentage modulation permits the second-order sideband amplitude ($KP/2$ in the figure) to be calculated accurately only when higher-order sidebands of the carrier are negligibly small. In that event the envelopes of Figs. 9*a*, 9*b*, and 9*c* are respectively linear, ellipsoidal, and sinusoidal. Otherwise the wave envelopes may be analyzed to yield the amplitudes of the second- and higher-order sidebands.

Another method for determining percentage modulation, generally used to evaluate intermodulation, employs a linear rectifier (envelope detector) to detect the modulated carrier wave with a minimum of audio distortion. The percentage modulation is then given as 100 times the ratio of the peak audio signal output to the d-c component. Where higher-order products are present, they may be evaluated by resonance or heterodyne-type analyzers.

HETERODYNE ANALYZERS. Dynamometer. Another method of analysis first used by Descoudres employs a dynamometer, in which the unknown wave and a standard wave of known frequency, amplitude, and phase are respectively connected to the two coils of the dynamometer. Since the dynamometer deflection is proportional to the product of the currents in the two coils, a constant deflection is obtained when the frequency of the sinusoidal standard is made equal to that of a component of the unknown wave. The magnitude and phase of the component are then found from a calibration when the standard phase is adjusted for maximum deflection. To determine the magnitude without regard to phase, the standard frequency is offset by a fraction of a cycle from that of the component under measurement, and the maximum swing is observed. The method is limited to comparatively low-frequency work.

From one standpoint the dynamometer may be regarded as fulfilling three functions: modulating the unknown with the standard wave, filtering the beat frequency output, and indicating the amplitude of the difference frequency component. Improvement in frequency response and in sensitivity has been obtained by replacing the dynamometer by a vacuum-tube modulator, and further increase in sensitivity is obtained again by amplifying the beat frequency output. As an indication of the component to be measured, use may be made of either the lower sideband or the upper sideband formed by the beating oscillator and the component under investigation. To select this product, mechanical, electrical, or piezoelectric filters and networks are conveniently located in the frequency range. These replacements of the functions discharged by the dynamometer result in the most widely used of all analyzers, the modern heterodyne type.

A particularly simple form of heterodyne analyzer has been adapted to the measurement of products not too small in relative and absolute amplitudes. In this arrangement no amplifier is used, and the mechanical movement of a meter connected in the plate circuit of a modulator tube serves to provide frequency discrimination as it does in the dynamometer.

General Tube Modulator Type. The heterodyne analyzer possesses a number of advantages over other types which have brought it into wide use. To mention the outstanding ones, first of all it uses a fixed discriminating circuit which is readily made highly selective and stable, and takes up little space. Next, the tuning-in of a desired band requires but a single adjustment—the frequency of the heterodyning oscillator. Finally the response can be made flat over an extended frequency range so that the substitution method of evaluating amplitudes is not required. Relative levels can be taken directly as the difference between attenuator settings.

Essential units of a representative model are shown in the schematic of Fig. 10. The principal elements comprise coupling unit, modulator, beating oscillator, filter, amplifier, and indicator.

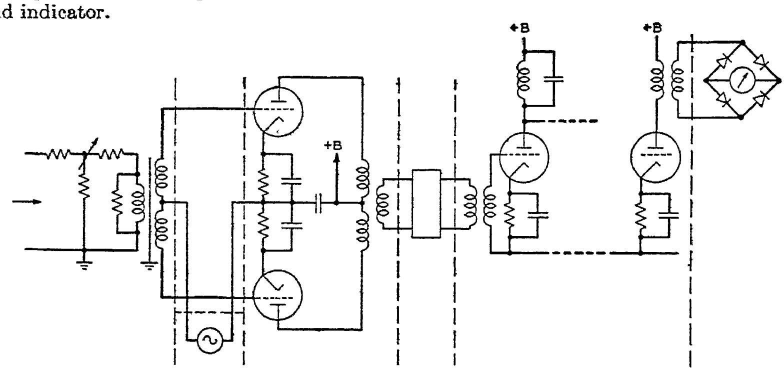

Fig. 10. Heterodyne Analyzer Circuit

The coupling unit is shown unbalanced to ground with a calibrated attenuator which serves to vary the input to the modulator. The analyzer therefore is used as a termination, but other coupling units for voltage or current analysis can be fitted to the input terminals of the attenuator.

The modulator is of the conjugate input type, to provide a convenient means for separating the signal and beat frequency circuits, to balance out the beat frequency oscillator wave in the output circuit, and to reduce the number of unwanted modulation components produced. Triodes have been used with the grid bias set close to plate-current cut-off. The shielded and balanced input coil shown should have uniform transmission over the frequency range of interest, and its modulation should be well below the amplitudes of the products measured. By the usual design procedure, the response of the modulator can be made uniform over a wide range of frequencies.

With values for noise, band width, and modulation which are readily attained, analyzers have been constructed capable of measuring second-order products 80 db down and third-order products 100 db down on their fundamentals. Here a three-stage amplifier was used with a gain of 130 db. The net analyzer gain including losses in the modulator and band filter was 120 db.

Where products larger in relation to their accompanying fundamentals are to be measured, the amplifier gain may be reduced. Where products smaller in relation to their fundamentals are to be measured, it becomes necessary to insert added discrimination against the fundamentals in the input to the modulator, so that we arrive at a combination of resonance and heterodyne types.

The oscillator used for heterodyning is designed to have a high degree of frequency and amplitude stability with supply voltage and temperature variations, and with time. Harmonics in the output are generally kept more than 40 db down on the fundamental. The oscillator amplitude applied to the modulator is made much greater than the signal input and slightly smaller than the grid bias, so that grid current does not flow in the modulator tubes. This amplitude, moreover, should be maintained fairly constant over the frequency range. All these requirements can be met readily with a bridge-type oscillator using thermistor or varistor stabilization. Frequency variation is most easily effected when the oscillator itself is of the heterodyne type, but frequency stability is not as high and spurious products have to be guarded against.

The ability of the analyzer to discriminate against neighboring input components is determined largely by the properties of the modulator tubes and by the selectivity of the selective network of Fig. 10, which may be made up of electromechanical, electrical, or piezoelectric elements. Which of these is used is a matter of convenience and of the frequency at which the band is to be located. Quartz crystals are generally used from 40 kc up to several megacycles. The band width is made narrow to cut down the noise introduced by the modulator to the greatest possible extent, as well as to reduce unwanted components. On the other hand, the band width should not be made so small that the tuning-in of the desired products becomes unnecessarily difficult and time-consuming. An equivalent band width of 5 to 20 cycles is found to be a useful compromise between the two requirements, the greater band width being used for measurements at radio broadcast frequencies. Analysis of waves in the short-wave region requires wider bands to accommodate incidental frequency variations; 2000-cycle bands have been used. The frequency at which the band is located depends upon the location of the frequency spectrum to be analyzed.

In order to avoid confusion of the measured components with extraneous products generated in the modulator, the band is placed either above or below the spectrum to be analyzed. Thus, in analyzers designed for use at carrier or radio frequencies, the band may be set at a low frequency; frequencies ranging from a fraction of a cycle to 1000 cycles have been used in various types. To avoid ambiguity in the measurement of small power-supply ripples or modulation products, the band should be made narrow and offset from harmonics of the power frequency. In an analyzer covering the range from 50 kc to 6 Mc, the crystal filter is located at 6.7 Mc and has a band width of 400 cycles. In audio analyzers the beat frequency is generally placed above the band; 11 kc, 50 kc, and 90 kc have been used. Figure 11 shows the frequency discrimination obtainable in several different types of selective circuits. The 100-cycle network referred to in that figure is a cumbersome multisection affair weighing close to 100 lb.

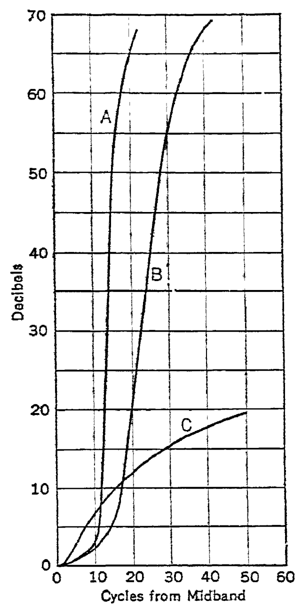

FIG. 11. Frequency Discrimination. *A*, electrical network, midband frequency, 100 cycles. *B*, piezoelectric network, midband, 50 kc. *C*, resonant circuit (Q = 100) tuned to 1 kc.

Since the amplifier is required to function over only the narrow band passed by the selective filter, it is conveniently built with screen-grid tubes or pentodes and tuned interstage coupling which permit of realizing comparatively high gains per stage. The tuned interstage coupling supplements the selectivity of the band filter and limits the noise output of the amplifier. An input transformer with a high step-up ratio may be used to minimize the effect of tube noise arising in the first amplifier stage.

Machine Noise Analyzer Unit; Mechanical Band-pass Filter. This device is used over the range from about 30 to 5000 cycles. It employs a mechanical band-pass filter working at 6000 cycles and having an equivalent band width of about 25 cycles. The effect of a double-balanced modulator is obtained in the electromagnetic structure through which the driving force is applied to the filter. In covering the above frequency range, the frequency of the heterodyning oscillator is varied from 6000 to 11,000 cycles. A discrimination of about 48 db 60 cycles from the tuned frequency is obtained in the four-section mechanical filter. The analyzer unit does not contain input or measuring circuits since it is intended to be used in conjunction with a noise meter which furnishes these circuits. It is readily portable. Figure 12 gives an example of the noise spectrum of a small synchronous motor obtained with this analyzer.

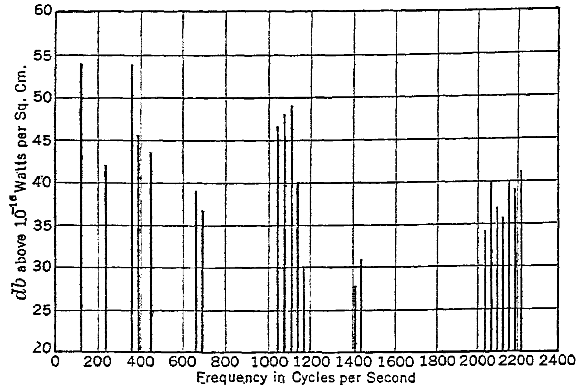

Fig. 12. Noise Analysis of Small Synchronous Motor—1/4 hp, 1800 rpm, 60 cycle, three phase, 220 volts, no load

General-purpose Analyzer Unit with Piezoelectric Band-pass Filters. With this device, it is possible to select either a 27-cycle band or 200-cycle band, from any part of the frequency range between 30 and 11,000 cycles. Lattice-type quartz crystal filters working at 50 kc are employed for both hands. For the narrow band, a discrimination of 52 db 60 cycles from the center of the band is obtained, while the wide band has a similar value 350 cycles from midband. The circuit includes a demodulator by means of which the wave components selected by the filter are translated to their original frequencies as indicated in the schematic of Fig. 13. This arrangement is particularly valuable in measuring closely spaced products, since it avoids output indication produced by transmission of the heterodyne source itself through modulator unbalance (carrier leak). The modulator leak here is translated to zero frequency and so is not transmitted by the a-c system connected to the demodulator output. The demodulator leak is far removed in frequency from the selected component and can be made harmless. Both modulator and demodulator are of the double-balanced copper oxide

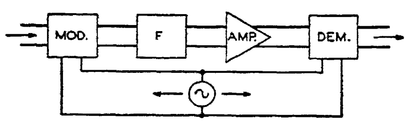

Fig. 13. Heterodyne Analyzer Circuit Used for Frequency Selection. The modulator-demodulator connection avoids spurious indications produced by leakage of the beating oscillator supply.

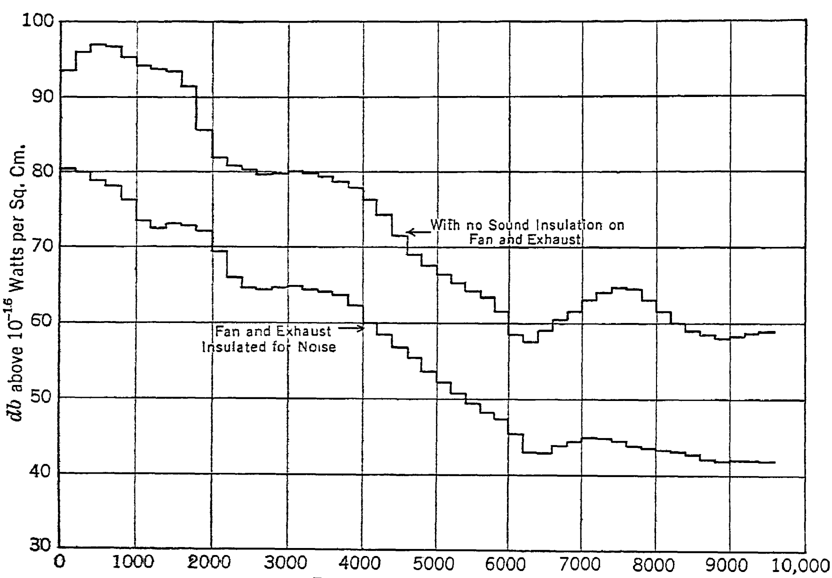

Fig. 14. Band-frequency Analysis of Exhaust Fan Noise

type and are supplied with carrier heterodyning power from the same oscillator through buffer amplifier stages. The analyzer unit does not include input or measuring circuits since it is intended as an attachment for a noise meter or similar measuring device of which these circuits are a necessary part. Figure 14 gives an example of the use of the 200-cycle band in the analysis of exhaust fan noise to determine the noise reduction obtained at various frequencies by means of sound insulation on the fan and exhaust.

31. SPECTROGRAPHS

Investigation of the spectrum of a complex wave by the methods just presented is a comparatively slow process at best since manual adjustment of a resonance frequency or of a beating oscillator frequency is required to shift the analyzer from point to point along the band to be studied. To speed up the process the analyzer may be tuned automatically, and the spectral distribution displayed in its entirety.

RECORDING TUNED CIRCUIT ANALYZER. Here the resonant frequency of a single electrical tuned circuit is varied in small steps over the frequency range by means of a player-piano pneumatic control. Simultaneously a photographic record is made of the current in the resonant circuit after amplification and rectification, the photographic paper being correspondingly stepped in position to accord with the frequency scale. Two frequency ranges are provided: 20–1250 cycles and 80–5000 cycles. The complete recording takes about 5 minutes. A 20-db amplitude range is the useful limit for a single record, the amplitude scale on the photographic record being approximately linear. Discrimination in the 80–5000 cycle band is about 20 db 60 cycles away from the tuning frequency, decreasing somewhat when the tuning frequency is above 1000 cycles. Figure 15 presents

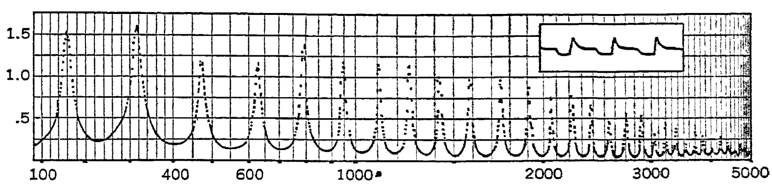

FIG. 15. Record of 160-cycle Buzzer Output

the analysis of a buzzer tone, each peak of the curve denoting the amplitude and frequency of an input component.

In any scheme of this kind which shifts a single discriminating circuit over the band, a definite compromise has to be made between the speed at which the circuit is shifted and the consequent resolving power, or ability to separate neighboring components. This relationship is discussed quantitatively below in the discussion of the Sweep Frequency Heterodyne.

TUNED-REED ANALYZER. This analyzer makes use of a series of electromagnetically driven reeds tuned to frequencies in the audio range, distributed with a uniform percentage difference in frequency. Each reed carries a small concave mirror which deflects a beam of light by an amount proportional to the oscillation amplitude of the reed. The vibrating

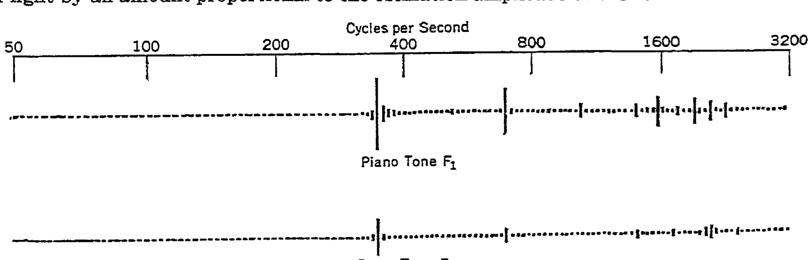

FIG. 16. Frequency Spectra Obtained with Reed Analyzer

spots of light indicate on a ground-glass screen the components present in the input wave which is applied to the electromagnets driving the reeds. Damping of the reeds is proportional to frequency and provides a discrimination of 20 db for components 2 1/2 per cent from the tuned frequency. A component 20 db down on the maximum can be evaluated with an accuracy of about 1 db when its frequency coincides with that of one of the reeds. A permanent record of a spectrum distribution constant in time can be obtained photographically. To record wave components varying with time a motion-picture camera must be used. Figure 16 shows spectrograms for two piano tones obtained with a demonstration analyzer of this type, covering the frequency range from 50 to 3200 cycles with 144 reeds.

COMMUTATED BAND ANALYZER. Selection of components is effected by a bank of contiguous fixed band filters extending over the frequency range to be covered. The output of each band filter is rectified, filtered, and amplified, as shown in Fig. 17. The vertically deflecting (*V*) plates of a cathode-ray tube are connected to each channel in turn by means of a commutator, while the horizontally deflecting (*H*) plates are connected to a synchronously operated stepped sweep. In this way, a linear frequency scale is laid out along a horizontal axis on the cathode-ray screen, and a vertical line represents the wave amplitude or energy within the corresponding band filter. The general aspect of spectrograms of this type is indicated on the oscilloscope screen depicted in the figure.

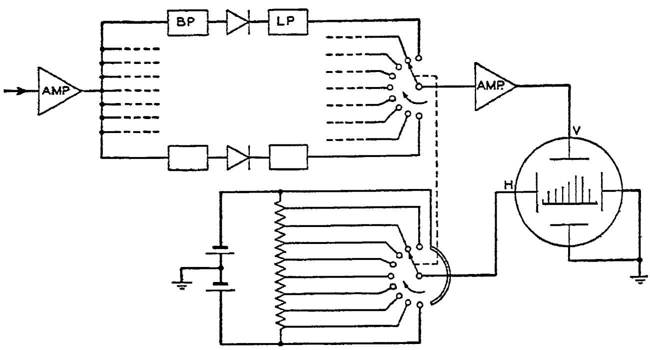

FIG. 17. Commutated Band Analyzer; Cathode-ray Presentation

From 10 to 30 filters have been used with band widths distributed linearly or logarithmically to cover the audio spectrum. With the linear distribution, bandwidths of 300 to 150 cycles have been used. Filter attenuations at the crossovers are 3 to 6 db, and at the mid-band frequencies of the immediately adjacent filters are of the order of 20 db. A non-linear compressor inserted in the lead to the vertically deflecting (*V*) plates of the cathode-ray tube helps to make the smaller amplitudes more readily perceptible. Accurate portrayal of an extended amplitude range, however, requires increase in filter selectivity to reduce interference from components falling within the attenuating regions of the filters. Commutation should be fast enough to reveal any envelope variations transmitted by the band filters. Thus if the widest filter band of the bank is B cycles wide, variations at a rate of $B/2$ are freely transmitted. The rectifier low-pass filter therefore should be $B/2$ cycles wide, or a little wider. For faithful indication, then, each channel should be sampled B times per second at least. While mechanical commutators have been shown for simplicity in Fig. 17, the channel sampling commutator may be replaced by electronic means, including clamps and a ring, with as many stages as there are bands to sample. Similarly the sweep commutator may be replaced by a properly synchronized electronic sweep developing a sawtoothed wave form.

SWEEP FREQUENCY HETERODYNE, CATHODE-RAY PRESENTATION. This method uses what is essentially an automatic heterodyne analyzer and is in general use throughout the radio frequency spectrum, from the broadcast band and below, to the centimeter region. A block diagram of the circuit arrangement is shown in Fig. 18. There a sweep generator provides a sawtooth wave at a sub-audio repetition rate for two purposes. First, it constitutes the horizontal sweep, and second, it provides a means for varying the beating oscillator frequency throughout a definite frequency range. To accomplish the second function, the sawtooth wave actuates a reactance tube associated with the frequency-determining circuit of the oscillator. Or, at ultra-high frequencies, the sawtooth wave is impressed directly upon an oscillator tube of the velocity-variation type. In either case, the oscillator frequency is made linearly proportional to the instantaneous amplitude of the sweep throughout its utilized portion.

The variable oscillator output then modulates the input wave to be analyzed so as to sweep its spectrum across the narrow pass band of the i-f amplifier. The i-f output is then detected, amplified, and applied to the *V* plates of a cathode-ray oscilloscope.

The amount of frequency variation (F) during a sweep cycle is made large enough to include the region to be analyzed. The sweep period (T) and the i-f band width (B) must be selected to accord with the resolving power required. If, for example, components equal in magnitude and separated by S cycles are to be displayed as distinct pips on the oscilloscope screen, the response produced by one of them must have built up and decayed to a sufficiently low value before the next component enters the i-f band. The transient response depends upon the i-f band width and has a duration of roughly $2/B$ seconds. This time is to be no greater than the time required for the sweep to traverse the frequency spacing between the two components, or ST/F. If then the i-f bandwidth is made, say, one-quarter the frequency separation between the components to be resolved, the sweep period T should be of the order of magnitude $F/2B^2$. Where the components to be resolved are not equal in magnitude, the sweep period or the sweep frequency deviation must be correspondingly reduced, if the two transients are not to overlap excessively. Resolution of a carrier and two sidebands is indicated on the oscilloscope screen of Fig. 18.

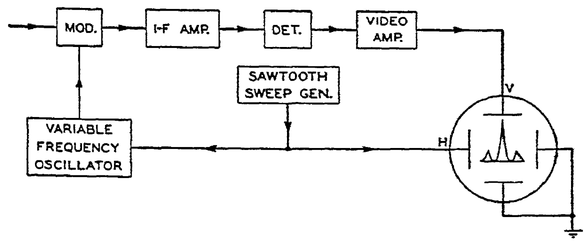

FIG. 18. Sweep-frequency Heterodyne Analyzer; Cathode-ray Presentation

In certain cases involving large numbers of components, it is desirable to display the envelope of the spectral distribution rather than to resolve the components individually. There the i-f band (B) is made wide enough to include a number of components, and the approximate relations given above remain applicable when the separation (S) refers to bands rather than to individual components. An example is shown in Fig. 19 of a spectrum envelope applying to a magnetron pulsed at 1800 cps, taken with an i-f band width of the order of 50 kc.

Various applications involve ranges of T from 1/100 to perhaps 1/2 second, of B from 2 to 100 kc, and of F from 100 kc to 200 Mc.

One of the most satisfactory methods for calibrating the frequency scale is to superpose on the modulator input of Fig. 18 a standard frequency source which is amplitude modulated by a sine wave at a known and adjustable rate. This superposes three pips at known frequencies on the signal spectrum, which can be varied in position to coincide with points of interest.

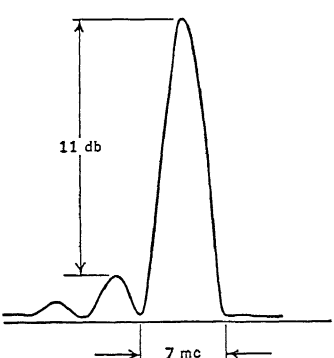

FIG. 19. Spectrogram of an Oscillating Magnetron Pulsed at 1800 ~; Pulse Duration Roughly 0.25 Microsecond. Wave components are not resolved.

For presentation of individual components a linear rectifier may be used to provide a linear output scale. For envelopes a square-law rectifier provides an output proportional to energy. Measurement of output levels may be carried out by one of two methods. The deflections may be read on a calibrated scale on the cathode-ray screen, or a calibrated attenuator in either input or i-f paths may be varied to bring to a fixed deflection the particular part of the distribution which is to be evaluated. In either method, overloading of the measuring system must be avoided.

A similar sweep type of heterodyne analyzer, developed primarily for the study of musical tones, has a galvanometer as output indicator A rotating mirror synchronized with the 10-cycle oscillator frequency sweep reflects the galvanometer light spot to a ground-glass screen. The rotating mirror thus provides the equivalent of a horizontal sweep. An electrical network is used at 20 kc with a band width sufficient to resolve tones separated by 200 cycles.

Another indicating and recording device used in conjunction with the sweep frequency heterodyne was developed primarily for noise and vibration studies in the audio band. It uses a scriber provided with a synchronous mechanical drive (like that of Fig. 20) which furnishes a permanent record of the spectral distribution upon waxed paper. Piezo filters make available analyzer band widths of 5, 50, and 200 cycles. The amplitude scale covers a range of 80 db. A complete record, directly legible, requires about 2 minutes' time.

SOUND SPECTROGRAPH. The sound spectrograph produces a visual record showing the distribution of energy within an audio band in both frequency and time. Though the development of this device must be regarded as still in the experimental stage, it constitutes as it stands a powerful means for the analysis of speech, music, and noise. Its power comes from the high concentration of information presented, which permits details of the spectral distribution to be followed as a function of time.

Figure 20 shows a simplified schematic of one form of the device which will serve to illustrate the basic idea. Three distinct functions are involved. First the sound to be analyzed is recorded so that it can be repeatedly reproduced. Here a magnetic tape recording is shown, mounted on a rotating disk which is driven by a synchronous motor. Second, analysis of the recorded sound is effected by a heterodyne type of analyzer in which the oscillator frequency is varied to move the analyzer filter in effect steadily over the sound spectrum. This variation is indicated in the figure by mechanical coupling between the varying condenser of the beating oscillator and the main drive shaft. In this way the analyzing frequency changes a small amount throughout each revolution of the shaft. Finally the analyzer output is recorded in synchronism with the reproduced sound. Recording is accomplished in the same manner as that practiced in facsimile reception. A drum bearing the recording paper is coupled to the main drive shaft, and the recording stylus is moved laterally a small distance in each revolution by means of a lead screw similarly coupled. The electrically sensitive paper mounted on the drum is marked by the stylus with gradations of density which accord with the analyzer output. The net result is to produce a sort of three-dimensional picture in which the energy distribution is depicted by density variations on a rectangular plot of frequency against time.

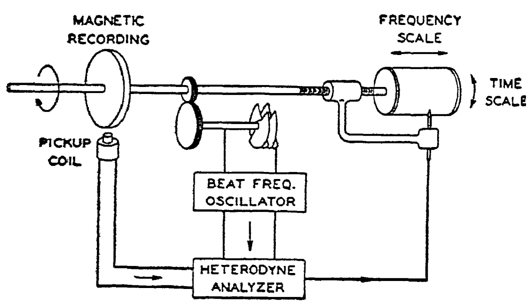

FIG. 20. Schematic Representation of One Form of Sound Spectrograph. The output of the sweep-frequency heterodyne analyzer is displayed as a pattern on electrically sensitive paper, exhibiting the energy-frequency distribution as a function of time.

A signal level range of 35 db is handled with the aid of automatic volume control which provides something like a threefold compression on a db basis. Two heterodyne band widths are available: one 45 and the other 300 cycles, as measured at the 3-db points. The linear frequency scale of the spectrogram is 2 in. high and covers the range from 100 to 3500 cycles. The linear time scale extends for a length of 12 in., corresponding to an original audio sample 2.4 seconds in duration. Two hundred rotations of the disk carrying the audio sample are completed in less than 5 minutes for the full analysis. The most recent development in this field speeds up the analysis by a factor of the order of 200.

Photographic reproductions of spectrograms of speech, music, and noise are to be found in the last four references listed under Spectrographs in the Bibliography. In the case of speech, the narrow band (45 cycles) analysis is adequate to resolve individual harmonics of the voiced sounds. The traces curve up and down as the pitch of the voice varies, and the spacing between harmonics gets bigger as the pitch increases at any particular instant. A definite loss of detail occurs when the wide band (300 cycles) is used since two or three harmonics are merged. A spectrogram of thermal noise shows energy concentrated in different frequency regions at different instants of time. Randomly spaced vertical spindles of the spectrogram correspond in length to the 300-cycle filter of the analyzer. Especially interesting are spectrograms of a warble tone which constitutes a frequency-modulated wave, produced by varying sinusoidally the frequency of an oscillator. The narrow filter reveals the presence of individual side frequencies of a tone warbled at a 50-cycle rate, but the wide filter cannot resolve them; they are integrated to reveal the instantaneous frequency.

The process of sound portrayal employed in the sound spectrograph described above results in a considerable simplification of apparatus where high resolution is desired. The equivalent machine to record high-resolution patterns directly would require something of the order of a hundred filters rather than a single one. Sound spectrographs of this type have been made to transcribe long samples of sound by employing the disk and drum arrangement of Fig. 20 with endless belts, one of magnetic tape and another of recording paper.

For special uses, such as experimental visual telephony for the deaf, low resolution patterns of the type provided by the sound spectrograph are formed at speech rates. Ten to twenty fixed filters or a scanning band affording equivalent resolution are used in this instrument, termed "visible speech translator." The outputs produce speech patterns in light upon a moving band of either phosphorescent or fluorescent material. Scanning and timing functions are controlled by synchronized electronic means. The accuracy and speed of these translators are sufficient to permit their use for the reading of continuous speech by trained observers.

MICROWAVE MEASUREMENTS

By E. W. Houghton

The electrical characteristics of any network can be completely expressed in terms of three quantities: impedance, power, and frequency. Attenuation ratio, although not a fundamental quantity, is of sufficient importance to warrant separate consideration. This section is concerned with methods and techniques for accurately measuring these quantities in the frequency range of roughly 1000–30,000 megacycles. The methods can be used to attain the accuracies summarized in Table 1.

Table 1. Microwave Measurement Accuracies

Quantity to Be Measured	Method	Accuracy
Impedance:		
Small standing wave ratios	Slotted line	±2%
	Directional coupler	±5% – ±0.2%
	Hybrid junction	±5% – ±0.2%
Large standing wave ratios	Slotted line	±5%
Power (averaged over several seconds)		
5–200 microwatts	Bolometer	±0.5 db
0.2–10 milliwatts	Bolometer	±0.1 db
0.01–100 watts	Bolometer-attenuator	±0.3 db
20–100 watts	Calorimeter	±0.3 db
Power (averaged over several microseconds)		
1–100 watts	Calibrated crystal	±0.6 db
0.1–100 kilowatts	Calibrated crystal	±1 db
Attenuation		
0–3 db	Bolometer	±0.05 db
0–13 db	Bolometer	±0.1 db
0–60 db	Heterodyne receiver	±0.2 db
0–40 db	R-f attenuator	±0.2 db
Frequency:		
Small differentials	Wavemeter	±0.005%
Absolute	Harmonic generator	±0.0001%
	Wavemeter	±0.01%

32. IMPEDANCE MEASUREMENTS

TRANSMISSION-LINE CALCULATIONS. At microwave frequencies practically all measurable impedances are in transmission lines (coaxial or wave guide), and the terminals of these impedances are transmission-line couplings (i.e., coaxial jacks and plugs or wave-guide choke or plane flanges) or simply specific transverse planes in the transmission line (see reference 17, p. 11-89). Absolute impedance values are rarely important, and in fact wave-guide transmission-line impedances can be defined in several ways (see reference 1). Ambiguity is removed by using a relative or "normalized" value which is the ratio of an impedance, Z, to Z_0, the characteristic impedance of the transmission line defined in the same way; thus $z = Z/Z_0$, where z is a complex value.

A section of uniform, lossless, transmission line, Fig. 1, transmits energy in a given mode between a source plane, s–s, and an impedance plane, t–t, by means of traveling electromagnetic waves. Unless the impedance at t–t terminates the line in its characteristic impedance, two such waves exist: (1) an incident wave which originates at the source and travels forward toward the impedance plane t–t, and (2) a reflected wave which originates at t–t and travels backward toward the source (see reference 2). The ratio of transverse voltage in the reflected wave to transverse voltage in the incident wave defines the reflection coefficient k, which is a complex quantity. Total transverse voltage and longitudinal current on the transmission line are the vector sums of the voltages and currents in the two oppositely traveling waves, which therefore combine to produce a standing-wave pattern distributed along the transmission line. The ratio of the maximum to the minimum total voltage defines (voltage) standing-wave ratio, S, which is not a complex quantity.

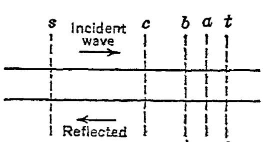

FIG. 1. Impedance Planes on a Transmission Line

The more general result of interference between oppositely traveling waves is to transform the impedance at t–t to new values at planes between s–s and t–t. The relationship between reflection coefficient and normalized impedance at t–t is: $K_t \angle\phi = (z_t - 1)/(z_t + 1)$, where z_t is a complex value. At some arbitrary plane a–a closer to the source and removed from t–t by line length $l/\lambda g$ wavelengths the reflection coefficient is $k_a = K_t \angle(\phi - 2\theta)$, where $\theta = 2\pi l/\lambda g$ radians. The normalized impedance at this plane is thus:

$$z_a = \frac{1 + k_a}{1 - k_a} = \frac{1 + K_t \angle(\phi - 2\theta)}{1 - K_t \angle(\phi - 2\theta)}$$

This can be expressed as $z_a = (z_t + j \tan \theta)/(1 + jz_t \tan \theta)$.

The oppositely traveling waves combine in phase opposition to give a minimum voltage standing wave at $2\sigma = (\pi - \phi)$ radians, or $(\pi - \phi)/4\pi$ wavelengths from t–t; at $\pi/2$ radians or $1/4$ wavelength closer to s–s the waves directly add to give a maximum voltage standing wave. The standing-wave ratio is thus $S = (1 + K_t)/(1 - K_t)$. From measurements of either K, or S, and σ, the normalized impedance at t–t can be computed (see reference 3) from

$$z_t = \frac{1 - j\,(S \tan \sigma)}{S - j\,(\tan \sigma)} \tag{1}$$

The transmission-line calculator (see reference 4), Fig. 2, provides a convenient graphical aid to visualization and computation of the above impedance transformations. An ex-

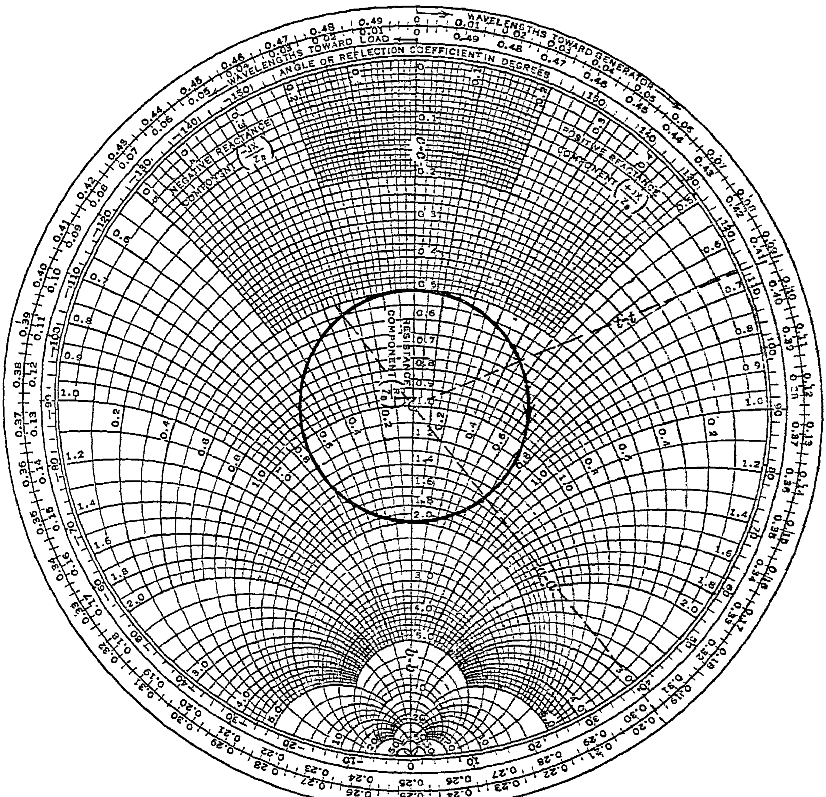

FIG. 2. Transmission Line Calculator

ample, drawn on the chart, will illustrate its use. As the line length between t–t and a–a increases, transformed impedance values are intercepted by the circle in the order indicated by the arrow on its periphery. Thus a normalized impedance $z_t = 0.65 + j0.45$ at t–t transforms to $z_a = 1.5 + j0.7$ at plane a–a located 0.102 wavelength from t–t. Normalized admittance values equivalent to series impedance values appear at points on the circle diametrically opposite; thus $y_a = 1/z_a = 0.55 - j0.25$. At b–b, z_t is transformed to a pure resistance $z_b = 2.0 + j0$; at c–c, z_t is transformed to $z_c = 0.5 + j0$, also a pure resistance. Planes b–b and c–c are the positions of the maximum and minimum standing wave voltages respectively, and the standing-wave ratio created by z_t is $S = z_b = 1/z_c = 2$. Following the above example in reverse order it is seen that the chart provides an extremely practical method for computing the impedance z_t from measurements which gave values of $S = 2$ and $\sigma = 0.408$. By this method eq. (1) can be solved rapidly and with a precision adequate for most measurements.

The results of impedance measurements are primarily used to study the electrical nature of the impedance, or to design networks for transforming this impedance to a new value (see reference 5) (usually the characteristic impedance of the transmission line, which it then terminates without reflection). However, in many cases a given impedance may be used to terminate an electrically long transmission line or a line of unspecified length. Under these conditions a measurement of the reflection coefficient phase angle would be trivial; thus in many practical cases impedance measurements are concerned only with ascertaining reflection coefficient amplitudes or standing-wave ratios produced by that impedance in a connected transmission line.

STANDING-WAVE DETECTORS. Of the three instruments most commonly used for impedance measurement the standing-wave detector is the most versatile since it affords information on both amplitude and phase of the reflection coefficient. It comprises: (1) a section of uniform transmission line (coaxial or wave-guide) which has a longitudinal slot in its outer conductor, and (2) a probe which projects through this slot and travels parallel to the axis of the line on a carriage. A standing-wave pattern of voltage is set up in the line when the test impedance is connected at one end and a source at the other. The probe, excited by this voltage, is connected to a detector whose output is a relative function of total voltage amplitudes along the slotted line. From readings obtained at the maximum and minimum voltage positions, the standing-wave ratio can be calculated, provided that the law of the detector is known or the detector has been calibrated. The detector may be a crystal (reference 6), bolometer (reference 8), or the mixer of a heterodyne receiver (reference 25). In the last case the mixer may be kept linear by operating at low levels; the second detector is used at a constant level by means of a calibrated i-f attenuator. The law of a bolometer detector and its bridge circuit can be obtained accurately by a low-frequency calibration. Specially selected crystals can be found to meet a square-law requirement over restricted input ranges, but they should preferably be calibrated against a bolometer power meter or heterodyne receiver.

A somewhat less accurate calibration method is to terminate the slotted line in a perfectly reflecting short and measure the standing-wave voltage distribution, which under ideal conditions approaches $V = C \sin (2\pi l/\lambda g)$, where C is a constant and $l/\lambda g$ is the displacement in wavelengths from a plane of zero voltage. A method for which the law need not be known is to operate the detector at a constant level by using a calibrated r-f attenuator between the slotted line and the source, or between the pick-up probe and the detector; standing-wave ratios are deduced from attenuator settings. The r-f attenuator method is satisfactory for measurement of high standing-wave ratios (10–100) but is generally considered inferior to other methods for low ratios (1 to 2).

In order to avoid reflection errors from the probe, its insertion is limited to small values (less than 10 per cent of wave-guide height or $^1/_4$ the difference between coaxial conductor diameters) for which its power output will be 20–30 db lower than the power in the slotted line. The most convenient oscillator sources are single-cavity klystron (reference 10) or Reflex (reference 8) oscillators which can be easily tuned over wide bands. After adequate padding these sources may deliver only 1–10 mw to the slotted line. High-sensitivity detecting and indicating methods are therefore often required. Three methods are common: (1) a heterodyne receiver can be used; (2) a simpler method is to 100 per cent modulate the source by a square wave (to avoid frequency modulation), then amplify and rectify the detector output in a high-gain amplifier-detector; (3) the simplest method is to use a sensitive galvanometer or microammeter driven directly by a crystal detector. A tunable transformer can be included in the probe-detector mechanism to give the highest sensitivity allowed by a given probe insertion; however, any variation in crystal or bolometer r-f impedance with standing-wave voltage variation may cause a change in the tuning and introduce a significant error. Since they are 15–20 db less sensitive than crystals, bolometer detectors are more satisfactory on high-power sources (magnetron test equipment, reference 11) for which high-sensitivity methods are not needed. For accurate measurements, stabilized power supplies must be employed, and spurious pick-up in microwave oscillators, high-gain amplifiers, and detector output leads must be avoided by complete shielding.

Design Requirements. The slot should be as narrow as possible, of uniform width, accurately centered in rectangular wave guide and parallel to the axis in the coaxial line, and long enough to allow a probe movement of at least $^1/_2$ wavelength. To prevent radiation the slot can be covered (by a contacting shoe or a shorting trap) for at least $^1/_4$ wavelength on each side of the probe. To avoid serious errors caused by small transverse variations of the probe in the slot the probe's outer conductor is sometimes imbedded in the center of a metal slug at least $^1/_2$ wavelength long, the bottom of which is flush with the inside of the outer conductor or wave-guide wall, and the sides of which definitely wipe (or definitely clear with very small gaps) the sides of the slot. In coaxial slotted lines the conductors must be accurately coaxial. The center conductor can be rigidly supported and centered at the source end, but at the load end it should be supported (if necessary) by a very thin washer of low-dielectric-constant material; the residual reflection (pure shunt susceptance) can be calibrated and allowed for subsequently. An assortment of low-reflection fittings (tapers, jacks, plugs, adapters) may be required for connection to the load, although greatest accuracy can be attained with as few attachments as possible. Wave-guide slotted lines are preferably terminated with a well-surfaced plane flange, to which adapters may be attached, or with a standard choke on one end and choke-cover flange on the other so that either type of connection is available by reversal of the slotted section.

The most serious requirement is that the bottom of the probe shall travel accurately parallel to the axis of the transmission line. The probe carriage may travel on the outside of the line itself, or on ways rigidly attached and made accurately parallel with the axis. It is generally possible by accurate machining or electroforming techniques (reference 12) to maintain parallelism within ± 0.0002 in. for at least $^1/_2$ wavelength of travel.

Accuracy. On standing-wave ratios above about 2, inaccurate assumptions (or calibrations) for the law of the detector and the amplifying-indicating system, and meter-reading errors, can easily limit the measurement accuracy to 10 per cent; by using a calibrated r-f attenuator, or preferably a heterodyne receiver, or by deducing the voltage standing-wave ratio from measurements confined to the region of the voltage minimum (reference 3), the accuracy can be improved to nearly that for low standing-wave ratios. Below ratios of 2, percentage accuracy is limited primarily by: (1) change in characteristic impedance and end reflections introduced by the slot; (2) reflections introduced by load connectors (flanges, jacks, tapers, or adapters), unless these are to be considered a part of the unknown impedance; (3) reflections from the probe; and (4) non-parallelism of probe travel. The effect of (1) can be deduced by measuring an impedance through two lines of the same dimensions, one with and the other without a slot. Sometimes errors from (2) can be reduced by determining an equivalent shunt susceptance (reference 16), but this is impractical when the connector introduces multiple discontinuities. It is possible, but not very easy, to measure and calculate errors from (3) (reference 13); this effect can be reduced by maintaining a matched impedance looking toward the source and eliminated by withdrawing the probe until there is no significant change in power delivered to the load (as monitored by another detector); but a compromise must usually be effected between this error and the error from (4) since (4) is reduced by larger probe insertions.

Experience has shown that carefully constructed coaxial standing-wave detectors can be used with an accuracy of about 5 per cent and the accuracy for wave-guide detectors is usually about 2 per cent.

DIRECTIONAL COUPLERS. Directional couplers (reference 14) are commonly included as a permanent section of the coaxial or wave-guide transmission line in microwave systems for monitoring incident and reflected power (reference 15). In such applications they (1) introduce negligible reflection in the transmission line (S less than 1.05), (2) create almost no high-power arcing problem, and (3) contain no moving parts. Compared to standing-wave detectors, directional couplers can be used for routine measurements of reflections with somewhat less accuracy by standard techniques, and with much higher accuracy by special techniques; they can be more conveniently used (1) to tune a load impedance to match the line, (2) to tune a source impedance to match the line, and (3) to correct for changes in interaction loss between the source and load impedance.

Power levels proportional to the power in the reflected and incident waves can be measured at the input and output ends respectively of an auxiliary transmission line coupled to the main line by means of two equal-sized probes, loops, or orifices separated by approximately $^1/_4$ transmission-line wavelength (reference 14). Illustrated in Fig. 3, this instrument comprises a directional coupler in its simplest form. A directional coupler can thus be used to measure reflection-coefficient amplitude, which is the ratio of the square root of the two measured power levels. Bolometer power detectors are convenient for high-power sources, and on low-power sources the same sensitive detecting and indicating methods previously described are applicable. It is preferable to switch the same detector-indicator alternately between incident and reflected wave outputs (alternately terminating the other output) so that only a ratio calibration is required. Low-reflection wave-guide and coaxial switches are convenient for this purpose, or special arrangements can be employed to transmit both waves to the same output. Detector law uncertainties can be eliminated by using a calibrated r-f attenuator to equalize incident and reflected powers. The attenuator method is best used for measuring nearly matched impedances, since, for example, a change in standing-wave ratio from 1.01 to 1.02 changes

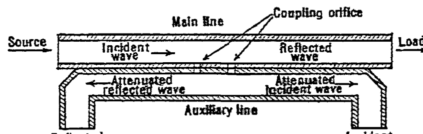

FIG. 3. Directional Coupler in Waveguide

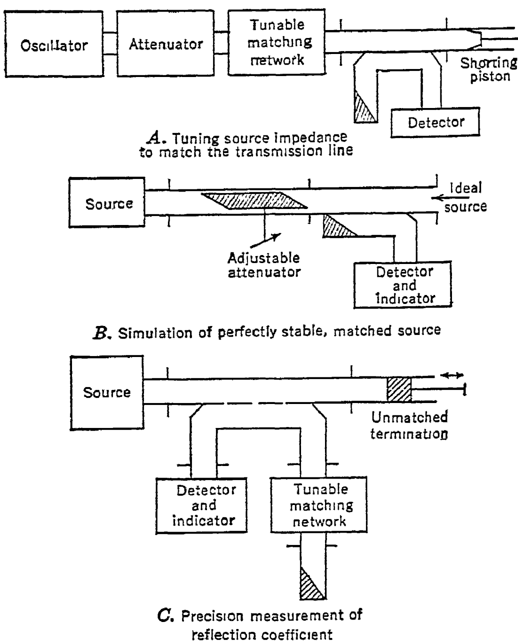
the reflected wave output power by 6 db whereas one from 2.02 to 2.04 changes the output power by only 0.12 db.

A directional coupler can thus be used as a sensitive indicator for tuning a load to match the transmission line, and, because reflection coefficient is continuously monitored, it is especially convenient.

In Fig. 4 a directional coupler is used for matching a source impedance to the line. As a shorting piston (or preferably a reflector with a constant K of 30 to 50 per cent) is moved back and forth in the line, the tuning controls are adjusted until the incident wave output remains constant. The oscillator must be sufficiently masked or decoupled to prevent changes in its frequency and efficiency as the load impedance varies.



A. Tuning source impedance to match the transmission line

B. Simulation of perfectly stable, matched source

C. Precision measurement of reflection coefficient

FIG. 4. Directional Coupler Applications

Without tuning for it, the condition prevailing for a matched source impedance (Fig. 7) can be simulated by monitoring and keeping the incident power constant by means of a variable attenuator ahead of the coupler, Fig. 4. The variation of power in the load as its impedance changes is reduced to that of reflection loss only. Power-time instability in the oscillator can also be corrected for by this method.

Design Requirements. Directional couplers for impedance measurement should not have losses much below 20 db (see p. 11-72) to avoid serious loading by the coupling holes and interaction between them. By careful machining or electroforming techniques (reference 12), inside dimensions and the wall thickness of the main line must be made precisely uniform over the longitudinal region occupied by the coupling slits or holes, which must be constructed with exacting tolerances. Transverse slits have been used both in coaxial lines and in wave guides (usually in the wide side), but for wave-guide couplers round holes in the narrow side are usually better since they give higher losses which can be more accurately controlled by standard precision boring techniques. In coaxial lines the center conductor must be accurately centered; reflection from any support at the load end cannot be calibrated out of the measurements which ordinarily do not contain phase information. Similarly, careful attention must be given to designing reflectionless fittings and connectors.

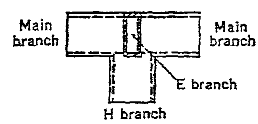
The most serious requirement for accurate measurements is that the directional coupler be designed for the frequency band in which it is to be used. Its directional coupling action (directivity) is frequency sensitive. As λg, the transmission-line wavelength (not to be confused with free-space wavelength) varies, the effect of a fixed hole spacing is to add a spurious vector voltage to the true reflected wave output in the auxiliary line. The ratio of this spurious voltage to the incident wave voltage (also in the auxiliary line) shall be designated "unbalance reflection coefficient," K_u. In the worst case, a measured value of reflection coefficient will be in error by $\pm K_u$. For a simple two-hole coupler in wave guide, K_u is zero at a λg approximately 1 per cent greater than four times the hole spacing, but for a ± 0.6 per cent, ± 1.3 per cent, and ± 3.2 per cent change in λg the values for K_u are approximately 0.01, 0.02, and 0.05 respectively. The band width can be greatly increased by increasing the total number of holes, and the simplest pattern is to separate equal-sized pairs of holes (spaced $1/4$ the mid-wavelength) by $1/2$ mid-wavelength. By this method K_u can be kept lower than 0.015 over an 8 per cent wavelength band in a four-hole wave-guide coupler and over a 20 per cent band for an eight-hole wave-guide coupler (reference 26).

Another spurious vector, adding to the true reflected wave output, comes from partial reflection of the incident wave from an imperfect termination of the auxiliary line. Where it is practical to position this termination for first a minimum then a maximum reading, it is possible to nearly eliminate its error by averaging the two readings.

Accuracy. In the laboratory where there is usually no serious limitation on length, it is practical to use four- or eight-hole couplers containing broad-band terminations with *VSWR* less than 1.05 in coaxial and 1.02 in wave guide. Under these conditions, routine measurements can be made with a *VSWR* accuracy of about 10 per cent in coaxial and 5 per cent in wave guide, since detecting-indicating systems can be made to contribute small percentage errors. In microwave systems directional couplers are often limited in size so that the realizable accuracy is usually lower.

Figure 4 shows a method wherein the auxiliary line termination is tuned to cancel the K_u of the holes, giving the effect of a perfect coupler and termination. As a mismatch of constant K is moved back and forth in the main line, the termination tuning is adjusted until the reflected wave output remains constant (not zero). Alternatively, if a termination of $K = 0$ is used the output can be directly tuned to zero. Loads (including their connectors) connected to the directional coupler can then be measured with an accuracy of about 0.1 to 0.2 per cent. Accuracy is limited primarily by the detecting-indicating equipment.

HYBRID JUNCTIONS. Hybrid junctions (reference 18) can be used in many of the applications described for directional couplers, compared to which they may possess certain advantages in sensitivity, size, design simplicity, and band width. It is possible to make hybrid junctions in either wave-guide or coaxial lines. However, a design which will give accurate measurements over a wide bandwidth does not yet exist for coaxial lines. Descriptions and examples in the following discussion are applied specifically to wave-guide hybrid junctions for which satisfactory designs are commonplace.



A. Hybrid junction in waveguide

B. Measurement of reflection coefficient

FIG. 5. Hybrid Junction

A type of hybrid junction commonly used for impedance measurement is formed by joining an H-plane T (off the narrow side) and an E-plane T (off the wide side) to a straight section of rectangular wave guide (reference 12). Projections of the central axes of both T's meet at a common point on the axis of the main guide, Fig. 5. This geometrical symmetry makes the E and H branches conjugate. When the main branches are terminated by equal impedances there is no transmission between E and H branches. Hybrid junctions can therefore be used to tune a load on one main branch (test branch) to match that on the other main branch (reference branch); the degree to which the tuned load matches the characteristic impedance of the wave guide depends upon (1) the intrinsic balance in the junction and (2) the reflection coefficient of the reference termination. The directional coupler has corresponding limitations; in fact, both devices separate out direct and reflected waves by a cancellation process. However, it is sometimes more helpful to visualize the hybrid junction as the microwave equivalent of a low-frequency hybrid transformer (reference 18) with the added complication that the input impedances at the junctions, unless matched, are transformed to new values along the transmission-line branches.

Looking toward the junction the impedances are inherently unmatched to the branch transmission lines; on well-constructed junctions the *VSWR*'s looking alternately into E, H, test, and references branches are approximately 2, 3, 1.3, and 1.3 respectively when the other three branch lines are terminated in Z_0.

By methods similar to those described for the directional coupler, hybrid junctions can also be used for routine and precise measurements of reflection coefficient. Figure 5 illustrates the circuit configuration. The E-branch output (detector input) is proportional to the vector sum of the reflected waves in the test and reference branches, and a wave created by junction unbalance. When the latter two are negligible, the detector input is proportional only to the power reflected from the unknown impedance; reflection coefficient can be deduced from the ratio of this power to the power incident upon the unknown. For sensitivity calibration a power level proportional to the incident wave (in the test branch) is most conveniently applied to the detector by substituting a shorting plunger for the unknown.

As a consequence of its reflection coefficient, k_t, the test branch carries a *total* reflected wave, V_r, which is not uniquely proportional to the product of the reference incident wave V_i and the unknown reflection coefficient k_x. In fact, $V_r = V_i k_x/(1 - k_x k_t)$, which is a complex quantity. Evidently the amplitude ratio V_r/V_i as measured on the hybrid junction is not the true reflection coefficient K_x; therefore the maximum error in routine measurements created by K_t (assuming that the effect is not canceled by purposely phasing the unknown along the line) is $1/(1 - K_x K_t)$. For example, a measurement which gave $K_x = 9.1$ per cent ($SWR = 1.2$) may be in error by a maximum factor of 1.01 since $K_t = 13$ per cent. The error increases at higher values of K_x, but nearer zero the error from this source will be negligible (reference 27).

When a short circuit is substituted for the unknown for sensitivity calibration, $K_x = 1$. As the position of the short circuit is varied the power in the detector will deviate from the reference value by maximum factors of $1/(1 + K_t)$ to $1/(1 - K_t)$. From an observation of the maximum and minimum detector outputs it is possible to deduce that reference detector output which is proportional to the reference incident power in the test branch. However, the impedance presented to the source will be seriously altered by the short circuit in the test branch, so the above factors can be applied exactly only when the oscillator is well masked and the source impedance is well matched to the line; alternatively the source's incident power can be monitored by a directional coupler and kept constant, Fig. 4. The detector must also present a well-matched, Z_0, load. An alternative method of calibration which reduces the interaction effects occasioned by introducing a shorting piston is to substitute a known impedance (calibrated by other means) of medium or low K. In this case, the net measurement accuracy can be no better than that of the calibrated impedance.

The above interaction effects can be materially reduced or even eliminated by introducing properly positioned susceptances (references 5 and 17) (matching posts, windows, or dielectric blocks) which cancel the junction's discontinuity reactances and transform the impedance of the H and E branches so that each branch is matched when the other three are terminated with matched loads. Under this condition, the main branches are also conjugate, and power sent into any one branch divides equally between the two nonconjugate branches (reference 18). Such an "ideal" hybrid junction can be used in all those applications described for directional couplers, except monitor, without disturbing the transmission line, with as good accuracy and higher sensitivity. For example, high- or low-impedance mismatches can be measured accurately, a load can be tuned, and a source impedance can be tuned to Z_0 by monitoring and tuning for constancy the incident wave output on one main branch while moving a shorting piston in the other main branch.

The above impedances may be matched over only a relatively narrow band, unless the posts or windows are put right in the junction. However, the unbalance reflection coefficient may be seriously increased by this method of impedance matching. Completely satisfactory wide-band solutions have not yet been found. Matching networks are not essential for many measurement requirements.

Accuracy. Accuracy of routine measurements is primarily limited by (1) interaction between unknown and test branch impedances, (2) reflection coefficient of the reference termination, and (3) junction unbalance reflection coefficient. For low mismatches (K less than 5 per cent) the first error is negligible, and under this condition the same techniques described for directional couplers can be used to (*a*) cancel the second error by positioning the reference termination and (*b*) cancel both second and third errors by tuning the reference terminations for precision measurements. On hybrid junctions constructed by precision electroforming techniques (reference 12) the unbalance reflection coefficient can be kept less than 0.005 over the entire wave-guide pass band. Therefore on low mismatches the accuracy of routine measurements can be as high as or higher than on well-constructed directional couplers with the added advantage that lower-sensitivity, more stable detecting and indicating equipment can be used.

Compared to directional couplers, hybrid junctions have the following advantages: (1) they are simpler to design for a low unbalance reflection coefficient over a wide band (geometrical symmetry is the only requirement); (2) they are smaller; and (3) they are more sensitive (the reflected wave power in the detector is at least 10 db higher than that for a 20-db directional coupler). However, (1) they cannot be incorporated in transmission lines (with negligible reaction) to monitor reflection coefficient; (2) interaction between "unknown" and test branch impedances may introduce a significant error in measuring reflection coefficients higher than about 5 per cent ($S = 1.1$); and (3) impedance interaction effects make it more difficult to calibrate sensitivity without introducing a calibration error.

33. ABSOLUTE POWER MEASUREMENTS

LOW-POWER MEASUREMENTS BY BOLOMETRIC METHODS. Microwave powers less than 10–20 mw are measured by bolometric methods which are, so far, the only ones available for accurate measurements in this frequency and power range. A transmission line carrying the unknown power is terminated in a bolometer detector, the only absorbing element of which is a thermally sensitive resistor. Its d-c resistance changes when r-f power is dissipated in it, and ideally the change is independent of the frequency of excitation. The resistance change can therefore be related to r-f power by a low-frequency or d-c calibration. Alternatively the resistance can be biased to a given value and kept constant when r-f power is applied by removing an equal and measured quantity of d-c or low-frequency power.

A bolometer detector (Fig. 6 is typical) comprises a thermal resistor and a reactance network for matching it to the transmission line. Sensitive thermal resistors are small, essentially "lumped," elements. Two types are commonly employed: thin, short, filament wires (reference 19), and bead thermistors, the thermal element of which is a tiny bead made up of a mixture of metallic oxides (reference 8) (see Table 2). The r-f resistance of the thermal resistor may be different from d-c resistance, but, in order to compare r-f power directly against d-c (or low-frequency) standards, (1) its d-c resistance change must be dependent only upon incremental heating power (when external temperature is constant), (2) the heat distribution from r-f power must be equivalent to that generated by a uniformly distributed d-c current, and (3) all the r-f power absorbed by the detector must be dissipated in the thermal resistor.

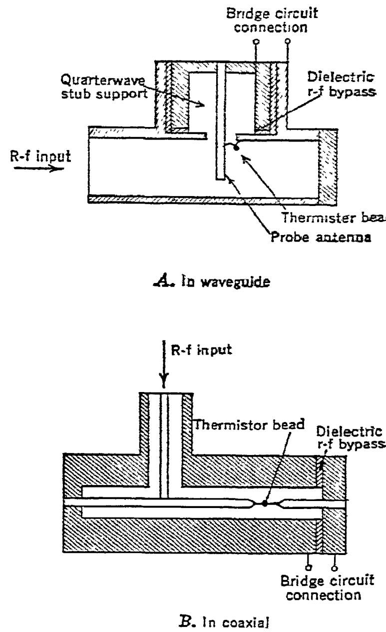


FIG. 6. Pre-tuned, Wide-band Bolometer Detectors

Requirement 1 is met on all thermal resistors when space-integrated values of resistance and heat are specified. However, the time constant of the thermal resistor may be of such a value that, in two extreme cases, resistance changes either (*a*) exactly follow or (*b*) completely fail to follow the modulation envelope of the r-f power (when amplitude modulated). In either case the average resistance change is proportional to average power, but in (*a*) envelope peak power can be measured. As sinusoidal modulation frequency is increased from zero (all other parameters remaining constant) the resistance modulation will decrease to half its maximum value at 36 cps and at 450 cps, respectively, for the thermistors and platinum wire listed in Table 2.

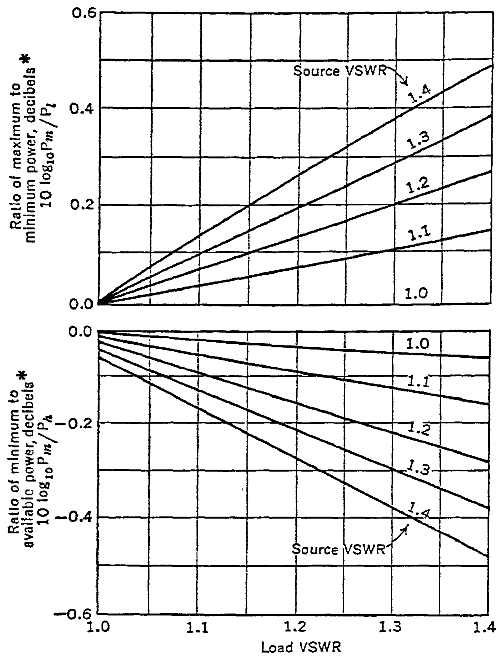
Table 2. Sensitive Thermal Resistors—Typical Characteristics

	Platinum Wire	Thermistor Bead		
Temperature	25° C	25° C	25° C	25° C
Resistance	200 ohms	200 ohms	125 ohms	50 ohms
Biasing power	15.3 mw	10 mw	13.5 mw	23.5 mw
Resistance-power coefficient	+4.5 ohms/mw	−29 ohms/mw	−14 ohms/mw	−4.8 ohms/mw
Power-temperature coefficient *	−0.05mw/deg cent	−0.1 mw/deg cent		
Time constant †	350 μsec	2500 μsec		
Safe maximum current	11 ma	200 ma		
Dimensions	0.118 × 0.00006 in.	Lead wires, 0.001 in. diameter; Bead, 0.020 × 0.010 in.		

* For constant resistance; also the ratio of power to temperature changes which produce the same resistance changes.

† For 67 per cent of ultimate resistance change.

Requirement 2 is met on filament wires by (*a*) designing a matching configuration which places the r-f current maximum at the midpoint of the wire, and (*b*) by limiting the upper frequency to that corresponding to a free-space wavelength of about 8 times the length of the wire (reference 7). Platinum wires have given satisfactory results up to 10,000 megacycles. Bead thermistors, which are more nearly ideal "lumped" elements, have been used up to 25,000 megacycles, where they have shown discrepancies less than 5 per cent when checked against calorimeter standards.



*For the above VSWRs, line lengths are chosen so that P_l = least power and P_m = most power in the load. Available power P_a could be delivered if conjugate impedence-matching transformers were used in the line.

FIG. 7. Power Delivered by a Mismatched Source to a Mismatched Load

Requirement 3 must be met by transforming the a-c resistance component to the transmission line's characteristic impedance with a matching network in which considerable care is taken to eliminate extraneous circuit losses from sliding contacts, joints, and conductors. This problem is simplified by (*a*) biasing the thermal resistor to a reasonable resistance (50–200 ohms) and by (*b*) designing a low-*Q* matching configuration, which tends to eliminate high current concentrations (standing waves) in the detector.

The power absorbed (and therefore measured) by a detector load is a function of both source and load impedances, and, depending upon relative phase angles (or line length), varies between the limits shown in Fig. 7 (reference 20). To eliminate these uncertainties in measurement and interpretation of power quantities it is evidently desirable to use a detector that presents a nearly matched impedance. Wide-band, pretuned detectors, in addition to being especially convenient to use, inherently meet the low-*Q* requirement. Table 3 lists the band widths that have been realized for typical pretuned bolometer detectors using thermistors.

Since the r-f impedance varies with it, the thermal resistor's d-c resistance must be kept nearly constant by varying (with temperature) the biasing power by methods peculiar to the bridge measuring circuit.

Table 3. Bandwidth-Impedance Characteristics of Typical Pretuned Thermistor Detectors

Frequency Band in Megacycles	Maximum VSWR	Transmission Line	Thermistor Operating Resistance in Ohms
5 to 600	1.2	Coaxial	Characteristic *Z* of line
700 to 1500	1.4	Coaxial	100
2900 ± 17.2%	1.4	Coaxial	100
3700 ± 8.1%	1.4	Coaxial	100
4500 ± 11.1%	1.4	Coaxial	125
4100 ± 12.2%	1.2	Wave guide 2 in. × 1 in. OD	75
4600 ± 8.2%	1.1	Wave guide 2 in. × 1 in. OD	75
9.050 ± 6.1%	1.4	Wave guide 1 1/4 in. × 5/8 in. OD	125
24,000 ± 4.2%	1.4	Wave guide 1/2 in. × 1/4 in. OD	125

Bolometer Bridge Circuits. Biasing and power-indicating circuits are designed to accommodate characteristics such as those shown in Table 2. Resistance changes are most accurately detected in bridge circuits such as Fig. 8 which illustrates the simplest method of introducing biasing power and measuring r-f power. Power can be directly measured as the difference of the two d-c biasing powers required for reference resistance, one before and one after r-f power is applied. However, this simple method contains three important disadvantages: (1) since the r-f power may be a small difference of two relatively large d-c powers, small meter-reading errors may introduce large errors in the difference power measurement; (2) r-f power is not continuously indicated; (3) the unbalance caused by external temperature changes subsequent to initial balance conditions are indistinguishable from r-f power changes.

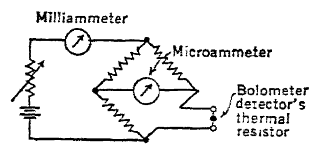


FIG. 8. Simple Bridge Circuit for Bolometer Detectors

Difference errors, (1), can be reduced by interposing a resistance network between the bridge and a current or voltage source which is kept constant at a precisely measurable single value. The network must contain accurately known resistance elements, one or more of which are switched in or out in small and known steps. Biasing powers are then deduced from settings on the switch.

Within the accuracy limitations imposed by (3), unbalance current can be used as a continuous indication of relative r-f power level; absolute power can be deduced from a calibration of the unbalance sensitivity. This sensitivity calibration will be an uncritical but not negligible function of temperature unless the d-c voltage across the bridge can be kept constant (this can be made possible by using variable low-frequency biasing power to balance the bridge initially). Resistance unbalance must be limited to a maximum value dictated by the detector's r-f matching requirements.

The lowest power that can be accurately measured is limited by (3) and the temperature coefficient of the thermal resistor. For example, from Table 2, a subsequent temperature change as small as ± 0.1 deg cent would cause a 3-db error in measuring powers of 2.5–5 μw and 0.1 db in measuring powers of 0.25–0.5 mw. These errors can be materially reduced by (*a*) using thermal insulation, (*b*) using large metal masses to limit the rate of temperature change, (*c*) interposing between the source and the detector an essentially instantly operable cut-out switch, reactive gate, or attenuator which can then be used to remove r-f power rapidly to check the initial balance, and (*d*) using temperature-compensating bridges. A combination of all the above techniques is usually required for accurate power measurements in the range of 5–100 μw.

A practical solution to the disadvantages of the simple bridge circuit has been to combine all the remedies into a more complex circuit such as Fig. 9. The thermal resistor in

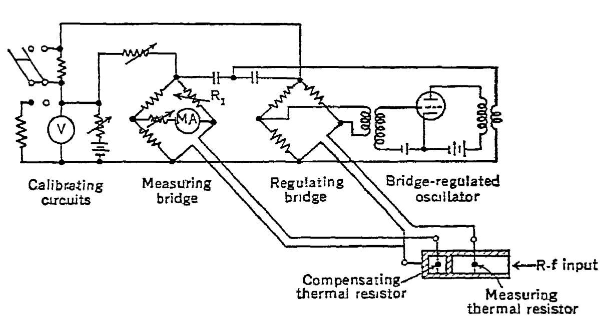

FIG. 9. Temperature-compensating, Self-calibrating, Direct-reading Bridge Circuit for Bolometer Detectors

the bolometer detector is used as the regulating element in a conventional bridge-regulated oscillator. The oscillator automatically delivers enough power to the thermal resistor to bias its resistance very close to the bridge-balancing value (within 1 per cent). The oscillation power level will therefore vary with ambient temperature with a coefficient determined by the temperature coefficient of the thermal resistor. From Table 2, this coefficient would be -0.05 mw/deg cent for the platinum wire and -0.1 mw/deg cent for bead thermistors.

The output of the low-frequency oscillator is also delivered to another bridge which contains a compensating and measuring thermal resistor (never excited by r-f power) of the same type as that used in the bolometer detector. When R_1 is properly adjusted the power received by the compensating resistor varies with temperature at a rate equal to that required by this resistor to be biased to a constant resistance. Both thermal resistors must be subjected to identical external temperature variations. Intimate thermal coupling can best be accomplished by burying the compensating thermal resistor in the same metal mass (preferably large) which forms the outside boundaries of the bolometer detector.

As a net result the measuring bridge remains balanced, even though temperature changes, until r-f or incremental d-c power is applied to the bolometer detector. The d-c biasing powers are kept constant so that the unbalance sensitivity of the measuring bridge does not vary with temperature. The overall sensitivity is established at one power level by using the d-c calibrating network which introduces a known increment of d-c heating power in the bolometer detector. Other unbalance current readings can be related to the calibrated point from a knowledge of the indicator law. Both the measuring bridge network and the intrinsic characteristics of its thermal resistor influence the law of unbalance current versus power input. In general, this law is not exactly linear, but it can be accurately calibrated by exciting the detector with a convenient low-frequency source whose relative output power is varied in known ratios by a low-frequency attenuator.

Accuracy. It is usually practical to limit errors from r-f sources to very low values, and then power-measurement accuracy is primarily governed by the d-c calibrating and indicating circuits. The circuit of Fig. 9 can be used to measure full-scale powers with less than ± 0.1 db error, half-scale powers within ± 0.2 db, and quarter-scale powers within ± 0.3 db. On an indicating meter whose resistance is equal to the bridge arms, deflections of 200 and 50 microamperes per milliwatt are typical for thermistors and platinum wires respectively. Therefore powers below $^1/_4$ mw cannot be very accurately measured unless meter-reading errors are kept low by using sensitive galvanometers or very stable indicator amplifiers; it is then possible to attain accuracies of ± 0.4 to 0.6 db down to 5–10 μw. However, the severe temperature drift problems must be solved by exacting methods as discussed above.

MEDIUM AND HIGH-POWER MEASUREMENTS BY BOLOMETRIC METHODS. Bolometer detectors containing thermal resistors which are less sensitive and require higher biasing powers than those in Table 2 (references 7, 8, 27) can be used to measure powers up to 100–200 mw. In general the methods are the same as those outlined above. Alternatively, fixed or variable r-f attenuation of known value can be interposed between the source and a low-power bolometer detector; this method is the more flexible since power levels are restricted only by the power-handling capability of the attenuator. Since attenuators capable of dissipating power up to several hundred watts (up to 1000 watts in some designs) have been realized in practice, the power range inherent in this method is at least 0–100 watts.

The attenuator's attenuation may be a significant function of frequency so that a calibration should be made (or obtained from the known frequency characteristic) at the measurement frequency. Interaction between the impedance of the source and the impedance at the attenuator's input, and between the impedance of the detector and the impedance at the attenuator's output, creates two sources of uncertainty in power measurement (see Fig. 7). These impedance interactions are preferably reduced or eliminated by an attenuator design which gives nearly unity match when alternate terminals are terminated in unity match.

Errors from attenuator calibration instability with respect to time, ambient temperature, power input level, and normal handling can usually be reduced to insignificance by (1) selection of an appropriate type of attenuator, (2) careful attention to design and construction details, and (3) frequent recalibration when necessary.

The most stable fixed coaxial attenuator types have been (1) resistance-film center conductor, (2) lumped-element π or T pad, and (3) lossy dielectric. The first two types are generally stable up to 1 watt; using lossy ceramics and heat-radiating fins type (3) can be designed to handle 100–1000 watts stably. Lossy-dielectric flexible cables have been generally unsatisfactory. In wave guides, resistance-film (parallel to the electric field) types are used up to 1 watt, and lossy ceramic dielectric types up to 100 watts. In many respects the most satisfactory fixed attenuators (in either coaxial or wave guide) have been directional couplers. Attenuation stability is unquestionably high. Attenuations above 10–15 db give the best impedance characteristics. Stringent directivity requirements are not necessary. Power-handling capability is limited solely, and input impedance primarily, by the main line termination, which may be a useful load or a dummy load of the lossy dielectric type (reference 15) or, for low powers, a resistance-film termination. The output impedance is governed primarily by the low-power termination in the auxiliary guide. It is practical to limit input and output impedance mismatches to 1.1 and 1.05 *VSWR* in cent higher than that of the inlet water and the rate of flow is m grams per second then $w = 4.18m\ \Delta t$ watts.

Temperature rise is most sensitively indicated on a microammeter deflected by d-c current generated by the differential action of series-connected thermojunctions placed alternately in the inlet and outlet water. The rate of flow is kept nearly constant during a measurement period by having a constant-head water source which is most simply a continuously refilled container of water mounted a fixed height above the water load. Calibration of the overall sensitivity can be accomplished by dissipating measurable d-c or low-frequency power in a resistor which is immersed in, and therefore heats, the water. A rate of flow different from that during measurement necessitates a proportional correction factor, so that relative flow rates must be checked. Alternatively, r-f power can be continuously compared to the low-frequency calibrating power by using a balanced bridge made up of thermojunctions in the water on each side of the calibrating resistor and on each side of the r-f water load; power measurement is then independent of water flow rate. Uncertainties about the effects of spurious heat conduction must be eliminated by having adequate thermal insulation between hot and cold junctions. Errors from heat lost by air conduction, and thermal conduction down the line, are minimized by keeping the temperature rise low (order of 1 deg cent), which requires a high rate of flow. Unfortunately this reduces sensitivity so that either a large number of thermojunctions or a sensitive microammeter is required to avoid meter-reading error. For example, a specific design using 16 hot and 16 cold junctions gave a 60-microampere deflection on a 10-ohm meter for an input power of 20 watts when the rate of flow was 3 cc/sec.

High-Q matching transformers such as the simple, single, quarter-wavelength dielectric retainer illustrated in Fig. 10, can match the water load to the transmission line satisfactorily over only a narrow frequency band (*VSWR* within about 1.2 over ±3 per cent) (reference 7), and the internally created high standing waves may cause arcing on high powers. Low-Q, wide-band, matching methods are usually preferable and may be required. One such method is to couple the main transmission line (coaxial or wave guide), by means of quarter-wavelength spaced holes (or slits) of progressively increasing sizes, to an auxiliary line containing a longitudinal dielectric tube through which the water flows; this tube forms the center conductor in coaxial line and is axially centered in wave guide. Or a tapered water termination can be simply accomplished in wave guide by mounting the wave-guide transmission line at a slight angle with respect to the horizontal.

Accuracy. Reflection loss and other r-f errors can be held to insignificant values by suitable design. Power-measurement accuracy is governed primarily by errors in calibrating standards, meter reading, and thermal loss. These errors are reduced in practice to values such that accuracies of 0.25–0.35 db are commonly attained for measurements of power between 20 and 100 watts.

COMPARISON OF CALORIMETER AND BOLOMETER-ATTENUATOR POWER READINGS. A calorimeter and bolometer-directional coupler attenuator combination can be simultaneously excited by the same source; it is thus possible to compare readings directly. Both devices, when carefully designed, are capable of such high accuracy that cross-checks usually show differences no greater than the possible inaccuracy of the attenuator calibration. If the calorimeter is the more reliable it can be used to calibrate the bolometer-attenuator combination, which can then be used with equivalent accuracy and greater convenience to measure high powers.

34. ATTENUATION MEASUREMENTS

Attenuation is defined as the ratio of the input to output power levels in a network when it is excited by a matched source and terminated in a matched load. When the latter specifications are met by the measuring circuit, uncertainties in the measured quantity are avoided, but in actual use neither the source nor the load may be exactly matched. To prevent uncertainties in its action under such conditions (see Fig. 7), accurately calibrated attenuators are usually designed to present nearly matched impedances when alternate terminals are terminated with matched loads.

Attenuation is most accurately measured by insertion methods. Readings are obtained first without the unknown, then with the unknown inserted between a source and an r-f detector (or mixer). To avoid impedance interaction errors (1) the r-f detector must be well matched (by preceding it with a well-matched attenuator if necessary), (2) the source oscillator must be adequately decoupled, and (3) the source impedance must be well matched. The last condition can be assured and additionally the source may be kept stable during the measuring period by monitoring its output with a directional coupler (see Fig. 4).

Three methods for accurate attenuation measurement will be discussed: (1) comparison against the calibrated law of a bolometer power meter, (2) comparison against a calibrated i-f attenuator in a heterodyne receiver, and (3) comparison against a calibrated or known r-f attenuator.

BOLOMETER POWER METER METHOD. The source is first terminated by the bolometer detector, then by the attenuator whose output is terminated by the bolometer detector. Attenuation is calculated from the ratio of the first to second power readings on the power meter. Since only a ratio is involved, absolute powers need not be known; therefore measurement accuracy is primarily limited by (1) meter-reading accuracy, (2) bolometer detector law calibration, and (3) temperature (zero) drift. Limitation (1) is the most important in measuring low attenuations (0–3 db) for which accuracies of ± 0.05 db are practical. The accuracy of 3–13 db measurements is limited by (1) and (2) to about ± 0.1 db. By using input and output power levels between 10 and $1/2$–$1/10$ mw, attenuations of 13–20 db are measurable within ± 0.1 to 0.2 db accuracy which is controlled by all three limitations.

HETERODYNE RECEIVER METHOD. In the heterodyne receiver method the input to the second detector is kept constant by using a calibrated attenuator preceding the intermediate frequency band-pass amplifier. I-f band widths of 0.1 to 3 megacycles with center frequencies of 30 or 60 megacycles are commonly used. Attenuation is deduced from two settings of the i-f attenuator, one with and one without the unknown between the source and the mixer. Differential frequency stability requirements can be met by incorporating an automatic frequency control circuit, or, more simply, they can be materially reduced by using a frequency-modulated mixer oscillator. Correct difference frequency occurs simultaneously with peak output which is displayed on an oscilloscope or a d-c meter preceded by a peak rectifier. Sweep methods permit the alternative use of video instead of i-f amplification and calibrated attenuation.

The minimum signal which is accurately discernible in the presence of noise interference, and the maximum signal on which the mixer is linear, usually bracket the maximum measurable attenuation to about 50–70 db; such high-level differences cannot be accurately measured unless high-level radiation and low-level pick-up are eliminated by carefully shielding all joints in the transmission line and r-f components. For example, oscillator tubes must be mounted in shielding containers into which power is supplied through r-f filters (reference 17). Maximum signal levels for which the mixer operates linearly can be determined by comparing its law against that of a bolometer power meter over a single or consecutive 10–13 db ranges. In the linear region a power meter, monitoring and indicating relative r-f signal levels, can also be used to calibrate or check the i-f attenuator. Attenuations between 0 and 60 db are measurable with an accuracy of ± 0.1–0.2 db with heterodyne receiver methods.

R-F ATTENUATOR METHOD. In the calibrated r-f attenuator method all questions about linearity are eliminated, since the input power to the first detector (or mixer) is held constant. Attenuation of the unknown is deduced from two settings of the r-f attenuator, one before and after insertion of the unknown.

A calibrated variable r-f attenuator may be a resistance-film type (reference 27) (one for wave guide is illustrated in Fig. 11), variable between 0 and 40 db by a precision mechanism which can be capable of a combined setting and reading accuracy of ± 0.1 db. Such attenuators must be calibrated and should be checked periodically by some other, more fundamental method, which may introduce an additional error of ± 0.1 db. However, the importance of this lack of accuracy is often outweighed by considerations of the convenience inherent in (1) measurement of unknown attenuation by r-f attenuator comparison methods, and (2) use of resistance-film attenuators in them.

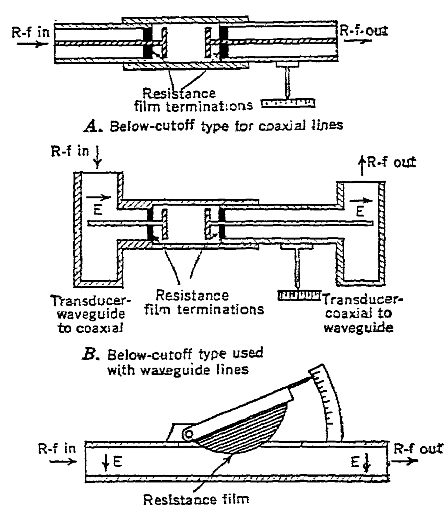

FIG. 11. Variable Attenuators

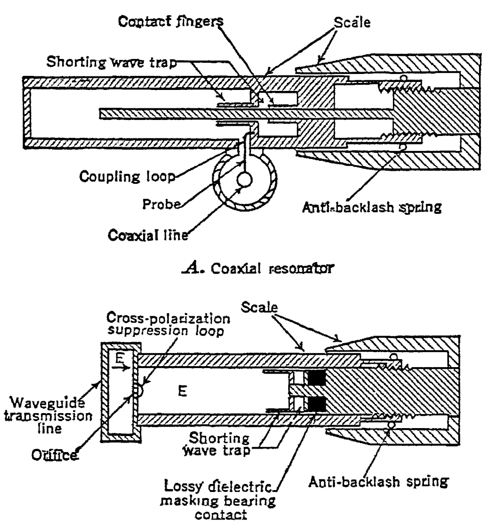
The most stable variable attenuator standards are of the wave-guide-below-cutoff type, and these are the only types for which incremental attenuation ratios can be calculated in advance (references 21 and 15). Measurement of unknown attenuation by comparison against such an attenuator is therefore a fundamental method. Unfortunately the minimum loss, above which the attenuation law is calculable without uncertainty, is around 20–30 db and may be higher if input and output impedances are corrected by using masking attenuation (reference 27). Below-cutoff attenuators therefore require the use of high-sensitivity indicators which may be (1) heterodyne receivers or (2) simply low-frequency band-pass amplifier detectors for which the signal must be amplitude modulated. The noise level may be higher in the latter system, but it is more conveniently used since only one r-f signal source is required. Accuracy is primarily limited by (1) imperfections in the attenuator mechanism, (2) indicator time stability, and (3) impedance interaction. In practice these factors have been controlled sufficiently well to allow ±0.2 db accuracy for 0–40 db attenuation measurements.

35. FREQUENCY MEASUREMENTS

Two general methods can be used to measure frequency: (1) direct comparison with harmonics of a known frequency source (reference 22) (heterodyne frequency meter method), and (2) resonance in a tunable resonator (wavemeter method). Except where the highest accuracy is needed, method (2) is the more practical since measurements can be made quickly and with the minimum of equipment. A transmission line propagating the unknown frequency is coupled to the resonator which is adjusted to resonate at that frequency; resonance is indicated by the response of a detector of relative power level in a load which terminates the transmission line.

Transmission-line resonators can be constructed to be self-calibrating by incorporating enough linear motion so that the positions of several resonances separated by half-wavelengths can be measured (lecher wire method). However, the calibration accuracy is only about 1 part in 10^3. The more accurate practice is to incorporate just enough travel to cover the desired frequency band and to calibrate the resonator by method (1) above; in this manner absolute accuracies of 1 part in 10^4 can be obtained.

RESONATORS. Resonators can be divided into two general classes: (1) resonant transmission lines (coaxial or wave guide), and (2) resonant cavities. Resonant transmission lines are shorted at one end and tuned by adjusting the line length to the other end where it is open or short-circuited. Resonant cavities are tuned by adjusting a reactance (physical discontinuity) in the electromagnetic field. On transmission-line resonators the calibrated line length changes almost linearly with transmission-line wavelength (reference 1); one specific type of cavity resonator, really a hybrid combination of TMO10 cavity and coaxial line, can be constructed to have a nearly linear calibration versus frequency over a band width as great as 12 per cent (reference 24).



B. TE11 mode resonator

FIG. 12. Wavemeter Resonators

Table 4 illustrates underlying requirements to be met for accurate frequency measurement by listing the general characteristics of two of the simplest types of transmission-line resonators (Fig. 12). These resonators are designed for approximately optimum performance when diameters are limited so that only the dominant mode (reference 1) (Section 7) can propagate. Coaxial-line resonators are generally satisfactory in the 1500–10,000 megacycle range; wave-guide resonators are superior in the 10,000–25,000 megacycle range where the Q of coaxial-line resonators become too low. In this latter range wave-guide resonators using the TE01 mode and special mode suppression techniques can be used to attain higher realizable Q's (see Section 7), but the advantage will be slight unless corresponding improvements can be introduced to reduce errors caused by imperfections in the tuning mechanism.

WAVEMETERS. The combination of a resonator coupled to a section of transmission line (to which an unknown frequency source and a detector can be coupled) will be designated as a wavemeter. Wavemeters are classified according to the way the resonator tuning affects transmission: (1) transmission type, and (2) suppression type. For the first type, the resonator must contain two orifices, probes, or loops, which allow the resonator to be connected in tandem with the transmission line; at resonance, power is transmitted through the resonator, and resonance is indicated by a maximum response on the indicator. The second type employs a single orifice, probe, or loop, to couple the resonator's impedance into the transmission line. The coupled impedance tends to suppress the resonant frequency which is indicated by a minimum response on the detector.

Table 4. Typical Wavemeter Characteristics

Transmission-type wavemeters are not favored for general frequency measurement, primarily as a result of the characteristic lack of energy transmission unless the tuning is adjusted for near-resonance. Failing to find a response on the detector, the operator is faced with uncertainty as to the adequacy of the power output of the source or the sensitivity of the detector, and this is especially troublesome if either or both must also be tuned. A suppression type is capable of just as accurate frequency measurements, and it is more convenient to use.

FREQUENCY MEASUREMENT WITH SUPPRESSION-TYPE WAVEMETERS. The simplest arrangement for measuring frequency on a transmission line is that shown in Fig. 13*A*. In the process of measuring frequency the impedance to the source is altered, and this may change its frequency unless avoided by keeping adequate attenuation between the oscillator and wavemeter. Normal operating conditions are restored by detuning the resonator. In good designs a detuned wavemeter should not create a *VSWR* in excess of 1.1. This circuit finds a wide application where only a spot check on the frequency of low-power sources is needed. Figure 13*B* shows an arrangement for continuously monitoring frequency with a negligible disturbance of energy level and impedance conditions in the main transmission line. In some cases it may be more practical to couple the auxiliary to the main transmission line by means of a single orifice, probe, or loop, but a directional coupler is preferred because less masking attenuation is needed for the wavemeter to operate out of a matched impedance, a condition for which it is calibrated.

Wavemeters should be calibrated and operated only in nearly matched circuits because reactances introduced by the source, or load, or both, change the frequency of minimum response. Using the lumped-element equivalent circuits in Fig. 14 for analysis, the magnitude of frequency change can be estimated from: $8\Delta f_z Q_{ab} = f(B_s + B_l)$, where the mismatched source and load introduce impedances having normalized susceptance components B_s and B_l at the plane of the resonator coupling. By using masking attenuators wherever necessary, it is usually practical to limit both the source and load impedance mismatch to 1.2 *VSWR*; highest value for $(B_s + B_l) = 0.4$. The errors in Table 4 were computed on this assumption and on the assumption that the wavemeter was calibrated in a perfectly matched transmission line.

The mechanical system used for tuning and indicating the resonant frequency contains potential sources of predominant error. The error in interpreting resonant frequency from a scale reading can be estimated from: $\Delta f_m = \pm M\Delta l$, where M is the rate of change of resonant frequency with tuning plunger movement in megacycles per inch and Δl is

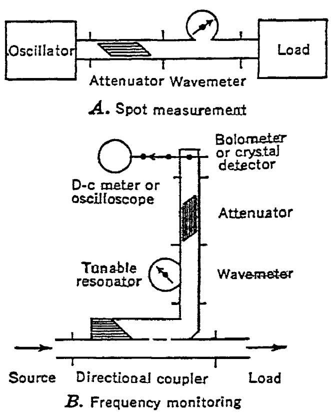

FIG. 13. Frequency Measurement Circuits

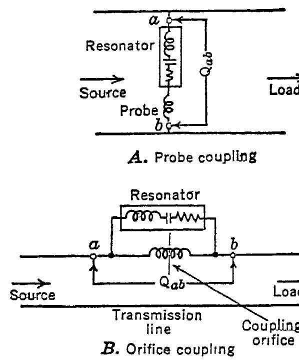

FIG. 14. Approximately Equivalent Lumped-element Circuits

the maximum possible sum of (1) backlash between the driving mechanism and the scale, (2) non-linearity in driving mechanism between calibration points, and (3) uncertainty in reading the scale. In Table 4, Δl was assumed as 0.0001 in.; even with this high order of mechanical precision the errors are large. These errors can be lowered by reducing M (band spreading). In resonant-line resonators this can be accomplished by increasing n, the number of quarter or half wavelengths. However, a compromise is usually made between tolerable error and the frequency range for which all resonant settings are unique. An alternative method for band-spreading wave-guide resonators is to operate near cut-off frequency for the resonant mode (reference 1); but this restricts band width more than the first method.

Both the resonator's Q factor and the tightness with which it is coupled to the transmission line influence the selectivity of response in the detector. Using the circuits in Fig. 14 for analysis it can be shown that the possible error in tuning the wavemeter resulting from inability to discern the absolute minimum response on a power indicator is:

$$2\Delta f_Q Q_{ab} = f\left[\frac{\Delta P}{P_m}\frac{A-1}{A^2}\right]^{1/2} \tag{3}$$

where Q_{ab} is the Q of the total impedance between terminals a–b (not the "loaded Q"); Q_{ab} is always less than the theoretical Q_1 (reference 1), and typical values for copper resonators, based upon experimental data ($A = 2$), are shown in the table. The suppression loss ratio, A, is the ratio of the power in the load when the resonator is completely detuned, P_m, to the power in the load when the resonator is tuned. The minimum discernible change in power expressed as a fraction of the detuned power is $\Delta P/P_m$. This equation is accurate only for $\Delta P/P_m$ below about 10 per cent. Assuming that P_m gives full-scale deflection and that a power change of 0.5 per cent of full scale can be discerned, Table 4 gives the possible errors for some typical resonators.

Differential Accuracy. For well-constructed wavemeters the exact calibration curve is everywhere smooth and regular. If terminating reactances remain constant the accuracy in measuring small frequency differences is primarily limited by the last two factors above.

Each one of these errors can enter twice. According to Table 4, differential measurements can be made with an accuracy no worse than about 1 part in 10^4. Accuracies of 5 in 10^5 are commonly realized in practice.

Wavemeter Calibration. Three somewhat different methods can be used to calibrate the wavemeter against low-frequency standards. In the first method the wavemeter is adjusted to resonate at a c-w frequency supplied by a local microwave oscillator; this frequency is then measured with a precision heterodyne frequency meter (accurate to 1 part in 10^6) such as shown in reference 22.

In the second method, microwave frequencies standards are harmonically generated from low-frequency standards; a calibration is then made by adjusting the frequency meter to resonate on these standards (reference 27). The response must be detected in a high-gain low-noise detector such as a double-detection receiver, since the harmonics power output is very low.

The third method is illustrated in Fig. 15, which combines advantageous features of both the above methods. The microwave oscillator is frequency modulated by a saw-tooth wave on its repeller (references 9 and 10). Its center frequency is adjusted until a low-amplitude marker oscillation appears superimposed on the rectified envelope of the oscillator output; this pip appears during the time interval for which the frequency zero-beats (2–50 kc) with a standard frequency generated by the crystal rectifier multiplier. The frequency meter is tuned until its null brackets the marker pip. Frequency-time stability of the f-m oscillator is unimportant, and the low-level output from the harmonic generator is used only for frequency marking. Additionally, a known c-w calibrating frequency can be obtained by gradually reducing the sweep to zero while keeping the marker in the center of the mode; a beat note in the head phones can be tuned in and retained by trimming adjustments on the frequency.

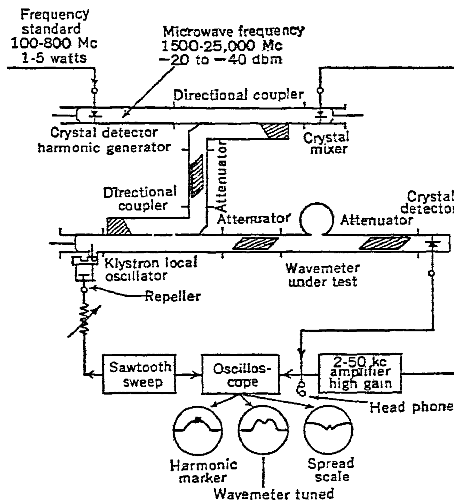

FIG. 15. Wavemeter Calibration Circuit

Conventional methods employing a master crystal-controlled oscillator and vacuum-tube multipliers can be used for generating the standard frequencies up to 800 megacycles (see p. 7-92). These frequencies are then multiplied 20 to 60 times in a silicon crystal rectifier mounted in the microwave transmission line. The harmonic number can be easily identified by a roughly calibrated or self-calibrating wavemeter. High burn-out crystals (reference 6) are recommended since they handle more input power. The microwave signal power so produced is of the order of −20 to −50 dbm. A severe requirement is therefore placed upon the noise figure of the high-gain detection system used to amplify the response to a usable amplitude.

Absolute Accuracy. By the above methods standard frequencies can be known to an accuracy of 1 part in 10^6. Adding to this the accuracy with which these standard frequencies can be transferred to the wavemeter calibration curve (limited primarily by the first two errors listed in Table 4) results in a typical absolute calibration accuracy of about 5 parts in 10^5. Then, assuming that corrections for temperature and humidity can be made with negligible error, adding all three errors in Table 4 to the calibration accuracy, a typical wavemeter can be used to measure frequency with an absolute accuracy of 1–2 parts in 10^4.

Correction for Temperature and Humidity. In order to interpret the resonant frequency from a scale reading and the calibration chart accurately, corrections must be made to allow for the effects of any change from the reference temperature and humidity conditions under which the resonator was calibrated. Two effects operate independently, and the corrections for them can be computed separately, then added algebraically: (1) temperature changes induce thermal expansion or contraction of the resonator's internal dimensions; (2) combined temperature and relative humidity changes vary the dielectric constant of the air inside unsealed resonators (reference 28).

The correction for thermal expansion of homogeneous resonators can be computed from: $\Delta f = -Cf_0\,\Delta t$, where Δf is the frequency correction to be added to the resonant frequency

f_0 indicated by the calibration chart, Δ_t is the change in temperature from that for which the calibration chart was prepared, and C is the coefficient of linear expansion for the resonator material. The correction is small for resonators made of Invar; $\Delta f/f_0$ is about $\pm 5.5 \times 10^{-7}$ for ± 1 deg fahr temperature change. For the same temperature change $\Delta f/f_0$ is about $\pm 6.6 \times 10^{-6}$ for steel resonators, and $\pm 1 \times 10^{-5}$ for brass resonators.

Corrections for the effect of dielectric constant changes are given in Table 5, which applies for unsealed resonators operated at sea-level atmosphere (reference 27). The corrections are to be algebraically added to the indicated resonant frequency (assuming that the calibration was made, or normalized, for 25 deg cent and 60 per cent relative humidity conditions). It will be observed that for ± 10 per cent change in relative humidity the correction is $\pm 1.3 \times 10^{-5}$ at 25 deg cent.

Table 5. Resonant-frequency Correction for Humidity Changes in Unsealed Resonators

50	+0.0014	−0.0031	−0.0075	−0.0119	−0.0163	−0.0209	−0.0252	−0.0295	−0.0340	112

Frequency correction, per cent to be added to indicated reading, for resonators calibrated at 25 deg cent and 60 per cent relative humidity.

Frequency Tuning. Suppression loss ratios lower than 2 increase the difficulty in finding the region of resonance when the response is indicated on a d-c meter; since meters are inherently sluggish the narrow resonant region can be easily missed. For example, the resonant region in terms of band width between the two frequencies for which the power change is half the total null change is only $\Delta f Q_{ab} = f\sqrt{A}$. On wide-range wavemeters it is often desirable to keep this resonant region relatively wide by purposely designing for only a moderate value of Q_{ab}.

High-suppression moderate-Q requirements are relatively unimportant when a-m (including pulsed) wave envelopes are displayed on an oscilloscope screen. Since oscilloscopes respond to rapid level changes a reaction can usually be discerned, even though the resonant region be tuned through rapidly. In some cases suppression-loss ratios as low as 1.1 to 1.2 may be desirable in order to avoid excessive distortion of the oscilloscopic pattern in the region of resonance.

The oscilloscope pattern in Fig. 16 illustrates the superposition of a wavemeter null ("pip") at two frequencies on the envelope of the output of a klystron oscillator which is being frequency and amplitude modulated by a sawtooth voltage on its repeller (reference 9). The "pip" can so easily be located on this type of wave that auxiliary facilities comprising an adjustable sweep voltage and a crystal detector with oscilloscope indicator provide a convenient method for quickly tuning klystron sources to required c-w frequencies (as set on the wavemeter). The initial sweep voltage is large enough to sweep through an oscillation mode completely, regardless of the initial settings of the oscillator tuning controls; tuning is adjusted until the wavemeter pip appears at the top of the mode. The sweep voltage is then gradually reduced to zero and the oscillator tuning controls are simultaneously adjusted to keep the "pip" centered on the mode.

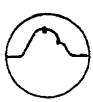

FIG. 16. Wavemeter "Pips" on Klystron Mode

SIGNAL GENERATORS AND POWER MEASUREMENT

By F. J. Gaffney

A signal generator is a source of alternating voltage, calibrated in frequency and voltage (or power output into a specified load), and with good modulation characteristics, and carefully shielded. Units are commercially available which collectively cover frequency ranges from audio to microwave frequencies. Designs are, in general, made as broad band as the limitations of oscillator-tube and power-output calibration devices (including the output attenuator) will allow. Problems encountered in the design of signal generators are: (1) the design of stable oscillator circuits, (2) the design of systems of modulation, (3) output voltage or power standardization, (4) attenuator design, (5) shielding.

36. OSCILLATORS FOR SIGNAL GENERATOR USE

Signal generator oscillators are designed for maximum frequency stability with temperature and line voltage. Wherever possible it is desirable to load the oscillator lightly. For this reason it is advantageous at some frequencies to employ buffer amplifiers which feed the output circuits rather than to feed these circuits directly from the signal generator oscillator itself.

Tubes and Circuits. Any oscillator consists essentially of a tuned amplifier with sufficient positive feedback to supply the grid losses. The frequency stability depends on the frequency shift necessary to restore proper phase in the grid circuit when the tube characteristics change as the result of line voltage, thermal effects, etc. This frequency shift is a function of the Q of the tuned circuit employed, of the feedback system used, and of the method of coupling to the tube.

AUDIO-FREQUENCY OSCILLATORS. For the range from a few cycles to 20 kc or more, various forms of rC oscillators have proved advantageous. This type of oscillator is essentially an untuned amplifier with an rC filter providing the tuned feedback. The filter may be of the twin T or Wien bridge type. A diagram of the latter is shown in Fig. 1.

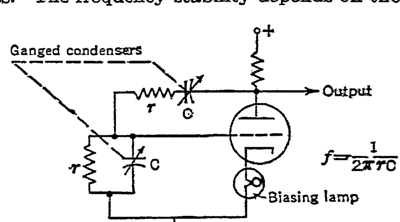

FIG. 1. Wien Bridge Oscillator

The purity of waveform depends on the sharpness of the filter, which in turn depends on the tracking of the tuning condensers. Means are usually incorporated for providing an automatic bias on the oscillator tube to insure class A operation as the oscillator output changes over the frequency band. This can take the form of a non-linear resistance such as a tungsten lamp in the cathode circuit of the oscillator. This type of oscillator if properly designed can be made extremely stable and pure in waveform. One disadvantage is the inability of a single tuning condenser to cover a large frequency range. For this reason a step switch is usually provided which switches the resistances in the circuit to provide multiple ranges.

For wider-range low-frequency oscillators (from a few cycles to several megacycles per second) beat-frequency oscillators may be used. A block diagram of such an oscillator is shown in Fig. 2. It consists essentially of two r-f oscillators, one fixed and one variable,

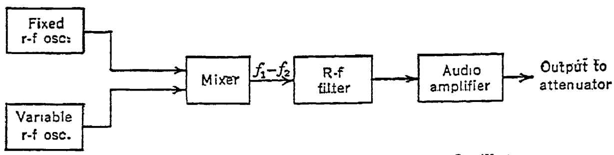

FIG. 2. Block Diagram of Beat Frequency Oscillator

which feed a mixer tube. The difference frequency between the r-f oscillators is then fed through an r-f filter to an audio amplifier. This type of circuit has the advantage that a very large frequency range can be covered with small changes in the frequency of the variable r-f oscillator. Its main disadvantage is that the audio frequency is the difference between two radio frequencies so that a small percentage variation in one of these frequencies will produce a relatively large variation in the output frequency. However, both r-f oscillators can be designed so as to be very similar in construction, and under these conditions they have a tendency to drift together so as to minimize the drift in the audio frequency. A serious problem which exists in the design of this type of oscillator is concerned with spurious outputs produced by the beating of harmonics of the r-f oscillators. These effects can be minimized by utilizing pure r-f waveforms, by the use of suitable filters between r-f and mixer stages, and by careful mixer design for large signal mixing.

RADIO-FREQUENCY OSCILLATORS. For the range of frequencies up to about 100 megacycles per second, conventional lumped constant circuits may be used. Several types of circuits such as those described in Section 7 may be employed. In order to obtain good frequency stability, either impedance-stabilized oscillators or oscillators of the electron-coupled type should be used. With the latter type of oscillator, frequency variation depends on the ratio of the screen-grid voltage to the plate voltage, and for some value of this ratio the frequency variation is extremely small with variations in plate voltage. The electron-coupled oscillator, though good from the standpoint of stability, produces a poor waveform which contains many harmonics. Care must therefore be taken in the use of such an oscillator to insure that the harmonic content does not affect the power-measuring circuit or the receiver being tested. The frequency stability of all types of oscillators is improved by regulation of the B voltage. Some frequency instability can be produced by variation in cathode heater voltage, but this is seldom compensated for in practical design. Frequency stability with variation in ambient temperature is accomplished through careful design of the tuned circuit of the oscillator. Coil forms should be wound on a material having a very low coefficient of expansion, such as Vicor. Special attention must be paid to the design of the variable condenser to minimize dimensional changes with temperature.

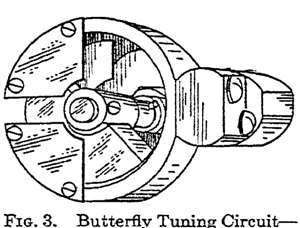

FIG. 3. Butterfly Tuning Circuit—400 to 1200 megacycles per second (Courtesy of General Radio Co.)

At frequencies above 100 megacycles per second considerable difficulty is encountered in the use of conventional lumped circuits. The losses in such circuits become excessive at these frequencies, and the tuning range becomes small, since, as the inductance is decreased to obtain higher frequencies, the tube and wiring capacitances become a larger proportion of the total allowable capacitance. One solution to this problem has been in the use of circuits of the butterfly type such as that shown in Fig. 3. Here the inductance and capacitance are varied simultaneously. This has the effect of increasing the tuning range and simultaneously maintaining the L/C ratio. Such circuits have been built for frequencies up to 2000 megacycles per second. At frequencies above 1000 megacycles per second, however, the losses are too great for practical oscillator applications.

Another approach to the problem of obtaining tuned circuits at high frequencies consists in the use of resonant sections of transmission line or in the use of cavity-type resonators. Here, radiation losses are eliminated and the distributed nature of the circuit allows currents to flow over larger areas, thus permitting low copper losses. For a lossless transmission line length l, short-circuited at the far end, the input impedance z_{in} is given by:

$$z_{in} = z_0 \tan \frac{2\pi l}{\lambda} \tag{1}$$

where z_0 = characteristic impedance of the line and λ = wavelength.

Thus, if $l = \lambda/4$, $z = \infty$. Actually, owing to losses, transmission lines dissipate energy and have a Q factor which is defined in terms of band width as in a lumped constant circuit. Transmission line Q is approximately given by:

$$Q = \frac{2\pi f_0 z_0}{rc} \tag{2}$$

where f_0 = frequency of resonance (cycles per second), z_0 = characteristic impedance = $\sqrt{L/C}$ (ohms), r = resistance per unit length (ohms/meter), and c = velocity of light (meters per second).

The input impedance of a quarter wavelength short-circuited line is then approximately given by:

$$z_{in} = z_0 Q$$

In the equation for Q, both z_0 and r vary with the dimensions of the line. For maximum Q there exists an optimum diameter ratio for coaxial lines (for conductors of the same resistivity) and an optimum ratio of spacing to the diameter of the conductors for parallel wire lines. Letting this ratio be b/a for the two cases, one value of b/a gives maximum Q and a second value gives maximum input impedance. The values, together with the corresponding characteristic impedances are given in the table.

	Coaxial Lines		Parallel Wire Lines	
	b/a	z_0	b/a	z_0
Max. Q........	3.6	76.8	4.0	851.
Max. z........	9.2	133.1	8.0	1934.

With b/a constant, both Q and z increase linearly with b. Such a line can then be used as an antiresonant circuit, with the resonance frequency determined by the line length. Actually the shapes of the curves of reactance and resistance as a function of frequency are not identical to those of lumped constant circuits but are quite similar near the resonant frequency. Parallel wire transmission lines, because of their simplicity of construction, are sometimes used in experimental oscillators, but coaxial transmission lines are more commonly used in signal generator applications because of their lower losses (the radiation loss being zero) and self-shielding construction. The only difficulty with such resonant lines is in the physical lengths required and in the mechanical difficulties with sliding contacts. For a frequency of 100 megacycles per second, for instance, a quarter-wavelength transmission line would have a length of 75 cm. The line may, however, be artificially shortened by the use of a fixed condenser across its input terminals.

Vacuum tubes designed for low-frequency applications fail at higher frequencies because of losses, limitations due to input and output capacitances, and transit time effects. To minimize these defects, special tubes have been designed for the higher-frequency ranges. By making the tube elements very small, spacings between elements can also be made small without the introduction of excessive interelectrode capacitances. Lead inductances may be minimized by bringing out more than one lead from each electrode as in some types of high-frequency acorn tubes.

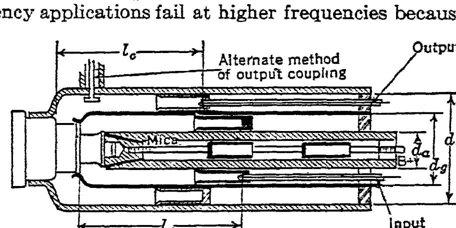

FIG. 4. Typical Double-concentric-cavity Circuit (Courtesy of General Electric Co.)

A better scheme is that exemplified by tubes of the 2C40 type which utilize disk seal construction to reduce lead inductances to a minimum. This type of oscillator tube lends itself particularly well to incorporation into a coaxial-line oscillator circuit. One such design showing a tuned plate-tuned grid oscillator is shown in Fig. 4. Owing to the difference in end effects and to the capacitive loading contributed by the tube elements, it is usually necessary to move the tuning plungers at a different rate. This causes some difficulty with mechanical tracking of the two cavities.

An alternative design known as a reentrant oscillator is shown in Fig. 5. This type of oscillator may be controlled by means of a single tuning plunger but will operate satisfactorily only over a relatively narrow frequency band. Oscillators using this type of circuit with a 2C40 triode tube have been made for frequencies as high as 3000 megacycles per second. Experimental tubes have been made to oscillate in this type of circuit at even higher frequencies. Because of the close grid cathode spacing a considerable frequency variation may be produced by variations of the tube heater voltage.

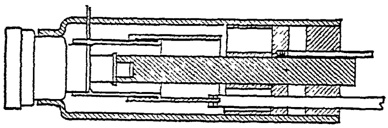

FIG. 5. Method for Tuning Re-entrant Oscillator Circuit (Courtesy of General Electric Co.)

At frequencies above 2000 megacycles per second, velocity variation tubes become useful. In this type of oscillator tube transit time is utilized to provide bunching of the electrons in a drift space. The efficiency of this type of oscillator is low and the frequency stability is relatively poor. No upper frequency limit exists for oscillators of this type except that imposed by problems of physical construction. This limitation occurs somewhere in the region of 60,000 megacycles per second. Cavity resonators which may either be external to the tube or integral with it are utilized with this type of oscillator. The type of cavity resonator used is one which develops maximum voltage across the bunching grids in the tube.

The type of velocity variation tube known as a reflex oscillator is most convenient for signal generator applications. An outline diagram of this type is shown in Fig. 6. In this tube the electron stream is velocity modulated by the bunching grids. The electrons then drift in a space between the bunching grids and a negatively charged reflector which turns them around and causes bunches to arrive again at the bunching grids in such phase as to deliver energy to the cavity resonator of which the bunching grids form a part. The resonant frequency of such an oscillator may be changed by varying the cavity dimensions. Alternatively, the frequency may be changed by changing the capacitance between the buncher grids. The latter method requires that the tube be built with a flexible diaphragm since the grids are of course in an evacuated space. The realizable tuning range with this type of tuning is only about 20 per cent. This design does, however, possess the advantage that the tube and the circuit are self-contained and troubles with sliding contacts are eliminated.

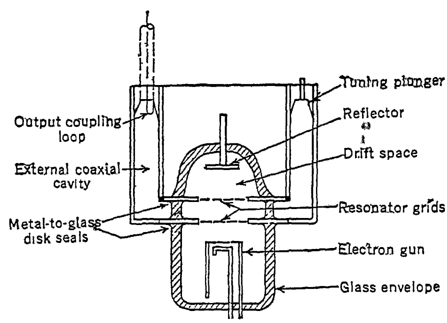

FIG. 6. Reflex Type Velocity Variation Oscillator

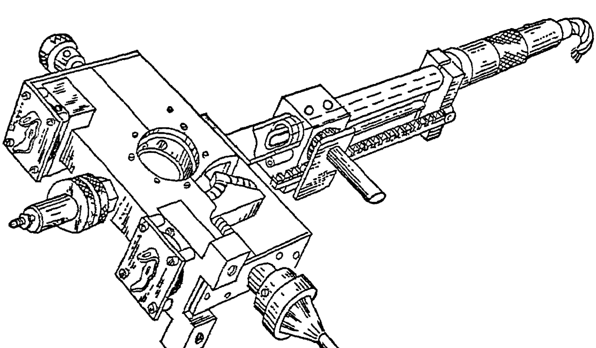

FIG. 7. TM-mode Cavity for Reflex Velocity Variation Oscillator

By bringing the bunching grids out through disk seals in a glass envelope, an external cavity may be used with this type of tube. Cavities of both coaxial mode and the TM mode have been employed successfully. A cavity of the coaxial-mode type is shown in Fig. 6; Fig. 7 shows an outline drawing of the TM-mode cavity. With the coaxial-type cavity frequency ranges of better than 2 to 1 may be achieved. Care is again necessary in the construction of tuning plungers so as to make good contact over the tuning range. In order to minimize rubbing contact, it is possible to design choke-type contacts which are themselves resonant sections of transmission lines.

37. MODULATION OF SIGNAL GENERATORS

In order to test the detection characteristics of receivers and to supply a signal that can be amplified by audio amplifier methods, signal generators are usually equipped with means for modulating the r-f voltage output. Several types of modulation are used, depending on the types of equipment with which the signal generator is most likely to be employed. Signal generators for use in the a-m broadcast band, for instance, are provided with amplitude modulation, and those for use in testing f-m receivers are frequency modulated. It is generally desirable to limit the modulation to one type and to provide means of reducing unwanted types of modulation.

AMPLITUDE MODULATION. Both the impedance-stabilized oscillator and the electron-coupled oscillator are susceptible to plate modulation with little accompanying frequency modulation. In the impedance-stabilized oscillator, the frequency is independent of applied plate voltage over a wide range if the proper value of stabilizing impedance is used. Since signal generator oscillators are tuned over wide frequency ranges, however, it is necessary to track the stabilizing impedance with the main frequency control if satisfactory performance is to be obtained. In the Hartley oscillator, the stabilizing impedance is a condenser for both the grid and plate stabilization types, and this condenser must be kept proportional to the total value of tuning condenser as the latter is varied. Figure 8 is a diagram showing this type of oscillator with plate modulation.

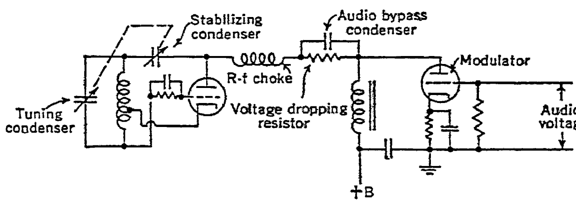

FIG. 8. Modulation of Impedance Stabilized Oscillator

The audio power output from the modulator tube must be about 3 times the r-f power from the oscillator if 100 per cent modulation is to be obtained. This can be accomplished by means of a voltage dropping resistor between the plates of the r-f and modulator tubes having a value such that the plate potential of the r-f tube is about 70 per cent that of the modulator. This resistor must be adequately bypassed for the lowest audio frequency employed. The time constant of the self-biasing circuit in the grid of the r-f oscillator must be such as to be able to follow the highest modulation frequency if the same peak audio voltage is to provide the same percentage modulation of the carrier.

The electron-coupled oscillator circuit depends for its frequency stability on the maintaining of a fixed ratio for plate and screen voltages. This is best accomplished by feeding the screen from a voltage divider between plate and ground of sufficiently low resistance that the screen voltage is invariant with screen current. The screen must be bypassed with a condenser having low impedance to the r-f voltage but high impedance to the modulating voltage. As in the impedance-stabilized oscillator, a dropping resistance must be employed between the plates of the r-f and modulator tubes if 100 per cent modulation is to be obtained. A possible variation, of course, is to supply the tubes from different taps on a power supply and to couple the modulator to the r-f oscillator by means of a transformer. A circuit diagram illustrating the former scheme is shown in Fig. 9, and the latter alternative is shown in Fig. 10. This eliminates the need of a dropping

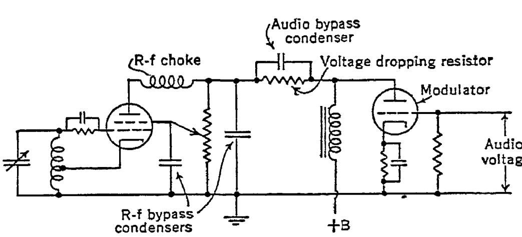

FIG. 9. Direct Coupled Modulation of Electron Coupled Oscillator

resistor but requires a tapped power supply voltage and a transformer of flat response over the audio band width used. Where extreme freedom from f-m effects is desired, an r-f amplifier is modulated rather than the r-f oscillator. Under these conditions, the r-f oscillator works at constant potential and is lightly loaded. This arrangement also makes the oscillator frequency stable with changes in loading of the output attenuator. The only disadvantage of the scheme is concerned with the necessity for providing a tuned amplifier which is ganged with the r-f oscillator. The increase in stability obtained, however, is sufficiently great to warrant the use of this method with signal generators of the precision type.

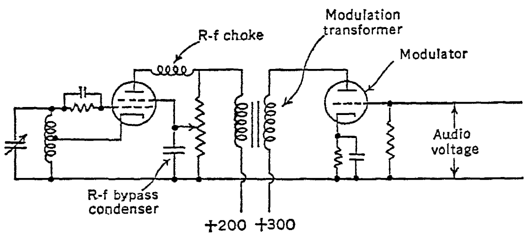

FIG. 10. Transformer Coupled Modulation of Electron Coupled Oscillator

Most signal generators for use in testing broadcast receivers are equipped with means of modulating at 400 cycles, this frequency having been standardized for receiver testing. Usually, provision is also made for modulation by means of an external oscillator operating at any desired frequency in the audio range. If suitable precautions have been taken in choosing the time constants of the grid leak and condenser biasing system and of the plate dropping networks, per cent modulation may be calculated by impressing various d-c voltages on the plate of the r-f oscillator and measuring the variation in r-f output by means of a vacuum-tube voltmeter or other method. A meter which measures the impressed audio voltage may then be calibrated in terms of per cent modulation. Various types of a-c meters have been used for this purpose such as thermocouple, vacuum-tube voltmeter, and rectifier-type meters. If other than sine wave modulation is externally applied, the indication of such meters must be corrected accordingly.

FREQUENCY MODULATION. For use in visual alignment of wide-band filters as well as for testing frequency-modulation receivers, a frequency-modulation generator is often required. Several methods for varying the radio frequency at an audio rate have been employed. The simplest of these consists of a rotating trimmer condenser, in parallel with the oscillator tank, mounted on the shaft of a small motor. This scheme allows wide frequency variation. It suffers, however, from several defects, among them being troubles encountered from vibration, contact troubles if slip rings are used for connection, variation in amount of frequency swing as the center frequency is varied, and production of undesired amplitude modulation. The audio waveform and frequency of such a device are usually fixed. A similar scheme makes use of a vibrating rather than a rotating plate. This allows modulation at higher audio frequencies and the frequency may be more readily varied. The obtainable frequency sweep is much smaller, however, and a frequency multiplier scheme must usually be employed to obtain the required sweep in the r-f output frequency.

A method which is more complex but considerably more versatile makes use of a reactance tube modulator. The frequency modulation obtainable with this method without large accompanying amplitude modulation is small, and a frequency multiplier scheme must be employed. To eliminate the necessity of tuning the multiplier stages, a heterodyne system such as that shown in Fig. 11 is usually employed.

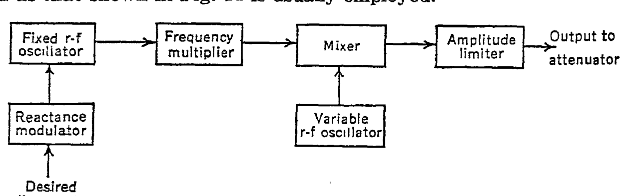

FIG. 11. Constant Deviation Frequency Modulator

With such a system, the frequency swing of the output frequency is independent of the center frequency. A typical generator of this type produces a frequency swing of over a megacycle per second at center frequencies from 60 to 120 megacycles per second.

At microwave frequencies, where velocity modulation tubes are usually employed, frequency modulation can readily be accomplished by applying the modulation signal to the reflector of a reflex-type oscillator. At 3000 megacycles per second, for example, a frequency swing of approximately 30 megacycles per second can be obtained with accompanying amplitude modulation of approximately 50 per cent. Frequency swings of 4 or 5 megacycles per second can be obtained with negligible amplitude modulation.

PULSE MODULATION. For testing radar, blind landing, and similar systems, pulse-modulated generators are required.

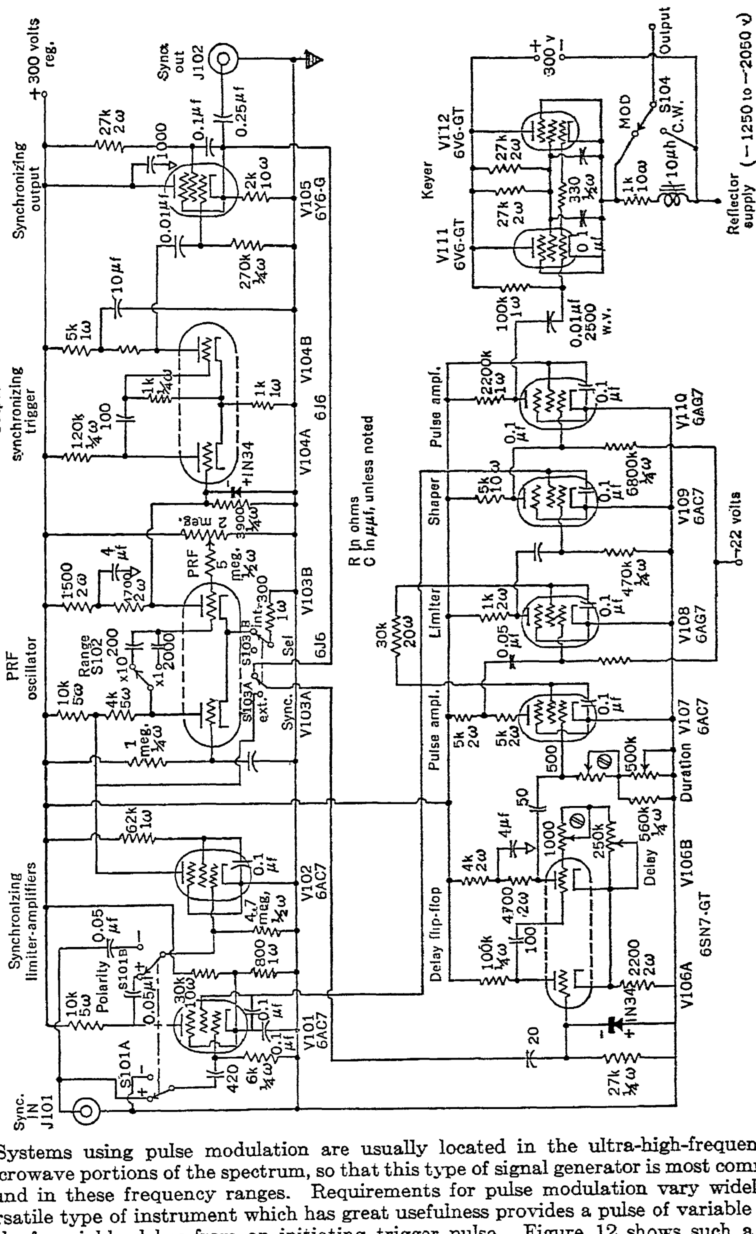

FIG. 12. Pulse Modulator

Systems using pulse modulation are usually located in the ultra-high-frequency or microwave portions of the spectrum, so that this type of signal generator is most commonly found in these frequency ranges. Requirements for pulse modulation vary widely. A versatile type of instrument which has great usefulness provides a pulse of variable width and of variable delay from an initiating trigger pulse. Figure 12 shows such a pulse modulator designed to operate with a velocity variation oscillator. The circuit is designed to operate either with an external trigger voltage applied at the *SYNC IN* jack (J-101) or with its own synchronizing signal developed by the *PRF* oscillator. In the latter case the forward edge of the square pulse produced by the *PRF* multivibrator V-103 is differentiated in the grid circuit of the output synchronizing trigger amplifier V-104 so as to produce a short pulse in the output of this tube. This pulse is then fed to a cathode follower output stage which delivers a positive synchronizing trigger from J-102. The output of either the external synchronizing pulse or the self-generated synchronizing pulse is selected by switch S103-A and fed to the delay multivibrator V-106. The trailing edge of the pulse produced in this multivibrator is differentiated in the grid circuit of the pulse amplifier tube V-107. The negative pulse so produced drives V-107 far below cutoff, and the time required to reach the conducting state again is determined by the time constant of the differentiating circuit in the grid of the pulse amplifier stage. This pulse is then squared and amplified in V-108, V-109, and V-110, and delivered to the keyer V-111 and V-112. The cathode return of the keyer tube is connected to the normal reflector supply voltage for the velocity variation tube, which may be adjusted to the correct value for proper operation of the tube when the *MOD-CW* switch is in the *CW* position. With the switch then thrown to the *MOD* position, and in the absence of a pulse, the reflector potential is such as to preclude oscillation. During the pulse, however, the reflector voltage is restored momentarily to its previous value. Pulsed operation of the velocity variation tube is thus achieved. The circuit is designed to operate with pulse recurrence rates from 50 to 5000 pps with pulses delayed from the trigger pulse from 1 microsecond to 100 microseconds, and having widths variable from 0.5 to 30 microseconds.

In using such pulse modulation systems, care must be exercised in assuring that the Q of the r-f circuit being modulated is sufficiently low to pass the sidebands generated by the pulse operation. For r-f frequencies below 100 megacycles per second this requirement is difficult to meet if stable oscillator performance is to be obtained. A method which is reasonably successful consists in pulsing an r-f amplifier driven by the oscillator. The main problem encountered here is to provide sufficient shielding so that no r-f output is present between pulses. The degree of shielding required is very great if it is desired to test sensitive receivers, and it is difficult to obtain largely because of coupling due to internal electrode capacitances of the amplifier tube. A second method consists of pulse-modulating a higher-frequency oscillator and obtaining the desired frequency by heterodyne methods. The problem in applying this technique is largely that of filtering out the undesired frequency components in the output.

38. STANDARDIZATION OF OUTPUT POWER

One of the most difficult problems in signal generator design is to determine the r-f power output accurately. One method that has seen considerable application in the lower-frequency ranges is to measure the current into a resistive output attenuator by means of a thermocouple. The quantity of interest is, of course, the output voltage (or power) into a specified load impedance. It is desired, then, to have the thermocouple read the voltage (or power) at the input to the attenuator so that, the attenuator having been calibrated, the output voltage (or power) will be known accurately for all settings of the attenuator. Several considerations enter into the validity of such a calibration.

In order that a given thermocouple reading will correspond to a given voltage or power level at the input to the attenuator, the impedance seen looking into the attenuator from the thermocouple must remain constant for all attenuator settings, assuming that the attenuator output is correctly terminated. At frequencies low enough so that the attenuator elements can be considered pure resistances, this condition can be met (see article 39). Difficulty is encountered at the higher frequencies, however, in that the attenuator input becomes reactive so that its impedance varies with frequency. Under these conditions the input current no longer bears a fixed relationship to the output voltage. At higher frequencies, the thermocouple impedance itself is also subject to variation due to the impedance presented to the heater by the couple and its associated measuring leads. The design of an output filter for the couple, which permits a very low capacitive admittance to ground at the higher frequencies, becomes very difficult.

The difficulty is minimized by using heater wires of very small diameter. Thermocouples of the separate heater type, where the couple is insulated from the heater by a small glass bead, minimize these effects. They are, in turn, sluggish in operation and less sensitive than direct-contact types. Correction must also be made for skin effect of thermocouples used at high frequencies.

At very high frequencies, where the physical distance between the thermocouple and the attenuator and between the thermocouple and the signal generator oscillator becomes an appreciable part of a wavelength, further trouble is encountered from reflections from the couple itself as seen by the signal generator oscillator and variations in the phase of such reflections as a function of frequency due to changes in the electrical lengths involved as the frequency changes. For these reasons, thermocouples have seen their greatest application in the frequency range below 10 megacycles per second although they may be used with special precautions at very much higher frequencies.

A second method for standardizing output consists in the use of a high-impedance vacuum-tube voltmeter at the input to the attenuator. It is usually desirable to have the reading of such a vacuum-tube voltmeter independent of modulation. This may be accomplished by utilizing an averaging type voltmeter circuit. This type of operation is obtained when the vacuum tube of the vacuum-tube voltmeter is operated with large voltage input and with grid leak and condenser time constant sufficiently small to allow it to follow the audio modulation. Under these conditions, the meter reads the average r-f voltage applied to its terminals. Diode voltmeters with large applied voltage may also be used; they have the advantage of maintaining calibration with tube life. It should be remembered that the power output from a modulated oscillator is proportional to $(1 + m^2/2)$, where m is the fractional modulation (per cent modulation/100), so that m must be known if it is desired to determine the power delivered to the attenuator (or effective voltage at the attenuator input).

Vacuum-tube voltmeters may be used at frequencies up to those where transit time effects reduce the rectification efficiency and thus introduce error. Transit time may be minimized by close electrode spacing and high applied voltages. Close spacing, however, introduces large interelectrode capacitance, and this may itself become a source of error. Interelectrode capacitance may be reduced by making the physical size of the electrodes small, so that an ideal tube for the purpose would have very small electrodes spaced close together. In addition, it is necessary to take special precautions to minimize the inductance of the leads to the tube electrodes. In the acorn-tube types lead inductances are sometimes minimized by bringing out two leads in parallel from each electrode. In tubes such as the 2C40, heavy cylindrical leads are employed. For acorn-type diodes, the reduction in rectification efficiency is of the order of 30 per cent at 500 megacycles per second for voltages of 0.5 volt or less. This effect, together with the change of input impedance with frequency, limits the range of usefulness of the vacuum-tube voltmeter as a power output monitor.

The deleterious effects of transit time can be minimized to some extent by substituting a crystal rectifier for a vacuum tube in a voltmeter circuit. A semiconductor such as silicon in crystalline form is embedded in a conducting material which forms one contact. The second contact is made through a tungsten whisker. The resistance between the whisker contact and the semiconductor is non-linear and may, therefore, be used to rectify an impressed alternating voltage. Though transit time in such a crystal rectifier is entirely negligible, a similar effect occurs which is due to the capacitance between the whisker contact and the crystal which may be thought of as shunting the non-linear resistance as shown in Fig. 13. Here, r_s represents the resistance of the bulk crystal between the barrier layer and the fusible metal in which the crystal is embedded, r_e represents the non-linear resistance between the whisker and the crystal, and C is the capacitance between the whisker and the crystal across the barrier layer. At high frequencies, the capacitance shunts the non-linear resistance in such a way as to reduce the rectification efficiency, producing an effect similar to that produced by transit time in tube rectifiers. With the type 1N21-B rectifier, however, this effect is small for frequencies at least as high as 1000 megacycles per second. Other disadvantages to the use of crystals exist, however, among them non-uniformity of characteristic and variation of impedance among crystals of the same type, and a change of characteristics with overload.

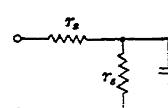

FIG. 13. Equivalent Circuit of Crystal Rectifier

For very high-frequency applications, the variation of indicated power with frequency due to variation in electrical length of the leads to the power indicator has led to the use of systems which divert a known fraction of the power from the signal generator oscillator to the power indicator. Bolometer elements are frequently used as the power-detecting devices in such a system (see article 11–33). They are sensitive detectors of r-f power, having resistance slopes of several thousand ohms per watt. For example, a 10-milliampere Littlefuse has a slope of 2800 ohms per watt, while a 5-milliampere Littlefuse has a slope of 5100 ohms per watt. Commercially available Littlefuses are often used as r-f power detectors and are quite satisfactory up to frequencies of several hundred megacycles per second. At higher frequencies, their geometry is undesirable and special bolometer elements such as that shown in Fig. 14 are employed.

The resistance-power curve of a thermistor is not accurately linear as is that of a hot-wire bolometer. This is of little importance when it is desired to monitor the r-f power at constant level but becomes important when it is desired to provide an easily calibrated indicator which will measure power over some range. The r-f impedance of a bolometer depends on its geometry as well as on its resistance. It has been found more difficult in manufacture to hold the r-f impedance of thermistor units than it is with special hot-wire bolometers.

If it is desired to operate any type of temperature-sensitive power indicator over wide ranges of ambient temperature, some form of temperature-compensating circuit must be employed. This problem becomes more acute as the sensitivity of the power indicator is increased. Temperature-sensitive elements such as those used in the power-measuring

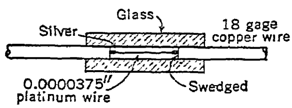

FIG. 14. Hot-wire Bolometer

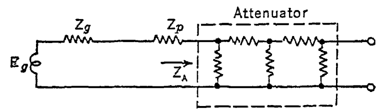

FIG. 15. Power Monitor Equivalent Circuit

circuit may be employed to accomplish the required compensation. For a direct-reading bridge circuit, two such compensating elements are, in general, used. One of these maintains the zero reading, and the other adjusts the slope of the indicator so as to maintain the correct calibration.

In the use of power indicators which absorb a fraction of the generator power, care must be taken to insure that the power split between the power indicator and the output circuit is maintained constant over the frequency band of operation.

At the lower radio frequencies where line lengths may be neglected this problem does not present serious difficulties. Here, an arrangement such as that shown in Fig. 15 may be used where the power-sensitive element is in series with the output attenuator. Here, if the line length between the power detector z_p and the output attenuator z_a can be neglected, the current in the two elements is common so that the power ratio is simply

$$\frac{P_p}{P_a} = \frac{r_e(z_p)}{r_e(z_a)} \tag{3}$$

where $r_e(z_p)$ represents the real part of the power indicator impedance.

At frequencies high enough so that the line length becomes an appreciable part of a wavelength, the current is no longer the same in the two elements and the equation holds only if the impedance of the attenuator is transformed down the line to a point close to z_p. Then, if the impedance of the attenuator is frequency dependent, changes in both the real and reactive components will affect the power split. The difficulty is overcome only by maintaining the attenuator impedance close to the characteristic impedance of the line over the frequency range.

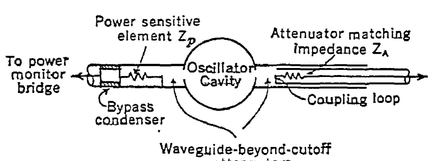

FIG. 16. Power Monitor for Cavity Oscillator

At very high frequencies, coaxial or wave-guide structures are used. One method of monitoring power from a cavity-type oscillator is shown in Fig. 16. Here the power from the oscillator is coupled through two openings in the cavity to wave-guide-beyond-cutoff attenuators which feed the power monitoring and output circuits respectively.

The power delivered to the monitor is then:

$$P_p = \left|\frac{E_p}{z_p}\right|^2 r_e(z_p) \tag{4}$$

where E_p = voltage induced in coupling loop feeding the power detector, z_p = impedance of power detector, and $r_e(z_p)$ = real part of z_p.

Similarly, the power delivered to the attenuator is given by:

$$P_A = \left|\frac{E_A}{z_A}\right|^2 r_e(z_A) \tag{5}$$

where E_A = voltage induced in coupling loop feeding the attenuator, z_A = impedance of attenuator seen looking from the loop, and $r_e(z_A)$ = real part of z_A.

The ratio of these two powers is then given by

$$\left|\frac{E_p}{E_A}\right|^2 \times \left|\frac{z_A}{z_p}\right|^2 \times \frac{r_e(z_p)}{r_e(z_A)} = \frac{P_p}{P_A} \tag{6}$$

Since the ratio E_p/E_A can be made quite constant over a wide frequency band, if symmetrical coupling to the cavity is employed, this reduces to:

$$\frac{P_p}{P_A} = K\left|\frac{z_A}{z_p}\right|^2 \times \frac{r_e(z_p)}{r_e(z_A)} \tag{7}$$

One way to make the right-hand side of this equation constant is to have both z_p and z_A equal the real characteristic impedance of the lines in which they are placed.

A similar situation obtains in wave-guide circuits where the monitor and attenuator are placed in two arms of a wavelength T and are fed from the third arm as shown in Fig. 17. Here the monitor and attenuator are effectively in series. The power split is given by

$$\frac{P_p}{P_A} = \frac{r_e(z_p)}{r_e(z_A)} \tag{8}$$

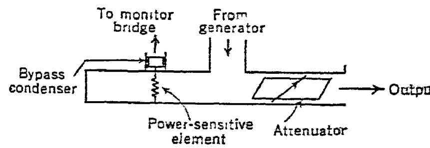

FIG. 17. Wave-guide Power Monitor

This can also be made constant by matching both attenuator and power indicator to the wave guide.

39. ATTENUATOR DESIGN

For frequencies up to about 2 megacycles per second, resistive attenuators using Ayrton Perry non-inductive wire-wound resistors may be used. In order to maintain the input and output impedance of such an attenuator constant as the attenuation is varied, iterative networks of the T or π type are used. Such a T network, designed to match without reflection the generator impedance r_g to a load resistance r_L, is shown in Fig. 18. If the generator and load are to be connected to the network without introducing reflection, r_{in} must equal r_g and r_{out} must equal r_L. The attenuation constant of such a network is defined by

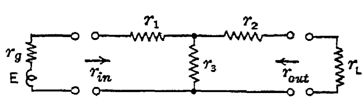

FIG. 18. T-type Attenuator

$$\frac{E_{\text{out}}}{E_{\text{in}}} = \frac{I_{\text{out}}}{I_{\text{in}}} = \varepsilon^{-\alpha} \tag{9}$$

or

$$\alpha = \ln\frac{E_{\text{out}}}{E_{\text{in}}} = \ln\frac{I_{\text{out}}}{I_{\text{in}}} \tag{10}$$

For given generator and load resistances and specified attenuation constant the elements of the network are given by:

$$r_1 = \frac{(r_g + r_L)\tanh\left(\frac{\alpha}{2}\right) + r_g - r_L}{2} \tag{11a}$$

$$r_2 = \frac{(r_g + r_L)\tanh\left(\frac{\alpha}{2}\right) - r_g + r_L}{2} \tag{11b}$$

$$r_3 = \frac{r_g + r_L}{2\sinh\alpha} \tag{11c}$$

In the special case where $r_g = r_L = r_0$, these expressions reduce to:

$$r_1 = r_2 = r_0\tanh\frac{\alpha}{2} \tag{12a}$$

$$r_3 = \frac{r_0}{\sinh\alpha} \tag{12b}$$

The unsymmetrical case is of interest in signal generators for the broadcast band since it is sometimes desired to make the output impedance sufficiently low that the voltage developed across it is independent of the impedance connected to the output terminals. The attenuation of the network may be varied and constant input and output impedances maintained if the resistances are kept in the ratio defined by the equations.

In practice, accuracy requirements and difficulty in shielding output from input make it undesirable to utilize a single T or π section for covering large ranges of attenuation.

For these reasons, a ladder-type attenuator is commonly employed. A useful form of such an attenuator is shown in Fig. 19. If K = the ratio by which the voltage across r_L is reduced in moving from one switch point to the next, the resistances r_1 and r_2 are given by:

$$r_1 = r_L\,(K - 1) \tag{13a}$$

$$r_2 = r_L\left(\frac{K}{K-1}\right) \tag{13b}$$

The input resistance r_{in} is independent of the position of the tap switch and is given by:

$$r_{\text{in}} = \frac{r_s r_L}{r_s + r_L} \tag{14}$$

where

$$r_s = \tfrac{1}{2}\,[\sqrt{r_1(r_1 + 4r_2)} + r_1]$$

Between r_L and the step attenuator, it is usually desirable to place a variable T pad attenuator of the type previously described in order to obtain a fine control. r_L may be the external load resistance into which the generator is designed to feed, or it may be made

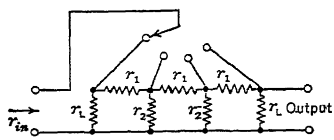

FIG. 19. Ladder-type Attenuator with Constant Input Impedance

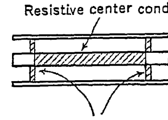

FIG. 20. Coaxial π Section

low in value and incorporated into the signal generator in which case the actual load impedance must be large compared to r_L for proper operation. For satisfactory operation, each section of the attenuator must be separately shielded and a separately shielded low-capacity switch must be employed.

For high-frequency applications, T or π sections may be built in coaxial line form as shown in Fig. 20. Units of this type may be used up to the frequency where the length of line becomes an appreciable part of a wavelength, and they have seen successful operation up to frequencies as high as 1000 megacycles per second. The resistive elements may conveniently be made of glass rods and disks coated with thin metallic films. A decade attenuator may be made by mounting several such elements in a turret arrangement.

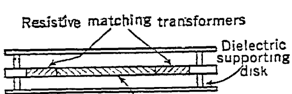

FIG. 21. Microwave Attenuator

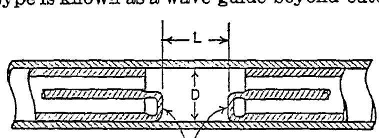
At microwave frequencies, attenuators consisting of resistive sections of coaxial line equipped with resistive matching transformers have been successfully employed. A diagram of such a unit is shown in Fig. 21.

The band width of such devices is limited by the change in attenuation with frequency and by the frequency sensitivity of the resistive matching transformers.

A type of attenuator which has seen increasing use in signal generator applications is shown in Fig. 22. This type is known as a wave-guide-beyond-cutoff attenuator and makes



$$\text{Loop coupling attenuation} = 32.0\sqrt{1 - \left(\frac{1.71D}{2}\right)^2}\ \text{db per diameter displacement of loops.}$$

$$\text{Disk coupling attenuation} = 41.8\sqrt{1 - \left(\frac{1.30D}{2}\right)^2}\ \text{db per diameter displacement of loops.}$$

FIG. 22. Waveguide-beyond-cutoff Attenuator

use of the fact that, for diameters below a critical value which depends on the frequency and mode of propagation, waves in a hollow tube suffer no phase displacement but are damped exponentially in amplitude. Inductive coupling between loops and capacitive coupling between disks in such a hollow tube may be thought of as taking place in this way. The attenuation in decibels is then linear with displacement and follows the law given in the figure for the two cases of loop and disk coupling respectively. The loop-coupled attenuator has the advantage that its rate of attenuation is lower than that of any other mode and is thus less susceptible to errors due to undesired coupling to other modes, since these die away more rapidly and become unimportant at any but the lowest attenuator settings.

At low frequencies, a coil of several turns is usually employed in order to reduce the minimum insertion loss. For low-frequency applications where the skin depth is appreciable, this effect must be taken into account since it modifies the effective diameter. This may be done by adding $2p$ to the measured diameter, where p is the skin depth. For copper, p is given by:

$$p = \frac{6.6}{\sqrt{f}} \times 10^{-3} \quad \text{cm} \tag{15}$$

where f = megacycles per second.

The input and output impedance of this type of attenuator is reactive, and it is necessary to provide resistive pads to match the generator and load. These pads contribute to the initial insertion loss, which is of the order of 25 db in practical designs. The high initial insertion loss limits the use of this type of attenuator, although it is satisfactory for many signal generator applications where the power level of an oscillator must be reduced to the noise level of a sensitive receiver.

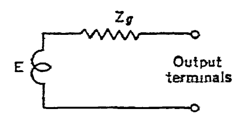


FIG. 23. Equivalent Circuit of Attenuator Output

The power delivered to a load impedance from any attenuator system can be analyzed in terms of Thévenin's theorem as shown in Fig. 23. Here z_g is the impedance seen looking into the output terminals and E is the open-circuit voltage measured at these terminals. At low frequencies, z_g is often made small compared to the load impedances with which the generator will operate so that the output voltage is essentially independent of z_L. A dummy antenna which simulates the impedance of an actual receiving antenna is then placed between the signal generator terminals and the receiver input.

At higher frequencies, line length between the signal generator and load cause considerable difficulty so that a better scheme is to make z_g equal to the characteristic impedance of the line which will be used. The load impedance is then also matched to the line so that the voltage at the load is $E/2$. If the receiver to be tested does not present an input impedance equal to the characteristic impedance of the line, it may be transformed to this impedance by means of a suitable transformer. If this is not done, an error will be introduced which can be calculated by means of the transmission-line equations.

40. SHIELDING PROBLEMS

There is usually a difference in level of the order of 100 db between the signal generator oscillator power and the attenuator output power when the generator is used for receiver testing. This makes necessary extreme precautions in the matter of shielding. The depth of penetration in a metal is defined as that depth to which the electric or magnetic field falls off to $1/\varepsilon$ of its value at the surface, where $\varepsilon = 2.718$. An attenuation of 100 db requires 11.5 skin depths. At a frequency of 1 megacycle per second, this corresponds to 0.076 cm in copper. Thus, except for very low frequencies, the thickness of the metal required is determined by mechanical rather than electrical considerations. The real problem is concerned with the bringing in of d-c leads and control shafts to the oscillator and with the necessity of providing removable covers for the shield case. Separate shielding boxes should be provided for the main units in the signal generator such as the oscillator, the power measurer, and the attenuator system. These individual shields are then enclosed in an overall shield and are preferably grounded to it at a single point to eliminate circulating currents which can induce voltages in lead filters or other output connections. Gaskets made of compressed woven metal are useful in preventing leakage from removable covers.

For low-frequency lead filters, conventional LC-type filters may be used. At higher frequencies, particular attention must be paid to the condensers used since these may, in fact, become inductive. Condensers of the button type are particularly useful for this purpose.

At frequencies above 2000 megacycles per second, lossy filters may be employed to advantage. A filter consisting of a coaxial line having powdered iron between the conductors represents one such type of filter which has seen considerable application. At 3000 megacycles per second, such a filter, 4 in. in length, can be made to have an attenuation of more than 100 db.

Control shafts may conveniently be brought into shielded generators by utilizing the wave-guide-beyond-cutoff principle and employing Bakelite shafts feeding through metal tubes which are soldered to the shielding box. A tube having an inside diameter of $^1/_4$ in. will, for instance, have an attenuation of about 100 db for each $^3/_4$ in. of length for frequencies up to 15,000 megacycles per second. Another method of feeding shafts through a shielded partition is by means of a flexible diaphragm type of coupler which solders to the shield box and which transforms a nutating motion into a rotary one in a manner which allows metallic continuity through the coupling.

41. POWER MEASUREMENT

Power measurers are of two types, one which samples the power in a transmission line between generator and load and which absorbs only a small fraction of the power being measured, and a second type which absorbs all the power being measured, in general converting it to heat. A vacuum-tube voltmeter of impedance high compared to the generator or load is an example of the former type; a bolometer or crystal power measurer terminating a transmission line is an example of the latter type.

All the types of power measurers discussed under the section on signal generators may be extended to measure higher powers through the use of attenuators appropriate to the frequency range involved. Bolometer-type power measures of the hot-wire or thermistor type are particularly adaptable to this use since they may conveniently be matched into coaxial lines. Again, broad-band designs may be evolved up to frequencies where the length of the bolometer element becomes an appreciable part of a wavelength. By means of special matching techniques, broad-band designs have been made up to frequencies of 10,000 megacycles per second.

Attenuators of resistive center conductor coaxial line using the thin metallic film on glass techniques can measure powers as great as a few watts. For higher power, lossy attenuators which can be matched over a considerable frequency range can be made by filling the space between conductors in a coaxial line with a lossy compound such as may be made with graphite or iron powder and a suitable cement binder. With proper proportions of lossy material to binder the loss per unit length can be adjusted to permit the power absorbed to be radiated adequately from the length of line used.

SECTION 12

ACOUSTICS

ACOUSTICS

THE SENSE OF HEARING

By John C. Steinberg and W. A. Munson

In the design of sound transmission and reproduction systems, consideration should be given to the physical and physiological properties of the voice and ear, and to the characteristics and psychophysiological effect of the different types of sounds that the systems are called upon to transmit and reproduce.

1. DESCRIPTION OF THE EAR

The hearing mechanism is usually divided into three parts, the outer ear, the middle ear, and the inner ear. A cross-section of the ear is shown schematically in Fig. 1.

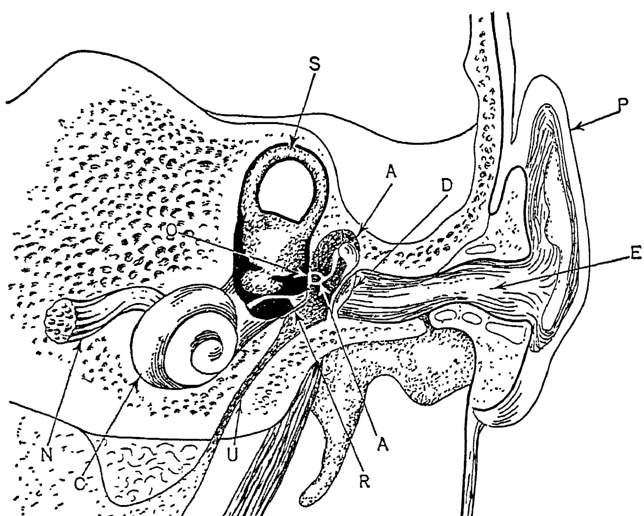

FIG. 1. Semi-schematic Section of Left Ear. *P*, pinna; *E*, ear canal; *D*, eardrum; *A*, auditory ossicles; *O*, oval window; *R*, round window; *U*, Eustachian tube; *S*, semicircular canal; *N*, auditory nerve; *C*, cochlea.

THE OUTER EAR. The ear canal (*E*) has a length of about 2.5 cm, a volume of 1.0 cu cm, and an area at the opening of 0.3 to 0.5 sq cm. The eardrum (*D*), stretched across the inner end of the canal, has a horizontal diameter of 1.0 cm, a vertical diameter of 0.8 cm, and an area of 0.6 sq cm. All these dimensions vary somewhat for different individuals.

THE MIDDLE EAR. The middle ear is separated from the outer ear canal by the eardrum. Motion of the eardrum is transmitted across the middle-ear cavity to the inner ear by means of a system of levers (*A*) called the auditory ossicles. The ossicles consist of three small bones, the malleus (hammer), attached to the eardrum, the stapes (stirrup), attached to the oval window (*O*) of the inner ear, and the incus (anvil), which is the connecting link between the malleus and stapes. The weights of the three bones are: hammer, 0.023 gram; anvil, 0.025 gram; and stirrup, 0.003 gram. The middle-ear cavity is normally filled with air maintained at atmospheric pressure by virtue of the Eustachian tube (*U*) which leads to the back part of the throat.

THE INNER EAR. The inner ear, which serves a dual purpose, is a complex labyrinth of liquid-filled passageways imbedded in the temporal bone adjacent to the middle-ear cavity. There are three semicircular canals, oriented so as to lie in three mutually perpendicular planes, and these ducts contain the nerve endings concerned with the maintenance of body equilibrium. Only one canal (*S*) is shown in Fig. 1. The cochlea (*C*) is a spiral duct containing the auditory nerve endings. In Fig. 1, it has been drawn on an enlarged scale relative to the middle and outer ears, and the bone in which the cochlea is imbedded is not shown. The mean diameter of a semicircular canal is about 1.0 cm. The cochlear spiral has a mean diameter of about 0.6 cm for the large turn at the base. As may be seen in the sectional view of Fig. 2, the cochlea is divided by flexible membranes into three canals, scala vestibuli (*V*), scala media (*M*), and scala tympani (*T*).

The auditory nerve fibers running between the cochlea and the brain number about 29,000 They terminate with complex interconnections along the basilar membrane (*B*),

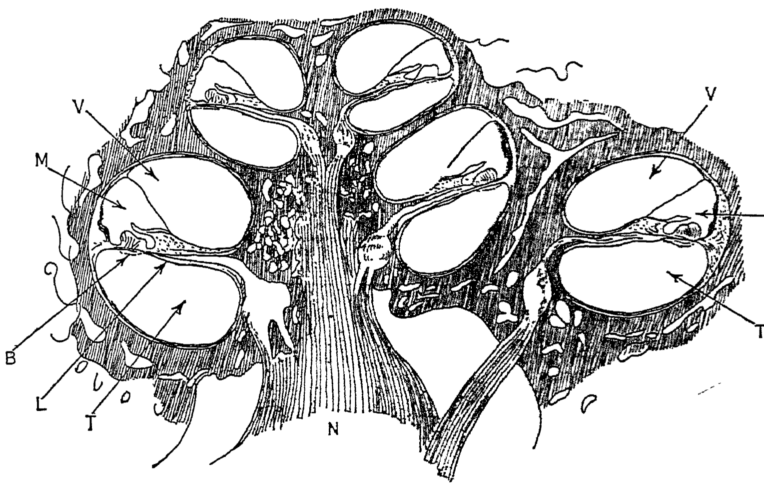

FIG. 2. Semi-diagrammatic Section of the Cochlea. (From Gray's *Anatomy*.) *B*, basilar membrane; *V*, scala vestibuli; *M*, scala media; *T*, scala tympani; *N*, cochlear nerve; *L*, lamina spiralis ossea.

which extends from the bony ledge (*L*) to the opposite wall of the cochlea, separating scala tympani and scala media. The nerve endings are associated with tiny hair cells which protrude into the liquid filling the small triangular scala media. Scala vestibuli and scala tympani are interconnected at the apex of the spiral by a small opening called the helicotrema. At the base of the spiral, scala tympani opens into the middle-ear cavity through the round window (*R*), shown in Fig. 1, but the liquid content is retained by a flexible membrane stretched across the opening. The oval window (*O*), between the middle ear and scala vestibuli, is closed by the foot of the stapes and connecting ligaments.

Excitation of the Auditory Nerves. A sound wave in the outer ear canal produces motion of the eardrum and associated ossicles which, in turn, agitate the liquid in scala vestibuli through the oval window. When the stimulus is a pure tone at a low level, this results in an excitation of a small number of the nerve endings enclosed by the adjacent scala media. When the frequency of the tone is changed, the excitation moves along the basilar membrane, engaging a different set of nerve endings. In this way the ear differentiates between tones of different pitch. When the intensity of the tone is increased, the excitation spreads out, and additional nerve endings are stimulated, but those comprising the initial group probably receive the maximum stimulation. The positions of the stimulation maxima are shown in Fig. 3 as a function of frequency.

At low frequencies the stimulation maxima are very broad and the positions are poorly defined. It may be that the pitch of low-frequency tones is sensed by the stimulation frequency as well as by its position.

NERVE CONDUCTION. Physiological research indicates that a nerve conducts on an "all-or-none" basis. The magnitude of the nerve impulse and the rate of propagation are independent of the manner of excitation. After an impulse has been transmitted by a nerve, it must recover its conducting properties before it is capable of being excited again. This recovery period lasts for a time interval of 1 to 3 milliseconds and varies somewhat with the intensity of the stimulus. Thus a nerve fiber is unable to transmit the wave form of the exciting stimulus. Excitation of the auditory nerves and conduction of neural pulses to the brain have been studied by placing a small electrode on a single auditory nerve tract of anesthetized animals and recording the potential generated. It was found that increasing the intensity of a pure tone increases the rate at which pulses are transmitted. Typical results are shown in Fig. 4. Since a maximum rate is attained when the sound level is increased about 50 db, other fibers must be involved in covering the full intensity range of the ear. It is believed that the loudness of a sound is related to the rate at which neural impulses reach the brain from all portions of the basilar membrane.

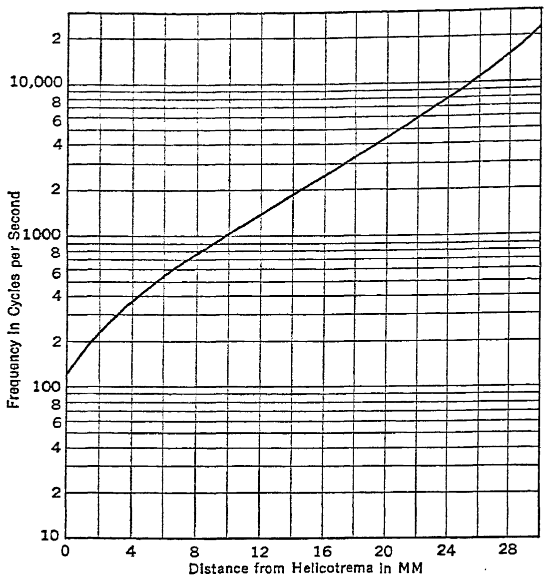

FIG. 3. Relation between Frequency of a Tone and the Position of Nerve Endings on the Basilar Membrane Which Receive Maximum Stimulation. (Steinberg.)

ACOUSTIC IMPEDANCE OF THE EAR. The acoustic impedance which an ear presents to a telephone receiver has been measured at the aperture of a receiver cap. The results depend to a large extent upon the way the cap fits the ear. Typical values are shown in Fig. 5 for the case when the cap is sealed to the ear and for the case when an air leak is present between the cap and the ear. These data are useful in receiver design, and Inglis, Gray, and Jenkins describe an artificial ear which they use for the measurement of telephone receivers. It consists of a conduit having the approximate dimensions and impedance of a typical ear canal over the important frequency range. The exposed end of the conduit is fitted with a tapered rubber seating surface on which the receiver is placed. The other end of the conduit is terminated by an acoustic network and by the diaphragm of a small condenser transmitter. The pressures developed at the transmitter diaphragm for a given voltage on a receiver placed on the artificial ear are closely equal to the pressures that would be produced by the receiver at the drum of a typical human ear.

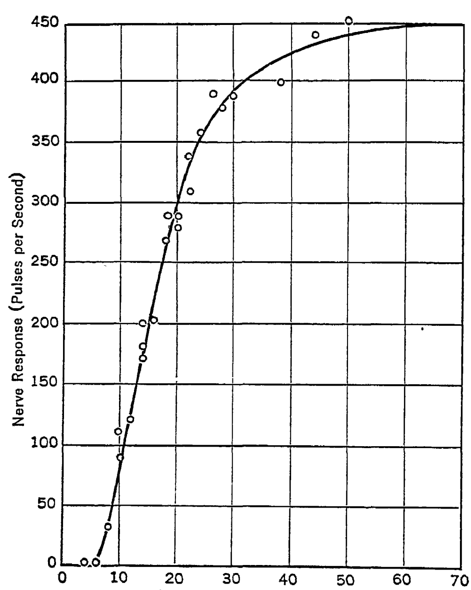

FIG. 4. Relation between Sound Intensity and Nerve Discharge Rate for a 1050-cycle Tone. (Galambos and Davis.)

NATURAL FREQUENCY AND DAMPING CONSTANT OF THE EAR. The work of Békésy indicates that the frequency with which the eardrum and ossicles vibrate when suddenly released from a displaced position is of the order of 1200 to 1500 cycles. The vibrations decay at a rate of 1200 db per sec. Davis and associates' experiments on the electrical response of the ears of cats indicate a natural frequency from 600 to 1000 cycles and a decay rate of 1000 db per sec. Their work also indicates that the time lag between the sudden application of a sound wave on the eardrum and the transmission of the impulse along the auditory nerve is of the order of 2 to 3 milliseconds. On the other hand, the sensory build-up time, e.g., the time needed for a suddenly applied steady wave to build up to a steady loudness, is of the order of 0.2 to 0.25 sec.

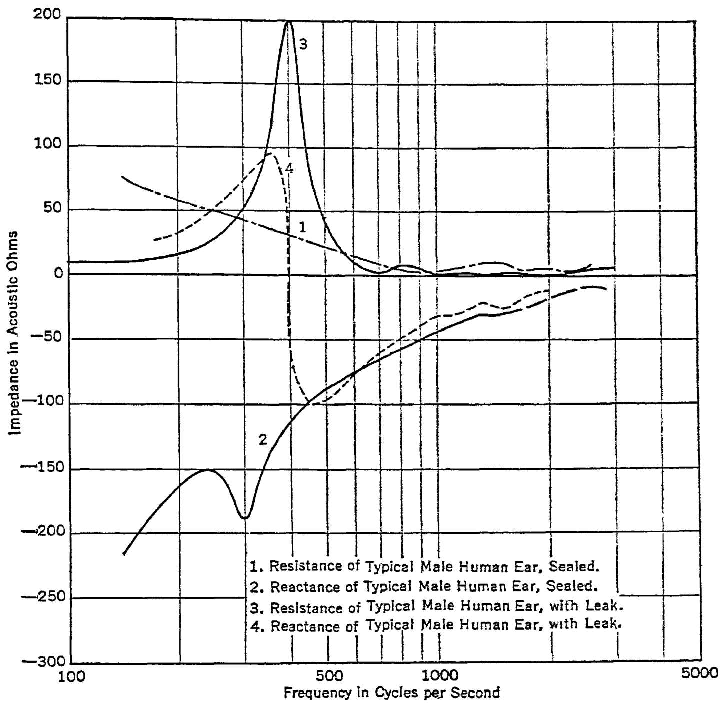

FIG. 5. Acoustic Impedance of Ears as Viewed through Aperture of Receiver Cap. (Inglis, Gray, and Jenkins.)

2. SENSITIVITY OF THE EAR

Ear sensitivity is concerned with the least intense sound that can be heard. Such a sound is said to be at the "threshold of hearing." Two classes of ear-sensitivity determinations have been reported, "minimum audible pressure" (M.A.P.) and "minimum audible field" (M.A.F.). M.A.P. is the just-audible sound pressure measured near the observer's eardrum. M.A.F. is the free field sound intensity of a plane progressive wave that is just audible to an observer facing the source and listening binaurally. The sound intensity is measured before the observer's head is inserted in the field. It is convenient to express minimum audible values in decibels from an arbitrary reference. Reference intensity has been chosen as 10^{-16} watt per square centimeter. Corresponding reference pressure at 20 deg cent and 76 cm of Hg is 2×10^{-4} dyne per square centimeter. Intensity and pressure levels are the number of decibels from the above references, respectively. Table 1 gives minimum audible values derived by Sivian and White from their own work and that of others when a small selected group of observers with excellent hearing is used.

Owing to the diffraction effect of the head and to the difference between one-ear and two-ear listening, it would be expected that M.A.P. and M.A.F. would differ considerably at high frequencies but not at low frequencies. Various possible causes of the differences shown in Table 1 at the low frequencies are discussed by Sivian and White, with the conclusion that, at the present time, a satisfactory explanation is not evident.

Table 1. Monaural Minimum Audible Pressure Levels in the Ear Canal and Binaural Minimum Audible Sound Field Intensity Levels

Frequency	60	100	200	500	1,000	2,000	5,000	10,000	15,000
M.A.P., db (Monaural)...	59	46	29	14	8	5	12	26	44
M.A.F., db (Binaural)....	45	33	19	8	3	−6	−3	11	22

BINAURAL VS. MONAURAL. Minimum audible values obtained with observers listening binaurally (two ears) are smaller on the average than those obtained with observers listening monaurally (one ear). According to Fletcher and Munson, the difference appears to be accounted for by inequalities in the sensitivities of the two ears of an observer. They report that the binaural sensitivity is practically equal to that of the better ear, and that monaural sensitivity is equal to that obtained by averaging the sensitivities of both ears. Figure 6 gives the differences between the sensitivity of the better

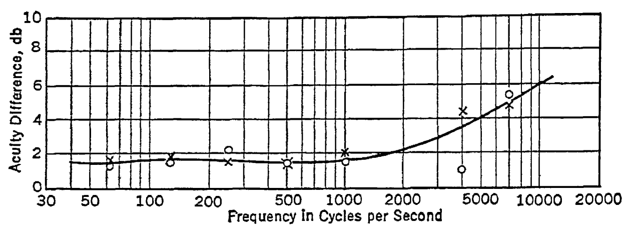

FIG. 6. Difference between the Sensitivity of the Better Ear and the Average of Both Ears. (Fletcher and Munson.)

ear and the average of both ears, based on the audiograms of 80 persons of normal hearing. It gives a means of converting binaural M.A.F. into monaural M.A.F.

VARIATION WITH DIRECTION. The values of M.A.F. given in Table 1 are for an observer facing the source, i.e., for a progressive wave whose wave front is vertical and whose direction is normal to a line joining the observer's ears. Owing to diffraction effects of the head, the ear is directive and generally hears best when the open ear is turned toward the source. The directivity of hearing as reported by Sivian and White is given in Fig. 7. Directivity is expressed as the variation in monaural M.A.F. with the azimuth of the vertical wave front: 0° corresponds to the observer facing the source; +90° corresponds to the open ear toward the source. The variation is expressed in decibels from the M.A.F. at 0°. A positive value of directivity for any angle means that the ear is more sensitive at that angle than at 0°. By means of the directivity data, Sivian and White have computed the sensitivity of the ear for the case when an observer is exposed to a diffuse sound field, such that sound waves of equal amplitudes and random phase angles are equally probable from all angles. Their results are shown in Table 2.

Table 2. Binaural Minimum Audible Sound Field (Random Horizontal Incidence).
(Sivian and White)

Frequency	60	100	200	500	1,000	2,000	5,000	10,000	15,000
Binaural M.A.F., db (random horizontal incidence)............	45	33	19	6	−1	−7	−7	2	18

POSSIBLE LOWER LIMITS OF SENSITIVITY. On certain assumptions, Sivian and White calculate that the intensity level of thermal-acoustic noise, i.e., noise originating from the thermal velocities of air molecules, has a value of 11 db below 10^{-16} watt for a frequency band from 1000 to 6000 cycles, and hence is of the order of the maximum ear sensitivity. Although the authors regard the calculation as very approximate, it suggests that the limit of sensitivity may be set by the transmitting medium. If this is so, man may have maximum sensitivities comparable with those of animals.

EAR SENSITIVITY OF THE POPULATION. The values of ear sensitivity shown in Table 1 are for a selected group of young people with excellent hearing; not all people hear this well. During the New York and San Francisco World Fairs in 1939, which were attended by people from all parts of the country, a survey of hearing was made in a large group of the United States population. The results, which are plotted in Fig. 8, show the percentages of thresholds measured which were above the levels shown by the contour lines. Thus the data show the percentage of people in the population within the age range from 10 to 59 years who cannot hear tones below the levels indicated by the contours.

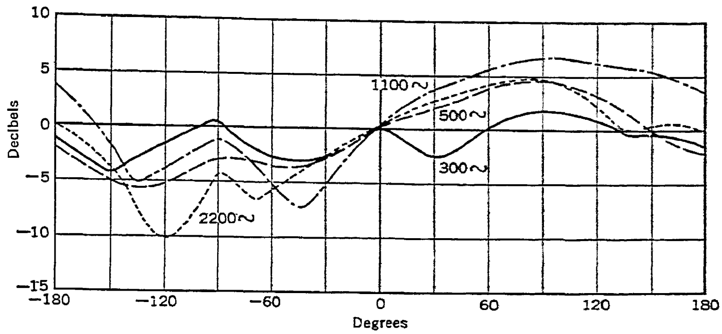

FIG. 7a. Increase of Monaural Acuity in a Free Sound Field When the Direction Which the Observer Faces Is Changed

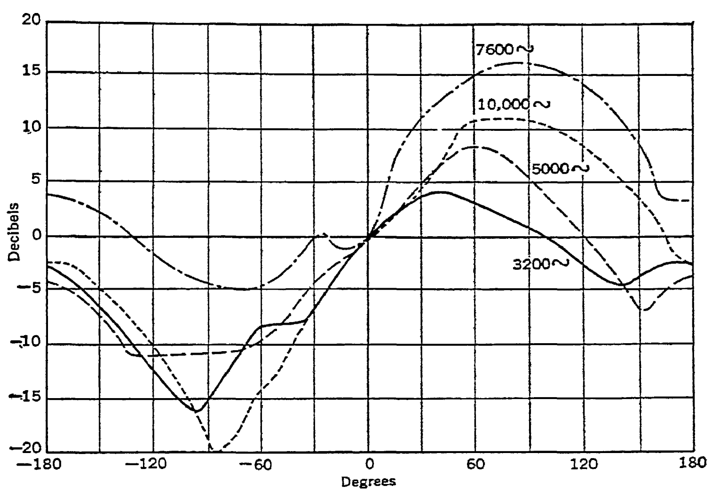

FIG. 7b. Increase of Monaural Acuity in a Free Sound Field When the Direction Which the Observer Faces Is Changed

For instance, 25 per cent of the population cannot hear a 1000-cycle tone if the intensity is below the 20-db level (zero = 10^{-16} watt per sq cm). The dotted portions represent extrapolations of the distributions beyond the intensity and frequency ranges used in the tests and are, of course, speculative.

VARIATION WITH AGE. Further analysis of the data revealed a progressive deterioration of hearing with age for the average individual, particularly at the higher frequencies. The hearing loss is somewhat greater for men than for women, as shown by the curves in Fig. 9. For this plot "zero hearing loss" refers to an ear sensitivity equal to the median value for the population tested. The contour marked "50 per cent" in Fig. 8 shows the median values as a function of frequency. When the hearing loss exceeds about 25 db at all frequencies lower than 2000 cycles, a person will experience difficulty at times in understanding speech in classrooms, auditoriums, churches, and similar environments where the speech level is not very high. A hearing loss of 45 db for frequencies below 2000 cycles results in some difficulty in understanding speech at distances greater than

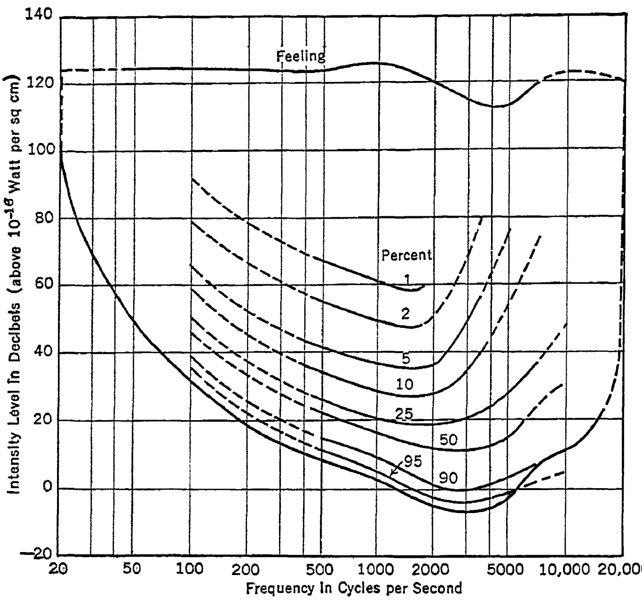

FIG. 8. Contour Lines Showing the Lower Limit of the Sensitivity for a Given Percentage of Tests in the Age Group 10–59. (Steinberg, Montgomery, and Gardner.)

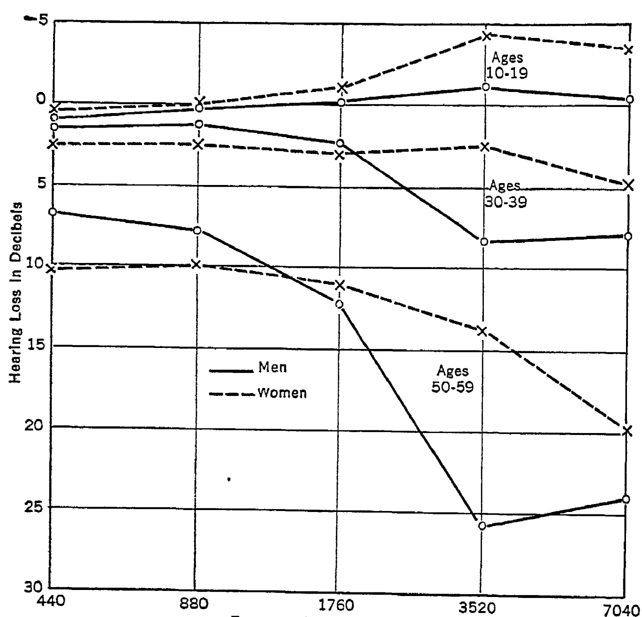

FIG. 9. Average Hearing Loss for Men and Women in Three Age Groups. (Steinberg, Montgomery, and Gardner.)

2 or 3 ft, and considerable benefit is usually derived from the use of a hearing aid. Table 3 shows the prevalence of hearing losses greater than 25 and 45 db among the people tested.

In the age group from 50 to 59 years, Table 3 shows that 3 or 4 per cent of the population have hearing losses exceeding 45 db and, therefore, would experience some difficulty understanding speech at a distance of 2 or 3 ft. Until the hearing loss exceeds about 65 db, a person will still be able to use the telephone without much difficulty.

Table 3. Percentage of Tests with Hearing Losses Greater than 25 db and 45 db

(Steinberg, Montgomery, and Gardner)

Age Group	25-db Loss				45-db Loss		
	Frequency				Frequency		
	880	1760	3520	7040	880	1760	3520
10–19							
Men	1.7	1.6	4.5	8	0.6	0.6	1.8

AUDITORY RANGE. As the intensity level of a sound is increased, a value is reached which causes a sensation of feeling in addition to the sensation of tone. Such intensity levels may be taken as practical upper limits of hearing, and they have been called the "threshold of feeling." The observed data on the threshold of feeling were the number of decibels between the hearing and feeling thresholds for pure tones and were obtained by means of telephone receivers held to the ear. The absolute threshold of feeling plotted in Fig. 8 was obtained by adding the observed data to the lower limit of audibility shown in Fig. 8. The lower limit is the M.A.F. determination of Table 1.

The lower limit and the feeling curve have been extrapolated until they meet, thus forming an enclosure called the "auditory sensation area." This area has the property that any sinusoidal sound wave having a frequency and an intensity level within the area will cause a sensation of tone. The dashed portions of the curves serve as a means of defining the upper and lower frequency limits, i.e., the lowest and the highest frequency that can be sensed as a tone. Measurements have been made using frequencies varying from about 8 to 40 cycles for the lower limit and from 12,000 to 35,000 cycles for the upper limit, but, for the most part, very little attention was given by the experimenters to the intensity levels at which the determinations were made. In drawing in the dashed curves, consideration was given to available data on frequency limits, and values of 20 cycles and 20,000 cycles were selected for the lower and upper frequency limits, respectively. These limits were taken as more or less typical for persons of normal hearing in the age range from 18 to 23 years but do not represent the extreme values found in exceptional cases.

3. DIFFERENTIAL SENSITIVITY

The differential sensitivity of hearing refers to some aspect of the smallest change of a stimulus that can be detected. Available data on the subject are confined almost entirely to measurements of the minimum perceptible increments of frequency and of intensity when the stimulus is a single-frequency tone. The values obtained depend to some extent upon the method of measurement, probably because the just perceptible change (difference limen) is affected by the rate at which the change is made as well as other variables common to tests of this type. Until a measuring technique is standardized, the data shown should be regarded as of the exploratory type. In Fig. 10 the results of extensive measurements of Δf, the difference limen for frequency, are plotted. For levels greater than 40 db above threshold, and for frequencies greater than 500 cycles, the frequency D.L. has the approximately constant value of 0.3 per cent.

These results were obtained by listening to the tones with head receivers. When the measurements are made by listening to a loudspeaker in a room, much smaller values can be observed. In this case the change in frequency is detected by intensity changes due to the shifting of the interference pattern in the room with frequency change. A

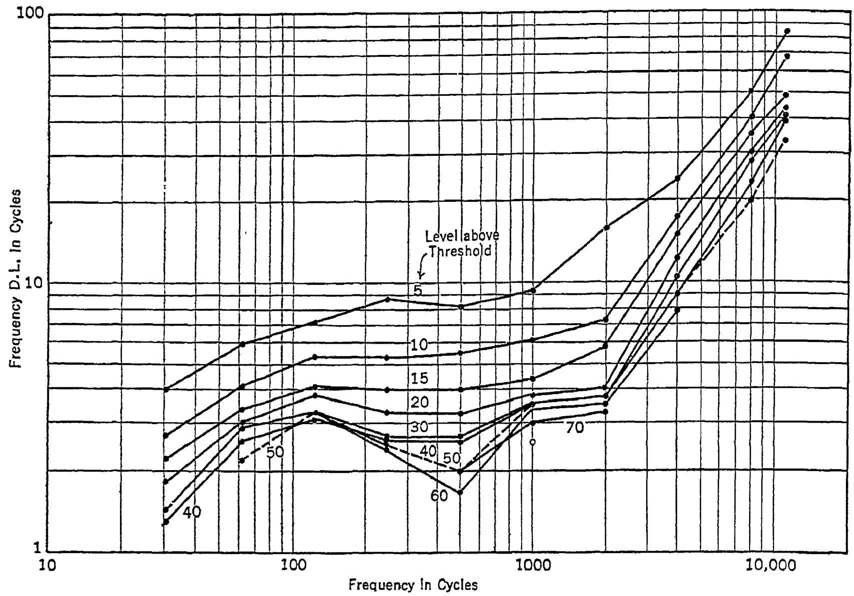

FIG. 10. The Frequency Difference Limen with Decibels above Threshold as a Parameter. (Shower and Biddulph.)

similar set of measurements of ΔI, the minimum perceptible increment of intensity, is shown in Fig. 11. For convenient use the increment of intensity expressed in decibels, $10 \log (I + \Delta I/I)$, is plotted as the ordinate. For levels greater than 40 db above threshold, and for frequencies between 200 and 7000 cycles, the intensity D.L. varies from 0.25 to 0.75 db.

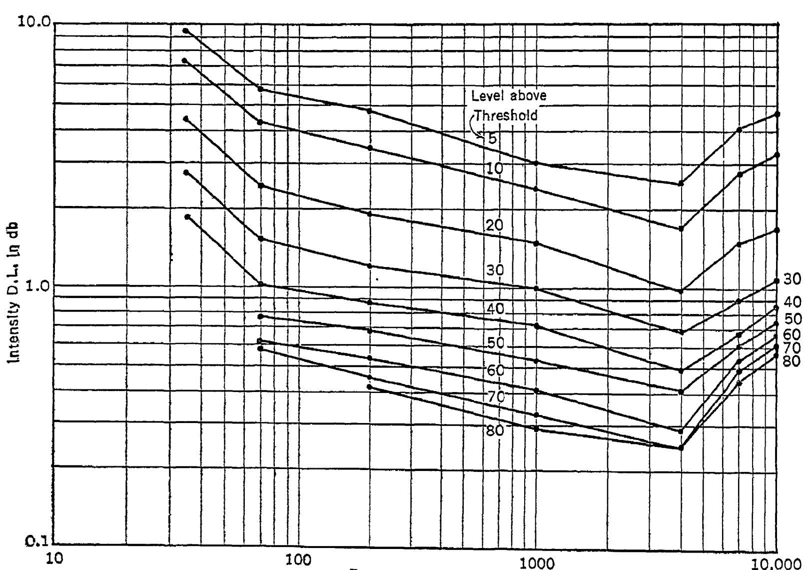

FIG. 11. The Intensity Difference Limen with Decibels above Threshold as a Parameter. (Riesz.)

4. MASKING EFFECTS OF SOUNDS

When listening to speech or music it often occurs that a disturbing noise interferes to such an extent that the desired sounds are partially or entirely obliterated. The noise is said to have a masking effect, and the magnitude of the effect is defined by a "masking spectrum" of the noise. Measurements of masking spectrums are made by determining the threshold of audibility of single-frequency tones in the presence of the noise and again when the noise is absent. If β is the intensity level of a tone of frequency f, that is just audible in the presence of a noise, and β_0 is the intensity level that is just audible under quiet listening conditions, then M, the masking at the frequency f, is defined by the equation: $M = \beta - \beta_0$. A plot of M as a function of the frequency of the tones is called a masking spectrum. If the intensity spectrum of a noise has been measured by means of a sound meter and filters, the masking spectrum may be derived by use of Fig. 12. Here the iso-masking intensity per cycle level of noise has been plotted as a function of frequency with masking as a parameter. The applications of these data are limited to portions of the noise intensity spectrum that do not exhibit the abrupt changes with frequency that occur when a prominent single-frequency component is present or a filter with a sharp cutoff limits the frequency range of the noise.

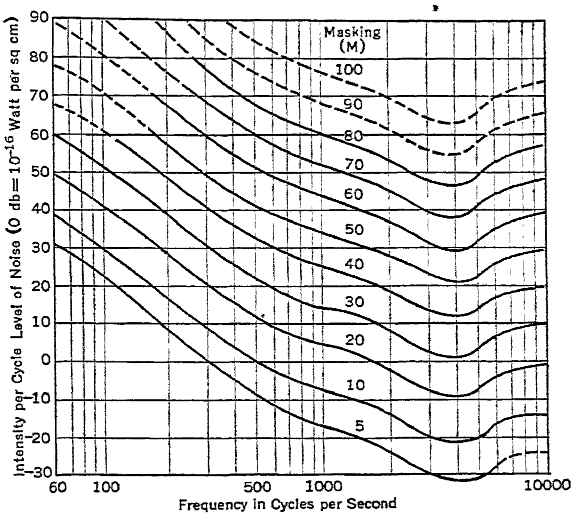

FIG. 12. Masking Contours for a Steady Noise. (Fletcher and Munson.)

5. LOUDNESS OF SOUNDS

Loudness is defined as the magnitude of an auditory sensation, and for steady sounds it is thought to be proportional to the rate at which neural pulses originating along the basilar membrane arrive at the brain. A scale of auditory magnitudes has been derived from loudness tests and can be used whenever the loudness level of a sound is known. A measurement of loudness level consists of a listening test in which the level of a 1000-cycle reference tone is adjusted until it sounds equally loud to the sound being measured. Errors in judgment may be large, and a number of observers may be required to obtain a reliable average result. The equivalent free field intensity level of the equally loud 1000-cycle tone is, by definition, the loudness level of the unknown sound.

The loudness level of a sound being known, its auditory magnitude is found by referring to Table 4, which gives the auditory magnitude, or loudness, as a function of the intensity level of the equally loud 1000-cycle tone. The figures for the intensity level (loudness level) of the 1000-cycle tone are in decibels relative to 10^{-16} watt per sq cm, and a level of 40 db results in an auditory magnitude of one sone. Thus, in Table 4, the loudness corresponding to a loudness level of 40 db is 1 loudness unit (1 sone = 1000 millisones). Increasing the loudness level from 40 db to 49 db gives a listener the impression that the magnitude has doubled, so a loudness level of 49 db results in a loudness of 2 units. Increasing the loudness level from 49 to 58.1 db again doubles the magnitude of the sensation for the average listener, so a loudness level of 58.1 db produces a loudness of 4 units. The empirical relationship between loudness and loudness level is shown in Table 4.

Loudness levels are given in steps of 1 db, or 1 "phon," and zero level is 10^{-16} watt per sq cm in a free sound field. The term "phon" is generally used as the unit of loudness level to avoid confusion with intensity levels of sounds other than a 1000-cycle tone. It is believed that the loudness of a steady sound depends upon the rate at which neural pulses reach the brain, and, although no measurements are available to substantiate this hypothesis, the concept is useful in explaining empirical methods of computing the loudness of complex sounds. It follows from the manner in which the loudness scale was developed that a 1-sone sound, for example, is equally loud to any other 1-sone sound, and four times as loud as a 0.250-sone sound. It is also true that a 1-sone sound will drop to a

Table 4. Loudness (Millisones) vs. Loudness Level (Phons)

(Fletcher and Munson)

Loudness Level, db	Loudness 0	1	2	3	4	5	6	7	8	9

100	100,000	108,000	117,000	126,000	136,000	147,000	159,000	171,000	185,000	200,000

half sone if only one ear is used for listening. These simple relations have all been verified experimentally. A complex sound having two 1-sone components will be equally loud to a sound of 2 sones if the components excite nerve endings located in different sections of the basilar membrane and thus contribute 1 sone each, even though they are sounded simultaneously. This is not likely to be the case when the frequencies of the components are close together or the levels are high, since many of the same nerve endings are then used by both components.

EFFECTIVE STIMULATION DENSITY. The response of the auditory nerve endings is dependent upon the density of stimulation. If the stimulus is localized, the response will be different, and the loudness sensation will differ, in general, from the loudness resulting when the stimulus energy is distributed among a large number of nerve endings. The relationship between the frequency of the stimulus and the position coordinate (X) of the nerve endings stimulated is shown in Fig. 13.

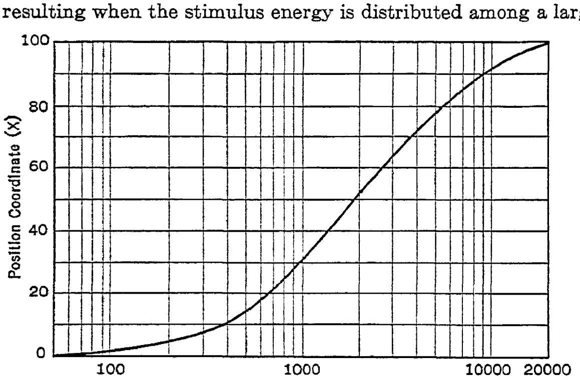

FIG. 13. Relation between Frequency of the Stimulus and the Position of Maximum Stimulation. (Fletcher.)

The ordinate of Fig. 13 gives the position of maximum stimulation of the nerve endings, with respect to the total number, when the stimulus is a single-frequency tone. For instance, at 1000 cycles the curve shows that 31 per cent of the nerve endings are on one side of the point of maximum stimulation, and 69 per cent are on the other side. The relationship shown can be derived in several different ways on the basis of different assumptions, but it has been verified only in a qualitative sense by actual nerve counts. To obtain the effective stimulation density as a function of frequency, for a sound with a continuous energy spectrum, measurements must first be made with a sound meter that will analyze sound at all frequencies within the audible range. If the analyzer measures the intensity (I) in a frequency band Δf cycles wide, then the readings are related to effective stimulation densities by means of the equation:

$$Z = 10 \log \frac{I \, \Delta f_1}{I_1 \, \Delta f}$$

where I_1 is the intensity level of a 1-millisone single-frequency tone, and Δf_1 is a frequency band enclosing a unit group (1 per cent) of the nerve endings. It is seen that Z is the ratio, in decibels, of the stimulation intensity per unit group of nerve endings to the intensity required to excite a 1-millisone response from the nerves. The equation for Z is usually given in the more convenient form:

$$Z = B + \kappa - \beta_0$$

where B is the measured intensity per cycle level of noise $[B = 10 \log (I/I_0 \Delta f)]$, I_0 is the reference intensity of 10^{-16} watt per sq cm, κ is the band width in decibels which includes a unit nerve group ($\kappa = 10 \log \Delta f_1$), and β_0 is the intensity level of a tone when the loudness level is zero $[\beta_0 = 10 \log (I_1/I_0)]$. Values of κ, B_0, and X are shown in Table 5 for use in computing and plotting the effective stimulation density for the nerve endings as a function of their position coordinate, X.

Table 5. Values of κ, β_0, and X

(Fletcher and Munson)

f	100	200	300	500	700	1,000	2,000	3,000	5,000	7,000	10,000

κ	16.5	15.0	15.0	15.0	15.3	16.0	18.6	20.7	23.9	26.1	28.6
β_0	37.4	22.9	14.6	5.7	2.0	0.0	−4.5	−8.5	−4.9	4.9	8.8

LOUDNESS COMPUTATION FOR SOUNDS WITH CONTINUOUS ENERGY SPECTRUMS. The loudness of a steady sound is believed to be proportional to the number of nerve pulses arriving at the brain in unit time from all parts of the basilar membrane. We may compute the loudness (N) from the expression:

$$N = \int_0^{100} N_X \, dX$$

where N_X, the sone density, is a measure of the number of nerve pulses originating from a unit group of nerve endings in unit time, and X is the position coordinate previously defined. The equation is solved by plotting N_X as a function of X and measuring the area under the curve. Thus the loudness, N, of any sound can be computed when the sone density is known as a function of X.

The relationship between sone density (N_X) and the effective stimulation density (Z_X) has been investigated for sounds characterized by a continuous distribution of energy, and it is shown in Fig. 14.

It is not applicable to sounds having single-frequency components or sounds in which the value of the slope, dZ/dX, exceeds the limits ± 2 db. In the latter case, masking measurements are a more reliable means of obtaining the sone density (N_X). The masking (M) is defined by the equation: $M = \beta - \beta_0$, where β is the intensity level of a single-frequency tone that is just audible in the presence of a masking sound, and β_0 is the intensity level when the loudness level is zero. Figure 15 shows the relationship between

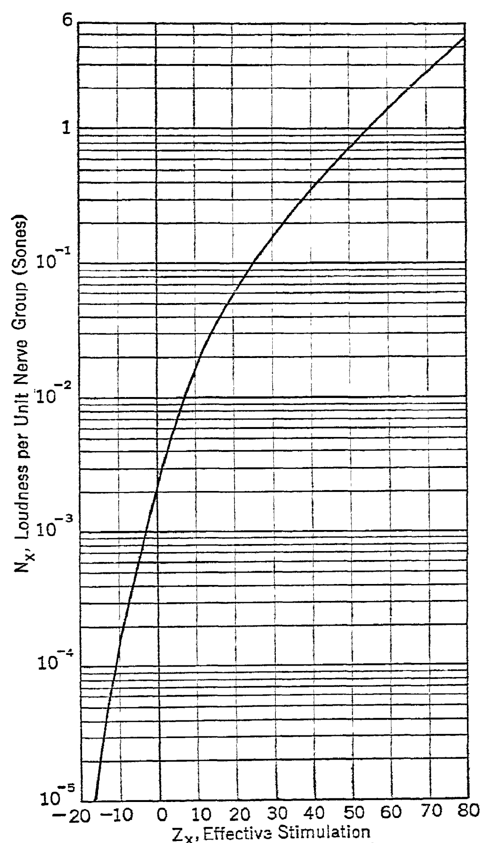

FIG. 14. Relation between the Loudness (N_X) per Unit Nerve Group and the Stimulation (Z_X) per Unit Nerve Group. (Fletcher and Munson.)

masking and sone density. The masking method of obtaining the sone density is valid for sounds exhibiting large values of dZ/dX but not for sounds with single-frequency components. The masking spectrum of a single-frequency tone is not an accurate indication of its sone density since the phenomenon of beats between the masking tone and the masked tone changes the conditions under which the masked tone is detected. This results in low values of masking at frequencies where the highest values would be expected.

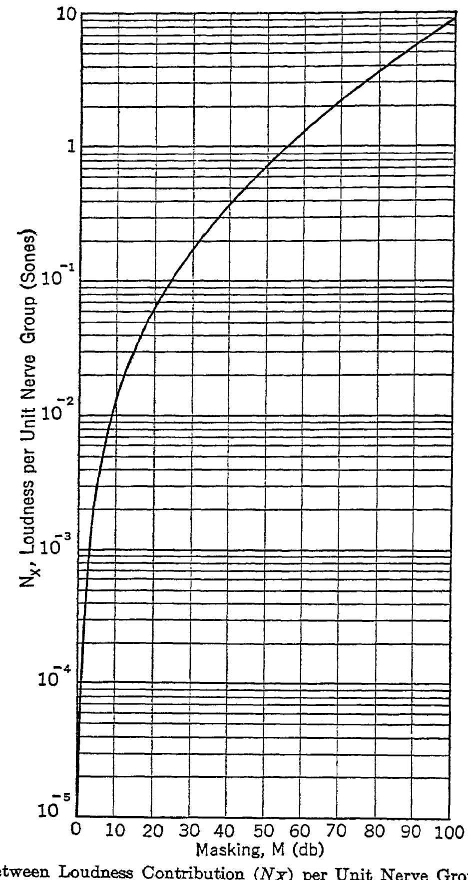

FIG. 15. Relation between Loudness Contribution (N_X) per Unit Nerve Group and Masking (M). (Fletcher and Munson.)

LOUDNESS OF SOUNDS COMPOSED OF SINGLE-FREQUENCY COMPONENTS. When a sound is a single-frequency tone at a low level, the nerve endings in a localized region of the basilar membrane are stimulated. As the level is increased, the stimulation pattern spreads to adjacent nerves, and at high levels a large proportion of all the nerves may come into use. The region of maximum stimulation probably does not change much when the level is raised, but secondary maxima appear at harmonic frequencies owing to non-linear distortion in the ear itself. The masking spectrums shown in Fig. 16 indicate the nature of the change of the stimulation pattern as the level of a tone is increased.

As explained in the previous section, the regions of maximum stimulation appear as depressions because of the beats which occur near the fundamental and harmonic frequencies. Measurements of the conditions for best beats have been used to determine the magnitude of harmonics produced in the ear. Figure 17 shows the equivalent magnitude of the subjective harmonics for different pressure levels of the applied sound. Taking the fundamental as the first harmonic, the abscissa gives the number of the harmonic. When plotted in terms of pressure level, the curves are independent of frequency. It is clear that the stimulation patterns of single-frequency tones are very complex, and it would be difficult to plot the sone density as a function of X, as was done for sounds with continuous energy spectrums. However, the loudness of any single component may be found from the loudness-level contours shown in Fig. 18.

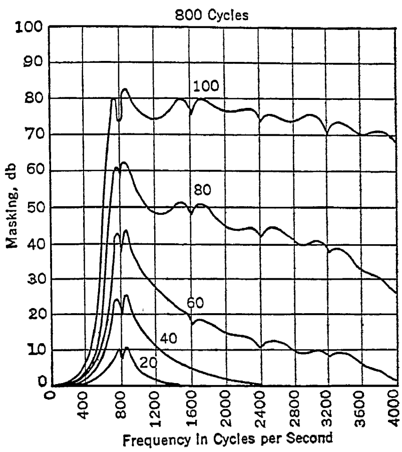

FIG. 16. Masking Spectrums of a Single-frequency Tone with Level above Threshold as a Parameter. (Fletcher, Wegel, and Lane.)

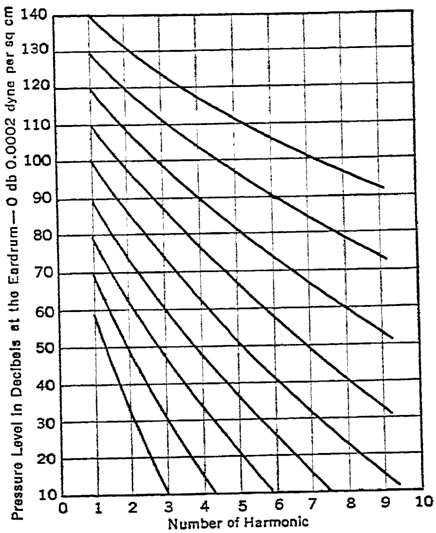

FIG. 17. Magnitude of Subjective Harmonics. (Fletcher and Graham.)

The ordinate here is the free field intensity level of a pure tone, and each contour line is marked with a loudness level. For instance, a 200-cycle tone at an intensity level of 60 db from 10^{-16} watt has a loudness level of 50 db. Turning to Table 4, we see that the corresponding loudness is 2.150 sones. If a sound has more than one component, the sone values may be added to obtain the total loudness, provided that the frequencies of the

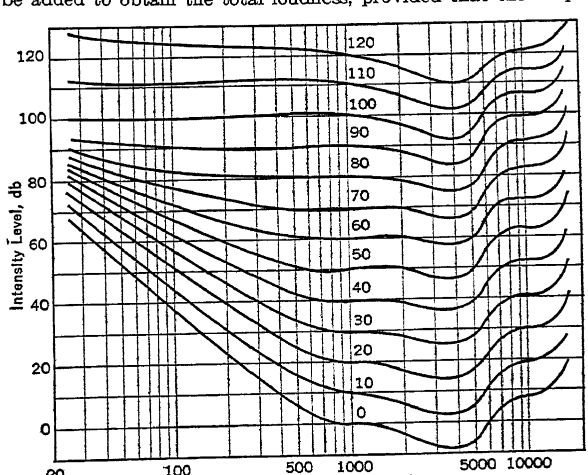

FIG. 18. Loudness-level Contours. (Fletcher and Munson.)

components differ enough so that different nerve groups are stimulated. The separation required is a complex function of level and frequency and will not be discussed here. Some idea of the effect of different separations of components may be obtained from

Fig. 19, which shows the loudness levels of several 10-component sounds as a function of the loudness level of each component.

The first sound had a fundamental frequency of 530 cycles and a difference of 530 cycles between components. The others had a fundamental of 1000 cycles and the differences indicated. The dotted line shows the loudness levels corresponding to 10 times the loudness of a single component. For a more extended treatment of the loudness of sounds with single-frequency components, refer to an article in the October 1933 *Journal of the Acoustical Society of America* entitled "Loudness, Its Definition, Measurement and Calculation," by Fletcher and Munson.

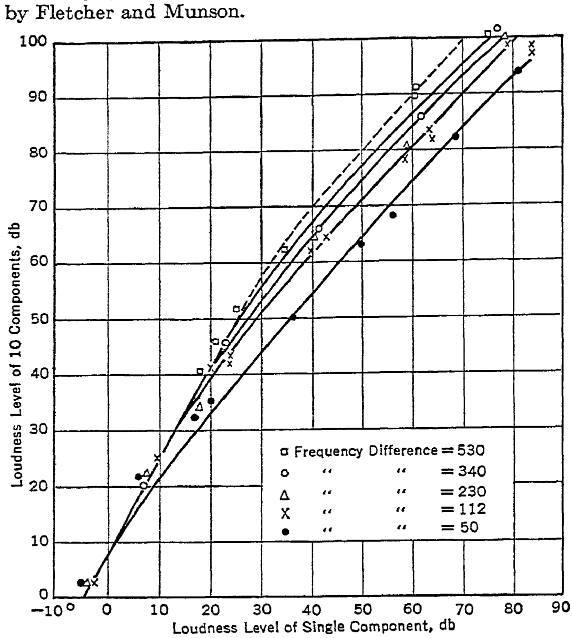

FIG. 19. Effect of Separation of Components on the Loudness Levels of Complex Tones. (Fletcher and Munson.)

6. THE PITCH OF STEADY SOUNDS

The pitch of a steady sound is the position on a musical scale that would be assigned to it by a listener. If the sound is a single-frequency tone, its pitch depends upon frequency and, to a slight degree, upon intensity. At loudness levels less than 40 db the pitch depends only upon frequency, and single-frequency tones at a loudness level of 40 db have been chosen as standards for comparison with sounds of unknown pitch. The results of pitch comparisons between single-frequency tones at a 40-db loudness level and tones at higher levels are shown in Fig. 20. The ordinate is the change in frequency, in per cent, of a tone that is necessary in order that its pitch remain constant as its level is raised.

For example, the curves show that a 100-cycle tone must be lowered 10 per cent when the loudness level is increased from the standard level to 100 db. This means that a 90-cycle tone at a loudness level of 100 will appear to have the same pitch as a 100-cycle tone at a loudness level of 40 db. The curves shown in Fig. 20 are based on data at low frequencies. Similar experiments by Zürmuhl and Stevens indicate that at frequencies above 2000 cycles there is a small increase in pitch as the level is raised. An observer's judgment of the pitch of a sound is thought to be related to the position of the stimulated region on the basilar membrane. In general, a sensation of lower pitch occurs when the stimulated region shifts towards the helicotrema.

Table 6. Judgments of Half Pitch

(Stevens and Volkmann)

Standard frequency	150	250	500	1,000	2,000	3,000	5,000	10,000
Frequency for half pitch	85	111	206	373	633	1,009	1,437	2,064

Experiments have been made to determine how much the frequency of a standard tone must be shifted to result in the sensation that the pitch has decreased by a factor of one-half. The results are shown in Table 6, where the first row is the frequency of the standard tone. The second row is the mean frequency of tones which were selected by twelve

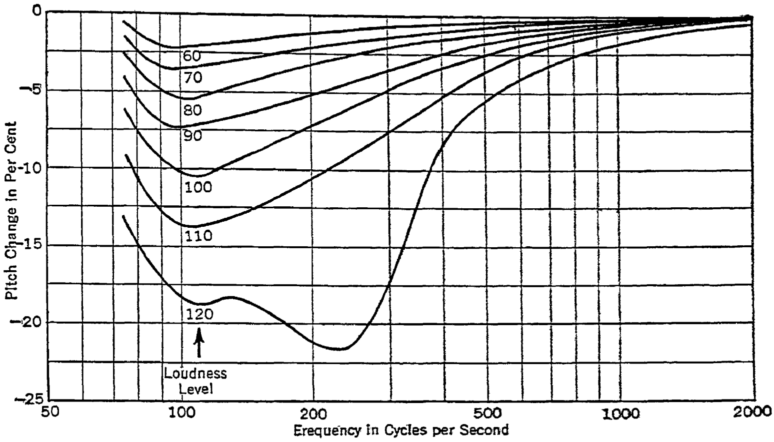

FIG. 20. Pitch Change of Single-frequency Tones at High Levels. (Snow.)

observers to be one-half the pitch of the standard. The loudness level of all tones was 40 db. Table 6 shows that a tone of 373 cycles will appear to be one-half as high in pitch as 1000 cycles. By use of these and other data on estimations of pitch intervals, Stevens, Volkmann, and Newman have devised a numerical pitch scale having the property that tones which appear to be 50 per cent lower in pitch will also be related in the same manner on the pitch scale. The unit of pitch is called a "mel," and the relationship between mels and frequency for pure tones at a loudness level of 40 db is shown in Fig. 21.

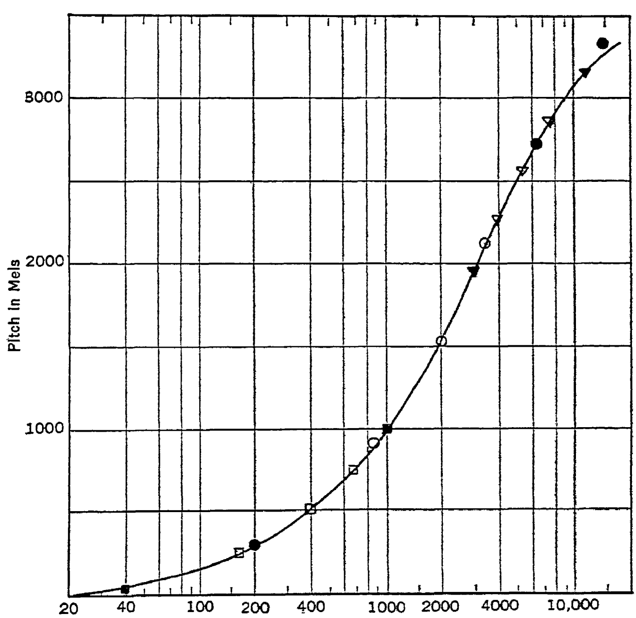

FIG. 21. Relation of the Pitch in Mels to the Frequency of Tones at a Loudness Level of 40 Db. (Stevens and Volkmann.)

7. LOCALIZATION OF SOUNDS

The ability to localize the direction and to form a judgment of the distance away of a source is a matter of common experience, but very few quantitative data on the subject are available. The localization of direction (angular localization) appears to depend upon the detection of phase differences at the two ears, loudness differences, differences in quality, and differences in arrival times at the two ears. Loudness differences, and quality differences (in complex sounds), and to some extent phase differences, arise from diffraction effects of the head. At low frequencies the loudness difference at the two ears is small, but localization by phase difference is effective. An angular accuracy of about $\pm 10°$ is obtained for sounds directly in front or in back of the observer. Much less precision is obtained when the source is at one side. Loudness differences are most effective in the frequency range above 3000 cycles and quality differences in the range above 1000 cycles. In general, complex sounds having prominent high-frequency components, hence large loudness and quality differences between the ears, are localized with greatest accuracy. Under familiar acoustic conditions, such sounds may be localized frequently by the use of one ear only. Presumably this is accomplished by recognizing the characteristic distortion introduced by the head. Steinberg and Snow report that the apparent distance of the sound source, i.e., depth localization, depends upon the loudness of a sound. When an observer is listening in a room, the ratio of the direct sound intensity (that reaching the ears without reflection) to the reflected sound intensity also enters into depth localization.

SPEECH AND MUSIC

By John C. Steinberg and W. A. Munson

8. DESCRIPTION OF SPEECH ORGANS

The speech organs consist of the lungs and respiratory muscles, the trachea or windpipe, the larynx, and the cavities of the throat, mouth, and nose. In speaking, a flow of air is produced by the lungs which is modified in passing through these passages to form speech sounds. The larynx is a cavity of irregular shape formed of cartilage located at the upper end of the trachea, a tube some 12 cm long and 2 cm in diameter leading from the lungs. A pair of muscular ledges, called the vocal cords, form a slit in the larynx through which the air must pass. When the vocal cords are set in vibration, the air flow is periodically interrupted and the sound is said to be voiced. Measurements reported by Riesz, on persons whose larynx had been removed by a surgical operation, indicate that the excess pressure in the lungs when producing sustained parts of speech, such as vowels, is of the order of 4 mm of mercury or 0.005 atmosphere. The rate of air flow is about 150 cu cm per sec. The normal capacity of the lungs is about 2500 cu cm, and the average expiration in breathing is about 500 cu cm.

By means of high-speed motion-picture photography, views of the vocal-cord movements in slow motion have been obtained at Bell Telephone Laboratories. Measurements on successive exposures of the vibrating cords indicated a displacement amplitude that was sawtooth in form. The cords tended to snap apart and close slowly and firmly together. The wave form contained a fundamental and higher harmonics which diminished in amplitude inversely as the square of the harmonic number. The length of the cords and maximum amplitude of opening varied with pitch. For example, in the subjects studied, the cords were about 1.2 cm in length and their widest opening was about 0.4 cm when vibrating at 120 cycles. At 300 cycles, their length was about 2.0 cm and the widest opening about 0.2 cm. Changes in the acoustic load by closing the mouth opening with a glass window or filling the vocal cavities with helium did not appear to affect the vibration wave form of the vocal cords markedly.

The opening between the cords is called the glottis, which, of course, varies in size as the cords vibrate. There appears to be little direct information on the acoustic wave form produced at the glottis by the vocal-cord vibrations. Indirect evidence based on harmonic analysis of vowel sounds reported by Steinberg and also Lewis indicates a sawtooth wave form in which the amplitudes of the harmonics diminish inversely as the 1.5 power of the harmonic number.

9. PRODUCTION OF SPEECH

MECHANISM OF SPEECH. As has been discussed by Dudley, speech may be regarded as a phenomenon of modulation in which the breath stream, a unidirectional flow of air produced by the lungs, is given intelligence-carrying variations. The breath stream is made audible by two kinds of modulation called *vocal-cord* and *frictional* modulation. The first is produced by the periodic interruption of the breath stream by the vibrations of the vocal cords. The second is produced by the turbulent flow of the breath stream through constrictions formed in the vocal tract. Both produce variations at relatively high rates, i.e., in excess of 70 cycles. The vocal-cord modulation produces fundamental and harmonic overtones such as characterize a vocalized or voiced sound. Frictional modulation produces a wide range of inharmonically related overtones such as characterize a hiss.

The audible components thus produced are in turn modulated by relatively slow variations, i.e., at rates definable by frequency components in the range below some 40 or 50 cycles. One of these is called *start-stop* modulation, which is accomplished by the muscles of respiration, the vocal cords, tongue, and lips. Another, called *cavity* modulation, is produced by changes in size and shape of the vocal passages extending from the glottis to the mouth and nose openings. These passages selectively transmit and radiate the audible frequency components produced in the breath stream by vocal-cord and frictional modulation. This results in a reinforcement, relatively, of certain frequency components or regions which are called vocal resonances.

Several other types of low-frequency modulation occur such as inflection, vibrato, and stress, but the four noted above are the ones of chief importance to the intelligibility of American speech sounds. Start-stop modulation is one of the principal characteristics of the plosive or stop consonant group, and frictional modulation is one of the chief characteristics of the fricative consonant group. In the vowel and vowel-like group of sounds, cavity and vocal-cord modulation are among the conspicuous characteristics.

CHARACTERISTICS OF SPEECH SOUNDS. As a result of cavity modulation, all sounds tend to show characteristic frequency regions of reinforcement in a greater or less degree. These vocal resonances are more conspicuous in the vowel and vowel-like sounds. In general, there is a resonance in the range from 300 to 1000 cycles, one in the range from 1000 to 2500 cycles, and one or more in the range from 2500 to 4000 cycles. The two resonances below 2500 cycles are the ones that vary most in frequency position from sound to sound. There has been a tendency to associate the low resonance with the pharynx or throat cavity and the next resonance (1000–2500 cycles) with the mouth cavity. Damping constants reported for the cavities range from 1000 to 4000 db per sec. With a vocal-cord vibration rate of 125 cycles, the cavities would be excited periodically at intervals of 0.008 sec, and the amplitude of the sound wave would be expected to decay to something between 0.4 and 0.03 of its initial value during the interval.

The steady-state resonance characteristics of the sounds can be expressed by the peak frequencies f_i of the vocal resonances, the levels L_i of the peak frequencies, and the damping constants Δ_i expressed in decibels per second which indicate the sharpness of the resonances. This information, together with the data on the acoustic wave form at the glottis given in article 8, permits an approximate construction of the spectrums of the sounds. The available data on these characteristics are summarized in Table 1. The columns designated f_1 to f_4 indicate the peak frequencies of vocal resonance. They were obtained from data reported by Kopp and Green, and represent values for one voice. Since the values vary somewhat from voice to voice, values for a single voice were chosen to permit a relative comparison of the different sounds. When "fundamental" appears in the column f_1, it means that the resonance was too close to the fundamental frequency to be resolved by the analyzing means. The vocal resonances shown for the voiced consonants, *v*, *th* (that), *z*, *zh*, *b*, *d*, and *g*, apply also to their unvoiced cognates, *f*, *th* (thin), *s*, *sh*, *p*, *t*, and *k*. For *g* (get) and also *k* (key), the frequencies of the vocal resonances vary depending upon the sound with which they are combined. The column L_1 shows the relative levels of the first resonance peaks as derived from Table X, Fletcher, *Speech and Hearing*.

The remaining columns, L_2 to L_4, show levels of the respective resonant peaks based on data from several sources. All levels are expressed in decibels below the level of the first resonant peak in *ah* (father). The damping constants Δ_i are not shown but vary from about 1200 db per sec for the first resonance to about 4000 db per sec for the fourth resonance. The band width of the resonance at points on the resonance curve 3 db below the peak response is given approximately by $\Delta_i/27.3$. The last column, designated n, shows the relative occurrence of the sounds in telephone conversation from a report by French, Carter, and Koenig. The figures indicate the percentage occurrence of the vowels shown among all vowels occurring in 95,522 vowels. The occurrence figures are indicated separately for initial and final consonants from 64,043 initial and 65,544 final consonants. The figures in parentheses indicate the occurrence of the unvoiced cognates of the voiced consonants shown. The figures were obtained from the words, syllables, and sounds occurring in telephone conversations after the exclusion of articles, names, titles, exclamations, letters, and numbers.

An interesting feature of the report is the extent to which a few common words or sounds, by being used over and over, from a large part of ordinary speech. For example, eight different words and four different sounds account, respectively, for 25 per cent of the total words and sounds used. Thirty words and ten sounds account, respectively, for 50 per cent of the total used.

ARTIFICIAL LARYNX. The artificial larynx is based on the principle that the vocal-cord tone need not necessarily arise in the larynx in order that cavity modulation occur to form speech. It may be introduced into the vocal cavities through the mouth opening. A means for accomplishing this has been described by Riesz and is used by persons who have had their larynx removed by surgery. In this case, the windpipe is terminated by a small opening in the neck, through which the patient breathes. In using the artificial larynx, a flexible rubber tube is fitted over the neck opening and leads to a reed which vibrates with the passage of air. The vibrated air stream is led to the mouth opening by a flexible tube, and, with practice, the patient learns to modulate the sound and form speech by the ordinary articulatory movements. Firestone has described and demonstrated a form of artificial larynx for introducing various types of sounds through the mouth opening for vocal modulation. Mr. G. M. Wright has developed an artificial larynx in which sound is introduced into the vocal tract by means of vibrators attached outside the throat. The device has been used to produce unusual vocalized sound effects in radio work.

ARTIFICIAL VOICE. An artificial voice described by Inglis, Gray, and Jenkins, designed for the measurement of microphones, consists of a small moving-coil loudspeaker having an opening somewhat larger than that of the human mouth. Its design provides for an undistorted acoustic power output comparable with powers produced in speaking. Its sound field approximates that of the human mouth to the extent that the loss in power delivered by a microphone with increasing distance between the mouth and the microphone is about the same for the artificial as for the human voice.

THE VOCODER. A means is described by Dudley for continuously analyzing speech and utilizing the results of the analysis to synthesize or remake the speech. It is based on the principle that the intelligibility of speech is carried by the relatively low-frequency components produced by cavity modulation and that the "buzz tone" (vocal-cord modulation) and the "hiss tone" (frictional modulation) simply act as carrier waves which are modulated by the vocal cavities. Frequency range reduction is achieved by transmitting only the low-frequency modulations and employing them to modulate locally generated buzz and hiss tones. In one variation called the voder, speech is produced artificially by using a keyboard manipulated with the fingers for generating the carrier waves and the low-frequency modulations.

VISIBLE SPEECH. A development described by Potter, in which speech is continuously analyzed and the results of the analysis portrayed to the eye in the form of visible patterns that one can learn to read, holds possibilities in the fields of visual hearing and visual telephony for the deaf, phonetic printing and retranslation into sound, the selective operation of automatic devices by voice sounds, and in the specialized fields of phonetics, linguistics, foreign language, music, etc To obtain readable patterns of speech sounds, the portrayal emphasizes the modulations that are important to intelligibility as illustrated in Fig. 1. Frequency is shown vertically, time horizontally, and intensity by shades of gray. The stop gap (start-stop modulation), the plosive release (frictional modulation), and the voice bar (vocal-cord) modulation are indicated for the voiced stop consonant *b*. Likewise the vocal resonance bars (cavity modulation) are indicated for the vowel *ē*. The *u* shows only two resonance bars which differ in position from those of the *ē*. The transition from *ē* to *u* is shown also. The fricative fill for *f* is an example of frictional modulation. The patterns for voiced sounds show regular vertical striations, the space between the striations indicating the pitch. Note the drop in pitch toward the end of "five." The unvoiced sounds (frictional modulation) show irregularly spaced vertical striations indicating a lack of pitch. The patterns are read from the characteristic modulations of the sounds and the transitions between them.

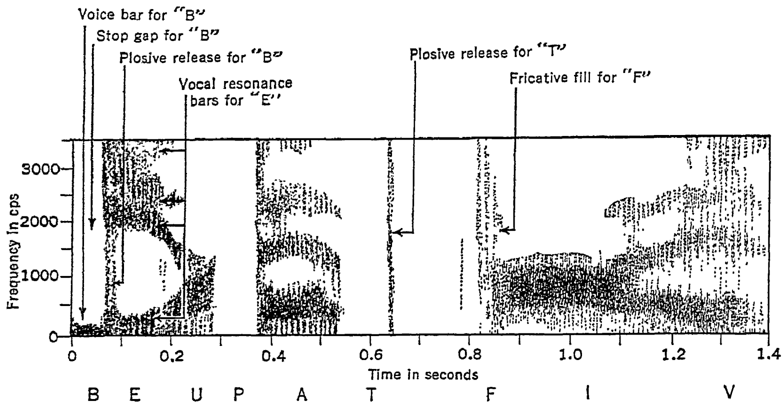

FIG. 1. Visible Patterns of the Words "Be up at Five"

10. SPEECH POWER

Since the wave forms of speech are complex, different types of speech power have been defined as follows:

Instantaneous. The rate at which sound energy is being radiated by the speaker at any given instant.

Average. The average speech power for any given time interval is the average value of the instantaneous speech power over that interval.

Peak. The maximum value of the instantaneous speech powers occurring in a given time interval.

Phonetic. The phonetic speech power is the maximum value of the average speech power in 0.01-sec intervals of a vowel or consonant sound. It is the maximum value of the envelope that results from plotting average power for 0.01-sec intervals against time, as the sound grows, remains steady, and decays.

The quantity usually measured is the speech pressure at some convenient distance and direction from the mouth. Dunn and White have reported the results of measurements of various types of speech pressure and comparisons with earlier measurements, and Dunn and Farnsworth have reported on the directional characteristics of the mouth as a radiator. The results are summarized in Table 2. They comprise statistical measurements of speech pressure vs. frequency range for conversational speech made with an arrangement for introducing any one of 14 band-pass filters into a speech circuit. The frequency range below 500 cycles was covered in one-octave steps. Above 500 cycles, each filter passed a range of about $^1/_2$ octave. Provisions were made for measuring instantaneous, peak, and rms pressures in alternate time intervals of $^1/_8$ sec and also, for certain cases, in time intervals of 15 sec. Some 600 intervals of $^1/_8$ sec were usually measured for a given condition representing an integrated time of 75 sec.

From the results it is possible to calculate the various types of speech power. This is done by converting pressure to power per square centimeter (intensity) by the relation $I = p^2/415$, where I = intensity in microwatts per sq cm and p = pressure in dynes per sq cm at a given distance and direction from the mouth. The intensities in other directions are obtained by weighting in accordance with the directional characteristics of the mouth, and P, the total power radiated, is then obtained by integrating over a spherical surface having a radius equal to the distance. The results of such calculations are given in the first row of Table 2 in the form of ratios expressed in decibels. The ratios depend upon the distance and direction from the mouth and the frequency range in which p is measured. The reference position is designated as 30, 0°, 0°, signifying 30 cm from the mouth at zero azimuth and altitude angles, i.e., directly in front of the mouth. The values when added to p expressed in decibels from 1 dyne per sq cm give P expressed in decibels from 1 microwatt. The values are based on distribution measurements for one voice.

Table 2. Summary of Data on Speech Powers

Quantity		Whole Spectrum	62.5–125~	125–250~	250–500~	500–700~	700–1000~	1000–1400~	1400–2000~	2000–2800~	2800–4000~	4000–5600~	5600–8000~

		Peak		20	18	16	14	11	9	6	4	0	−6
Distribution of long-interval rms p among speakers. % of speakers for which long-interval rms p exceeds average long-interval rms p by indicated amounts	% of speakers			1	5	10	20	30	40	50	60	70	80
	db from average long-interval rms p			9	5.5	4.0	1.5	0	−1.0	−2.5	−4.0	−6.0	−8.0

The second and third rows give the long interval rms pressure p at 30, 0°, 0° in decibels from 1 dyne per sq cm. The rows designated "men" and "women" are averages for 6 male and 5 female speakers, respectively. By long interval is meant a time average over some 600 $^1/_8$-sec intervals or 75 sec. Corresponding values in other bands may be obtained by taking p^2 as proportional to band width in cycles per second. Rows 4, 5, 6, and 7 show pressures p at different directions relative to the reference position. The mouth radiates maximally in a direction about 45° down from the horizontal. Rows 8 and 9 show peak pressures that are exceeded in 1 and 10 per cent of the $^1/_8$-sec intervals relative to the long-interval values. One per cent peaks more than 20 db above long-interval pressures occur frequently. Corresponding values for other bands may be obtained approximately for peaks occurring less than 10 per cent of the time, by proceeding as though they were rms pressures. The peak-factor data are essentially the same for both men's and women's speech.

Rows 10, 11, and 12 show the distribution of $^1/_8$-sec rms pressures relative to the long-interval values given in rows 2 and 3. Distributions for the three low-frequency bands are very similar to the whole spectrum distribution, row 11. Distributions for the remaining bands are very similar to that for the 700 to 1000 cycle band given in row 12. These distributions are about the same for both men's and women's speech.

Rows 13, 14, and 15 give distributions of instantaneous and peak pressures relative to the long-interval rms pressure. The distribution for instantaneous pressures is based on data for a single male voice.

The last two rows give data on the distribution of long-interval rms pressures among various speakers reported by Fletcher.

The results in Table 2 indicate a long-interval total speech power, averaged for 6 men, of 34 microwatts. The corresponding figure averaged for 5 women is 18 microwatts. These values are somewhat larger than that of 10 microwatts given formerly. Some 2 db of this difference is due to the method of converting measured pressures to radiated powers. These values obtain for continuous connected speech. If the silent intervals (about $^1/_5$ to $^1/_3$ of the total time) are excluded, the average is increased about 25 to 50 per cent. The above values hold for about 30 per cent of the speakers. One per cent of the speakers may radiate powers in excess of 272 microwatts. If one shouts as loudly as possible, the total power may reach 3400 microwatts, an increase of 20 db. For a very faint but intelligible whisper, the total power may fall to 0.0034 microwatt, a drop of 40 db.

In 1 per cent of $^1/_8$-sec intervals, the peak power may exceed the long-interval total power in connected speech by 20 db. Thus total peak powers of the order of 3400 microwatts may be reached by average male voices.

The *ah* (father) is about the loudest sound in speech. Fletcher reports a total phonetic power of 41 microwatts for this sound. Corresponding values for other sounds may be obtained from the column designated $L1$ of Table 1. These obtain for discrete words or syllables spoken at conversational level. Peak powers of the order of 1600 microwatts for the *ah* sound were obtained under these conditions. Wolf, Stanley, and Sette report total phonetic powers of 1 watt when the vowel *ah* is sung by professional singers. To be consistent with the data reported in Table 2, the total phonetic powers given above should be increased by 2 db.

Sivian reports on changes in the frequency distribution of speech power as a speaker changes from a low (confidential) talking level to a normal (conversational) level and to a high (declamatory) level. The total change in power from low to high was about 24 db. In general, power was transferred from the frequency range below 500 cycles to the range between 500 and 4000 cycles as the talking level was raised. To be representative of declamatory speech, the values in the bands below 500 cycles given in row 2, Table 2, should be decreased about 4 db and values between 500 and 4000 cycles should be increased about 3 db.

11. POWERS PRODUCED BY MUSICAL INSTRUMENTS

In music, as in speech, various aspects of power—peak, average, etc.—must be dealt with. A comprehensive report on the powers produced by the various musical instruments and by orchestras has been given by Sivian, Dunn, and White. The report also describes in some detail the band-pass filter apparatus discussed in article 10 on speech power. Two types of measurements were made on the waves, the average pressure in 15-sec intervals and the peak pressures in $^1/_8$-sec intervals. The pressures are the field pressures at the position in the field where the microphone of the measuring circuit was placed. For the measurements on individual instruments, the position of the microphone with respect to the source varied with instrument. For the orchestra, the microphone

Table 3. Peak Powers in Music

Instrument	Microphone Position and Assumption in Converting to Total Sound Power	Field Pressure dynes/cm²		Total Peak Power Watts	Percentage of Intervals	Band Containing Maximum Peaks	Field Pressure dynes/cm²		Total Peak Power Watts	Percentage of Intervals
		Average	Peak				Average	Peak		
Bass drum 36″ × 15″	3 ft in front, on axis. Radiation confined to a cylinder having drum diameter.	99.0	1260.0	24.6	6.0	250–500	35.0	792.0	9.8	1.0
Bass drum 30″ × 12″		35.0	980.0	13.4	1.0	125–250	12.0	392.0	1.7	1.0
Snare drum	4 ft in front, 90° off axis. Peak pressure increased 8.5 db for 1-ft distance. Radiation confined to hemisphere.	14.6	365.0	11.9	2.5	250–500	8.8	193.0	3.7	1.0
15″ cymbals	3-ft distance. Peak pressure increased 7.2 db for 1 ft. Radiation confined to hemisphere.	18.0	360.0	9.5	7.5	8,000–11,300	2.5	128.0	0.95	1.0
Triangle	3-ft distance. Conversion as for cymbals.	2.3	25.8	0.05	1.0	5600–8000	0.9	11.5	0.017	6.0

						8,000–11,300	0.2	4.6	5.3	1.0
Pipe organ	Effective distance 15 ft. Radiation assumed uniform over 1/4 sphere.	20.0	90.0	12.6	36.0	20–62.5	19.0	80.0	10.0	1.0
								40.0	2.5	22.0

was placed near the conductor's stand. By making assumptions as to the radiating properties of the instruments, and of the orchestra, their total power outputs could be estimated.

Table 3 gives the average and peak pressures at the positions of measurement as indicated. The columns "total peak power" give the total power radiated by the instruments, computed on the basis of assumptions indicated in the table. The left half of the table applies to the whole spectrum; the right half to the bands containing the maximum peaks.

An average of three methods was used for determining the total power radiated by the piano. In the first method, the diffuse pressure in a room of known reverberation was measured and the power calculated. In the second method, from auxiliary measurements, it was shown that the measured diffuse pressure was the same as if the total power output were distributed over a sphere of radius 5.37 ft. In the third method, the diffuse pressure was compared with the pressure measured in the opening between the raised top (grand piano) and the sounding board. The radiated power was assumed to be uniform over the area of the opening, 3 ft by 6 ft. The three methods gave peak powers of 0.166, 0.437, and 0.198 watt, respectively.

The measurements on the 15-piece orchestra were made in the same room as the piano measurements, and methods 1 and 2 were used to obtain the total power. The sounds from the 75-piece orchestra were picked up in a theater, and suitable acoustic data for using the above methods were not available. It was assumed that the radiation was uniform over a hemisphere of 15-ft radius. The measurements on the pipe organ were made in the same theater.

Because of the uncertain assumptions in calculating total powers, the measured values of pressure are also given in Table 3. The peak pressures were measured within a range of ±3 db, and the percentage of $^1/_8$-sec intervals that the power fell within this range is indicated. The peak pressures are useful in determining the amplitudes that pick-up instruments and amplifiers must handle, and the total peak powers for determining the requirements that must be met by power amplifiers and loudspeakers when reproduction of the original level is desired. The most powerful single instrument is a bass drum, which radiates a power of about 25 watts, primarily in the low-frequency ranges. A large orchestra is capable of radiating power of about 60 to 70 watts. This is about 70,000 times the peak power of speech.

Figure 2 (from Fletcher) shows the frequency distribution of the maximum and most probable peak powers for a 75-piece orchestra. The curves are based on average measurements of four selections which gave whole-spectrum peak powers from 8 to 66 watts, and

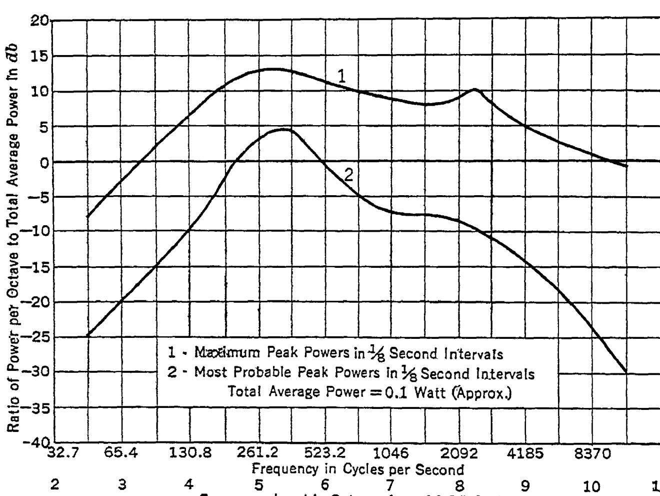

Fig. 2. Maximum and Most Probable Peak Powers

average powers from 0.08 to 0.13 watt. The zero line corresponds to an average power of about $^1/_{10}$ watt. The ordinate is the ratio expressed in decibels of the peak power per octave to the whole-spectrum average power.

A violin player, when asked to play at the lowest level that could be used with an audience, produced a whole-spectrum average pressure of 0.52 dyne per sq cm for a 3-ft distance. The highest peak observed for the bass drum was 1260 dynes per sq cm. Thus a range of at least 68 db is indicated between the highest and lowest amplitudes in music. The estimated range probably errs in the direction of being too small rather than too large.

12. TESTS OF SPEECH AND MUSIC TRANSMISSION

The performance of a system for the transmission and reproduction of speech or music can be expressed in terms of objective measurements involving a determination of its characteristics for steady-state sinusoidal waves of different frequency, or in terms of subjective measurements involving the satisfactoriness of the system from the viewpoint of the person receiving the signals. This section is concerned with the subjective type of measurement which involves, for speech, the recognizability and the naturalness of the reproduced sounds, and for music, the emotional and esthetic properties of the reproduction. Measurements of this kind may be classed as laboratory and field measurements. The former are particularly adapted to fundamental studies of the effects of various physical factors on the reproduction; the latter, to evaluating performance under conditions of actual use.

LABORATORY TESTS. The articulation test has come into wide use as a laboratory method of measuring the recognizability of received speech sounds. One form of the test which was used in obtaining the data given in the next article has been described by Fletcher and Steinberg. In this form, a speaker utters the various speech sounds and an observer writes down the sounds which he hears. The observed sounds are compared with the called sounds, and the percentage of the called sounds that were correctly recognized is obtained. This percentage is the articulation. To call the sounds, they are combined in a random manner into syllables of the consonant-vowel-consonant type which have no meaning in English. The syllables are spoken as parts of introductory sentences, such as, "Please record the syllable ——." The sounds used are those shown in Table 1 (p. 12-20), and they occur with uniform frequency in the testing lists. The percentage of the total number of spoken syllables which are correctly observed is called the "syllable articulation." The "sound articulation" is the percentage of the total number of spoken sounds which are correctly observed. When attention is directed toward a specific fundamental sound, e.g., *b*, the term "individual sound articulation" is used. Similarly, "vowel articulation" is the percentage of the total number of spoken vowel sounds which are correctly observed.

To obtain reproducible and representative results it is important that the testing crew have normal voices and hearing and that they be thoroughly familiar with the method. The best number of voices and observers and the amount of testing material required depend on the discrimination which is desired. For most of the data reported in the next article, each of 8 callers reads a list of 66 syllables to 4 observers. Practice effects of two kinds occur, a short-term period of improvement when the crew tests unfamiliar conditions, and gradual long-term changes in skill. The first may be eliminated by repeating tests; the second may be evaluated by suitable control tests on reference circuits. The use of automatic equipment to facilitate the control of variable factors is very advantageous, particularly when considerable testing is done. Castner and Carter have described equipment of this kind. The sounds that the observer hears are recorded, and the recorded result is analyzed into various articulation values, automatically within a few seconds after the test is completed, by suitable selecting and recording equipment. In addition, various circuit conditions to be tested are set up at the proper time, the talking levels of the callers are measured, and numerous other steps in a test are accomplished automatically.

Another type of test that has been used somewhat is the "intelligibility test." In some such tests, short sentences of the interrogative or imperative form containing a simple idea are used. The sentences are considered to be understood if the observer either records the sentence or records an intelligent answer. In others, English words, selected at random from print, are used. The "discrete sentence intelligibility" is the percentage of the total number of called sentences which are correctly understood. Similarly, the "discrete word intelligibility" is the percentage of called words correctly observed. Figures 3 and 4 illustrate the types of relations between these intelligibilities and syllable articulation. The intelligibility tests are useful in testing very poor systems having an articulation of only a few per cent, which are used sometimes in fundamental studies.

Articulation and intelligibility tests afford a quantitative measure of the intelligibility of reproduced speech. The naturalness of speech and music, and the emotional and esthetic appeal of musical sounds, are less definite, and have been studied principally by means of the *AB* judgment test. In this test, the observer listens to two conditions, *A* and *B*, and judges which condition is distorted, or which condition is the poorer, etc., depending on the study. Sometimes one condition may be the original sound and the other condition the reproduced sound. Although such tests do not always give a quantitative measure of the effects of distortion on naturalness, esthetic appeal, etc., they do afford a means of measuring the just-noticeable amounts of distortion. This type of test was used in studies on the audible frequency ranges of music, speech, and noise which have been reported by Snow.

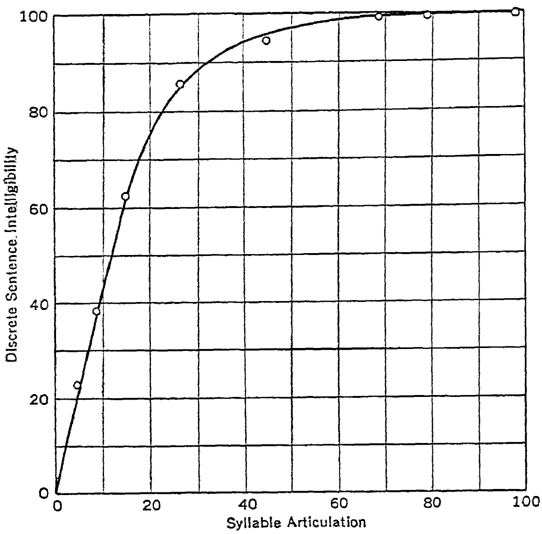

FIG. 3. Discrete Sentence Intelligibility vs. Syllable Articulation

FIELD TESTS. The results of such laboratory tests cannot be taken to indicate directly the performance of actual circuits under service conditions. In service, there is a wide range of variation in a number of conditions, such as the subject matter of conversations, the manner in which the transmitter is spoken into, the way in which the receiver is held to the ear, and the reactions of telephone users to the various circuit conditions. Because it is difficult to specify definitely such conditions and hence simulate them in the laboratory, the repetition test, which has been described by Martin, has come into use. In this test, observations are made on telephone circuits under service conditions. Essentially, the test is that of noting the repetitions in a telephone conversation and from a number of observations determining the repetition rate. Martin's paper describes repetition observations on conversations between several hundred stations in the American Telephone and Telegraph Company headquarters building and a similar number of stations in the Bell Telephone Laboratories building. To provide data for rating transmission performance, the station instruments and the transmission characteristics of the interconnecting trunks were varied and the effects on repetition rate determined. McKown and Emling have described a system of effective transmission data for rating telephone circuits, based on the results of such tests and articulation tests

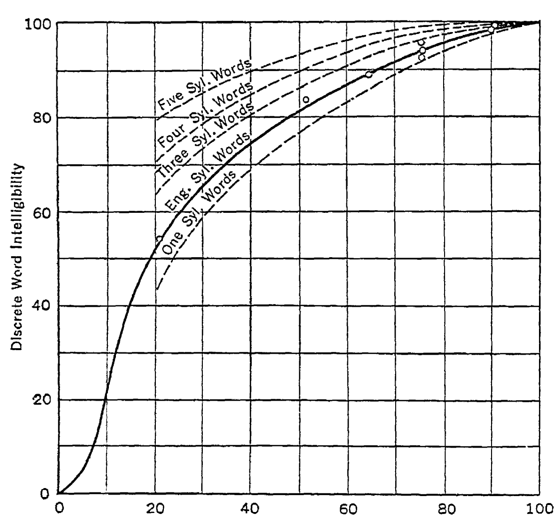

FIG. 4. Discrete Word Intelligibility vs. Syllable Articulation

OTHER TESTS. During the war a number of new tests were devised for testing speech transmission under conditions obtaining in military operations. See: *Transmission and Reception of Sounds under Combat Conditions*, Miller and Weiner, Columbia University Press, New York, 1948.

PREDICTION OF ARTICULATION TEST RESULTS. On many types of speech-transmission circuits it is possible to measure the circuit characteristics and noise levels and by means of these data compute the articulation score that would be obtained. Computational methods are also useful in the design of equipment for speech circuits and of considerable theoretical interest in the study of the interpretation of speech sounds. See: Beranek, L. EFFECTS OF DISTORTION ON SPEECH AND MUSIC

By John C. Steinberg and W. A. Munson

In studies of the effects of distortion, it is desirable to have a suitable reference system. Under certain conditions, air transmission from speaker to observer approaches such a reference. Owing to practical difficulties in changing and controlling an air transmission system, it is convenient to use electrical systems composed of transmitters, amplifiers, and receivers or loudspeakers. By suitable calibration and equalization, such systems can be made to approach air in transmission properties, and various amounts of degradation or improvement can be introduced. Circuits of this type have been studied by means of articulation and judgment tests and the effects of various kinds of distortion determined.

13. EFFECT OF FREQUENCY DISTORTION

AUDIBLE FREQUENCY RANGES OF MUSIC, SPEECH, AND NOISE. One step in the evaluation of the effects of distortion on the interpretation of sounds is the determination of the just-noticeable amounts of distortion. Snow has reported the results of tests on the lower and upper frequency limits of various types of sounds. The sounds as produced in one room were picked up by a microphone and transmitted to a second room where they were reproduced by means of loudspeakers. By means of filters, all frequencies above or below any desired cutoff could be suppressed. By comparing the unfiltered with the filtered transmission, trained observers determined the just-detectable upper and lower cutoffs. The results of the tests are shown in Fig. 1. The ends of the

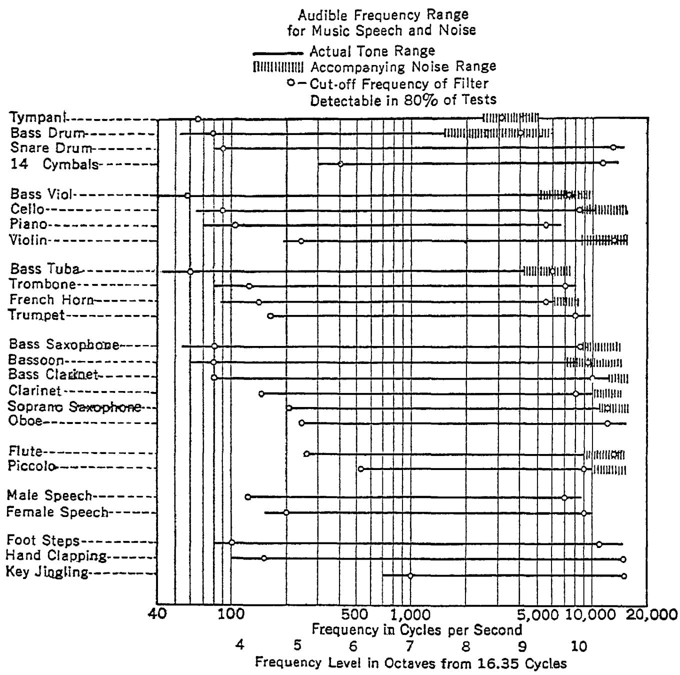

FIG. 1. Audible Frequency Ranges

lines representing the audible ranges are the cutoffs where the correct judgments amounted to 60 per cent. Circles mark the cutoffs where 80 per cent correct judgments were obtained. The musical sounds produced by many of the musical instruments were accompanied by noise such as key clicks, lip noises, "buzz" of reeds, and hissing of air. As far as possible, the observers tried to distinguish between tone and noise. The lines indicate their decision as to the actual tone range, and the short vertical lines indicate the noise range. In all cases, the upper frequency limit exceeds very greatly the frequencies of the highest notes that the instruments were capable of producing. Except for the piano, the lower limit was always set up by the frequency of the lowest note that could be produced.

EFFECT OF CUTOFF FREQUENCY ON ORCHESTRAL QUALITY. An additional type of test was made with music furnished by an 18-piece orchestra. In this test, the filtered reproduction was always presented on the *B* condition, and the unfiltered on the *A* condition. The observers were asked to rate the quality of the *B* condition as a percentage of the *A* condition. A rating of less than 100 per cent indicated a degradation; a rating of more than 100 per cent indicated an improvement. The various cutoffs occurred on the *B* condition in random order. The results of this test are given in Fig. 2. The judgment of the ten observers taking part in this test was that the quality increased rapidly as the cutoff was extended upward to 8000 cycles or downward to 80 cycles.

The results, in view of the nature of the test, were surprisingly consistent. In only about 3 per cent of some 400 observations was the quality of a filtered system given a rating greater than 100 per cent, so that, in general, the reproduction of the full audible range was preferred.

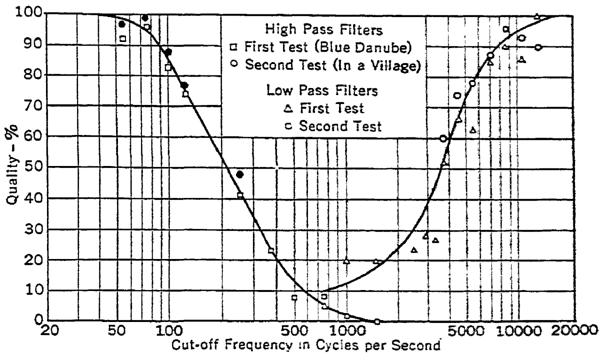

FIG. 2. Orchestral Quality vs. Cut-off Frequency

14. ARTICULATION TESTS

RELATION BETWEEN ARTICULATION AND LEVEL OF SPEECH ABOVE THRESHOLD. The articulation test affords a means of dealing with the effects of distortion in a more quantitative way than does the judgment test. An extensive series of articulation studies have been reported by Fletcher and Steinberg, for widely varying types of distortion. Figure 3 shows the effect, on syllable articulation, of changing the received speech level (see also article 31). In the range from 10 to 40 db above threshold, the articulation increases rapidly with increasing level. In the range from 50 to 90 db there is little change with increasing level. Experimentally it has been determined that, if a speaker radiates the average speech power of 10 microwatts, a listener of normal hear-

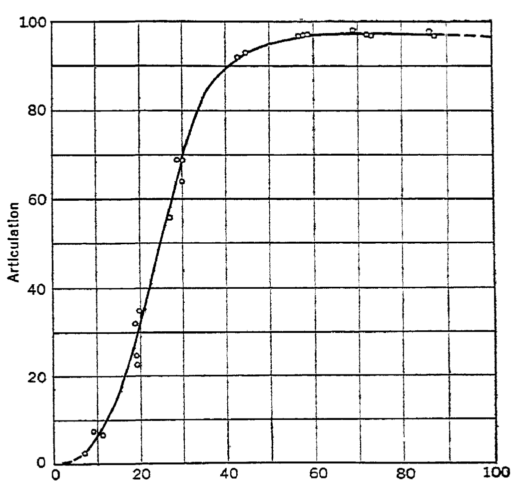

FIG. 3. Effects of Speech Level on Syllable Articulation

ing 1 meter away in the undisturbed sound field will hear the speech at a level of about 62 db above threshold. Figure 3 shows that this level is sufficient to insure very good articulation. It is a level that would obtain in conversing at a meter's distance in a quiet, well-damped room. A more detailed picture of the effects of speech level on articulation is obtained by grouping the sounds into five groups, where the sounds in each group have somewhat similar properties. The grouping used is: long vowels—*a*, *ā*, *ē*, *ō*, *o′*, *ū*; short vowels—*a′*, *e*, *i*, *o*, *u*, *w*, *y*; nasal consonants—*l*, *m*, *n*, *ng*, *r*; stop consonants—*b*, *ch*, *d*, *g*, *h*, *j*, *k*, *p*, *t*; fricative consonants—*f*, *s*, *sh*, *st*, *th*, *th′* (then), *v*, *z*, *zh* (see Table 1, p. 12-20). Figure 4 shows the group articulation vs. speech level. As the level is increased from threshold, the vowels are the first to be recognized and are followed in order by the nasal, stop, and fricative consonants. The apparent differences between the levels of the sound groups, as judged from articulation tests, correspond approximately with the differences in average phonetic powers shown in the insert. For example, the vowel articulation at a level of 25 db is about 90 per cent. The nasal consonant group must be increased 6 db from the 25-db level for an articulation of 90 per cent, and the stop and fricative consonants must be increased by 10 and 13 db, respectively.

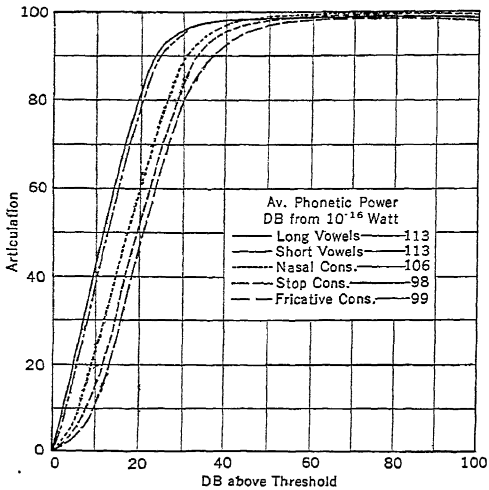

FIG. 4. Effects of Speech Level on Sound Articulation

EFFECT ON ARTICULATION OF REMOVING PORTIONS OF THE SPEECH FREQUENCY RANGE. To determine the effects of frequency distortion on articulation, electrical filters were introduced into a circuit that was otherwise reasonably free from distortion. One type of filter (low-pass filter) eliminated all components above a chosen cutoff frequency and uniformly transmitted the remainder of the range. Another type (high-pass filter) eliminated all components below a chosen cutoff frequency. Figure 5 shows the effects on articulation of changing the cutoff frequency of these filters. The level of the speech, before the filter was introduced, was held constant at 70 db above threshold. The curves marked L.P. are for the case where components below the cutoff frequency were transmitted; for the H.P. curves, components above the cutoff frequency were transmitted. The cutoff frequency at which the L.P. and H.P. curves intersect is

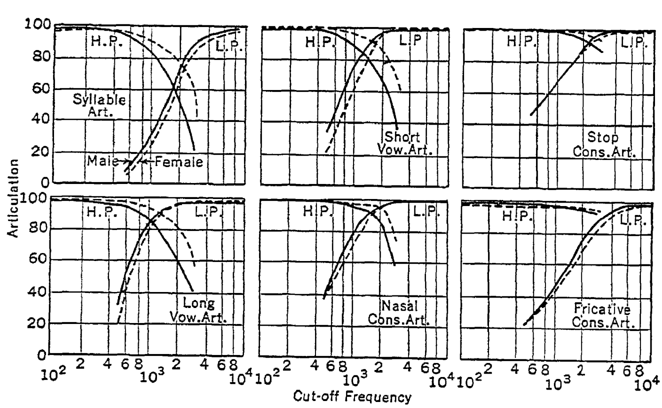

FIG. 5. Articulation vs. Cut-off Frequency

a frequency such that the frequency range below it has an articulation equal to the frequency range above it. This intersection frequency is always higher for female than for male speech, indicating that the higher-frequency ranges are more important for female speech. The frequency range in which the curves bend down is the range of importance in articulation, which as may be seen varies from one sound group to another.

EFFECTS OF AN EXTRANEOUS NOISE ON ARTICULATION. As pointed out in the article on masking, noise has the effect of shifting the threshold of audibility of other sounds heard in the presence of noise. If the masking of a noise is reasonably uniform over the important speech frequency range, articulation tests made in the presence of noise show that the main effect is to shift the curves of articulation vs. level above threshold. Figure 6 shows articulation vs. level for a quiet circuit and for the circuit with noise present at three different levels. The corresponding masking effects of the noise are shown by the insert (noise audiogram). The abscissa of the articulation vs. level curves gives the decibels above threshold of the speech on a quiet circuit. The amounts of the shift in the articulation curves correspond reasonably well with the average amounts of masking produced by the noise. When both the speech and noise levels are high, the

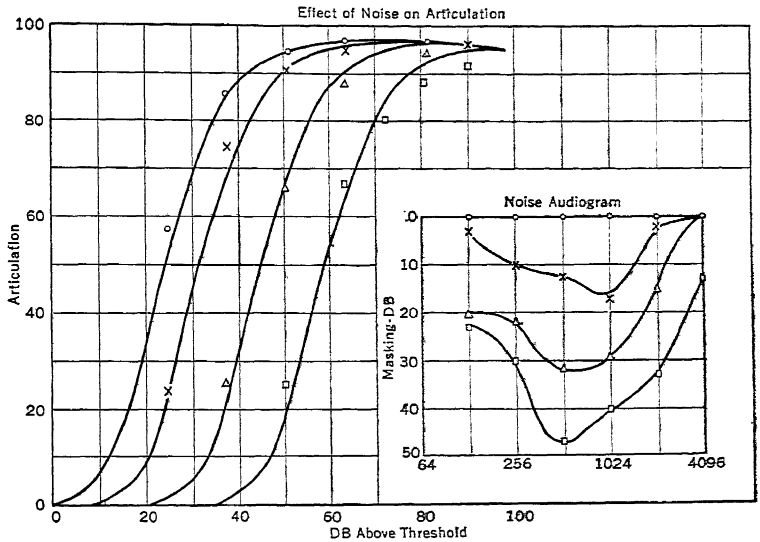

FIG. 6. Effects of Noise on Articulation

observed articulation values are less than would be indicated by a simple shift in the articulation-level curves. Modulation between the speech and the noise then takes place in the ear, which decreases the maximum value of articulation that can be obtained. When the masking is confined to a limited portion of the speech frequency range, such as that produced by a 2000-cycle tone, the effects on articulation cannot be represented by a simple shift in the articulation vs. level curves. In this case, the curves are both shifted and changed in shape. Moderate amounts of deafness affect articulation in much the same way as noise. When the hearing loss is uniform with frequency, the articulation to be expected is that obtained by a corresponding shift in the normal articulation vs. level curve.

EFFECT OF RESONANCE TYPE OF FREQUENCY DISTORTION ON ARTICULATION. A very common type of distortion occurring in transmission systems is that of resonance. Figure 7 shows the effects of a resonant peak at 1100 cycles, on articulation. The left-hand curves, numbered 2 and 3, show the loss in decibels at each frequency relative to the loss in the uniform system designated as 1. The right-hand curves show articulation vs. level for the three systems. The abscissa is the decibels above threshold of the normal speech, i.e., before inserting the resonance distortion. At the lower speech levels the decrease in articulation due to the distortion is much greater. Most of the articulation loss for a resonance type of distortion appears to arise because those sounds which have their important components in the frequency ranges removed from resonance are received at effectively lower than normal levels. For example, a large part of the important frequency range for fricative consonants is received at a level some 30 to 40 db below normal in curve 3. When the normal level is low, this further reduction causes appreciable articulation losses. Although the articulation at optimum received levels may not be seriously affected by resonance distortion, the tonal character or naturalness of the distorted speech is appreciably impaired.

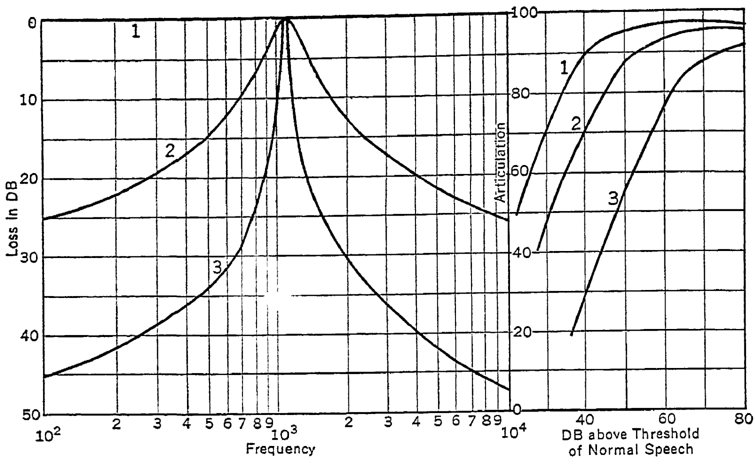

Fig. 7. Effects of Resonance Type of Frequency Distortion on Articulation

EFFECTS OF NON-LINEAR DISTORTION ON ARTICULATION. Non-linear distortion arises when the output of a system is not proportional to the input. There are two cases of interest: (*a*) when the output increases at a more rapid rate than the input; (*b*) when the output increases at a slower rate than the input. In both, modulation products or extraneous frequencies are introduced for the intense sounds when they cover an appreciable part of the curved portion of the input vs. output characteristic. The result is a decrease in the articulation of such sounds. The amount of the decrease depends upon the amount of the curvature. In addition, in (*a*) the intense sounds are amplified relative to the faint sounds, which has the effect of decreasing the articulation of the faint sounds. In (*b*) the faint sounds are amplified relative to the intense sounds. This has the effect of increasing the articulation and may, if the received speech level is below the optimum receiving level, offset the decrease due to modulation effects. For optimum receiving levels, however, the net result is always a decrease in articulation when the system is free from noise.

EFFECTS OF CLIPPING ON ARTICULATION. Articulation tests that have been made with voice-operated relays give an indication of the importance to articulation of

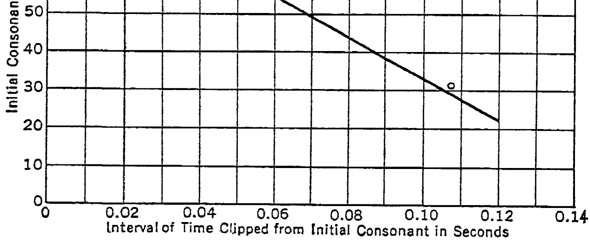

Fig. 8. Effect of Clipping an Element of Time from Speech Sounds

initial portions of the duration intervals of speech sounds. In the tests, syllables of the consonant-vowel-consonant type were spoken at intervals of about 3 sec. A circuit having a relay adjusted so as to break contact almost simultaneously with the beginning of a syllable was used. The contacts of a second relay formed a short circuit across the receiver. The operation of the first relay caused the second relay to break contact after an interval of time depending on the time constants of the relay circuit alone. The time taken for the second relay to operate represents the time clipped from the initial consonants of the syllables. Figure 8 shows the initial consonant articulation plotted against the operating time of the second relay. The data indicate that equal elements of time in the duration intervals of the sounds were of equal importance to the average articulation. For example, the average duration time of the initial consonants in these tests was about 0.16 sec. When a time interval of 0.08 sec was clipped from the sounds, the articulation was decreased by a factor of about 50 per cent.

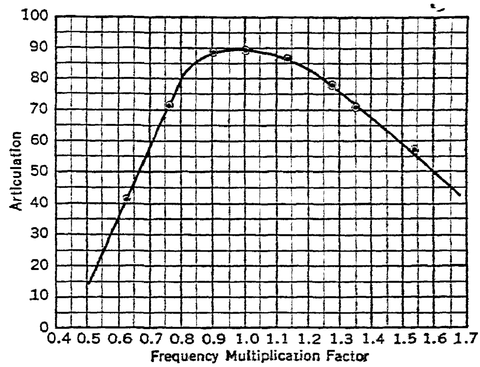

FIG. 9. Effect on Articulation of Multiplying Frequencies by a Constant Factor

EFFECTS OF FREQUENCY SHIFT ON ARTICULATION. One type of frequency shift, namely, the multiplication of frequencies by a constant factor, occurs when the speed of a sound film or phonograph turntable during reproduction is different from the speed used during recording. The effect of this type of distortion on articulation is shown in Fig. 9. Another type, the addition or subtraction of a constant number of cycles to all frequencies, occurs when the frequency of the carrier at the modulating end differs from that at the demodulating end of a carrier system. The effect of this type of shift is shown in Fig. 10. In general, the decrease in articulation is greater when the frequencies are shifted to lower values than when they are shifted toward higher values. In the first type of distortion the duration of the sounds is changed, whereas in the second type the duration is unchanged. In the first type the harmonic relationship is maintained, whereas in the second type this relationship is not preserved. In order to interpret speech sounds perfectly it seems to be necessary to preserve both these properties.

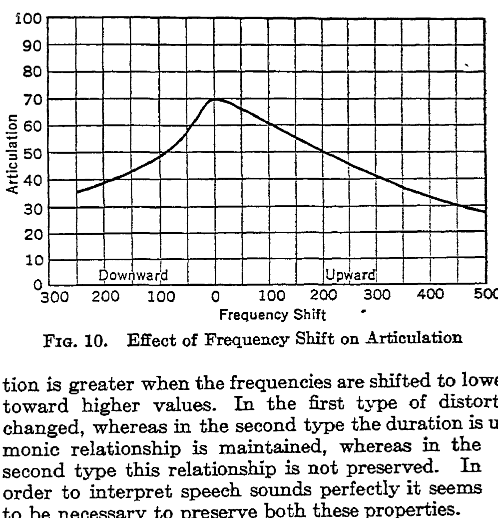

FIG. 10. Effect of Frequency Shift on Articulation

EFFECTS OF PHASE DISTORTION ON ARTICULATION. The aspect of phase distortion that has received most attention is the so-called "delay distortion" which arises when the phase characteristic of a transmission system is not proportional to frequency but is of the type shown by the curved line in Fig. 11. This type is of interest because it occurs in loaded lines and in low-pass filters. The delay distortion (see Section 5, article 9) is the difference between the slope of the phase characteristic at any frequency f and the minimum slope, and is usually expressed in the form

$$\left(\frac{\partial\beta}{\partial\omega}\right)_f - \left(\frac{\partial\beta}{\partial\omega}\right)_{\min}$$

where β is the phase shift in radians and $\omega = 2\pi f$. The approximate effect of this type of distortion is

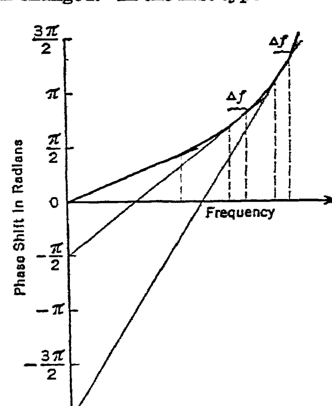

FIG. 11. A Curved Phase Characteristic

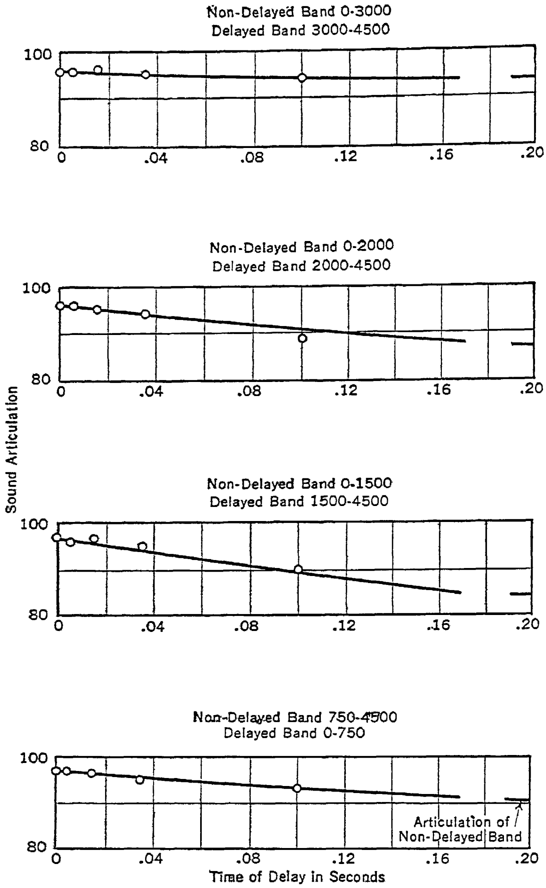

FIG. 12. Effects of Delay on Articulation

to delay the frequency components near f, with respect to those components in the range of minimum slope, by the amount of the delay distortion. The effects on articulation of delaying various portions of the speech frequency range are shown in Fig. 12. In these tests, a nominal undistorted speech frequency range of 0 to 4500 cycles was divided into two parts by means of filters and each part transmitted through a different channel. After transmission the two parts were recombined. The phase characteristic of each channel approximated a straight line over the greater part of the frequency range. The slope of the characteristic of one channel could be increased by various amounts over that of the other channel. One channel thus introduced a definite time delay, in the sense used here, with respect to the other channel, i.e., a delay given by the difference in the slopes of their phase characteristics. The articulation values decrease with increasing delay and approach the articulation of the more intelligible band which was also the least-delayed band.

To determine the effects on articulation of delay distortion which varied continuously with frequency, a system having the delay-distortion characteristics shown in Fig. 13 was studied. These characteristics were obtained from network sections of the all-pass type. By using different numbers of sections, different amounts of delay distortion could be obtained. The attenuation characteristics of the networks were equalized to 2500 cycles, and a 2400-cycle low-pass filter having negligible phase distortion was associated with the networks. Figure 14 shows the effect of the delay distortion on articulation.

To study the effects of delay distortion at higher frequencies, articulation tests were made on a system containing first one, and then twenty-five, 5000-cycle low-pass filters in series. In both cases, the attenuation was equalized to 5000 cycles. The delay-distortion characteristics and the results of

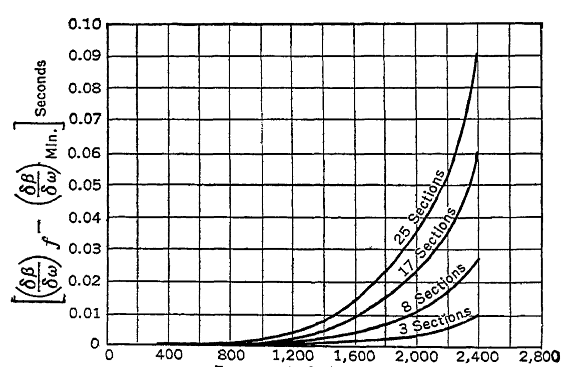

FIG. 13. Delay Distortion for an All-pass Network

the tests are shown in Fig. 15. Because the component frequencies near the cutoff are delayed by phase distortion of this type, they fail to contribute their normal amounts to the total articulation carried by the unattenuated frequency band. Thus the distortion has the effect of reducing the transmitted frequency range, so that the effective transmitting range depends upon both the phase and the attenuation characteristics.

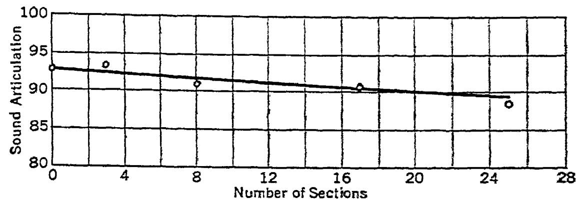

FIG. 14. Articulation vs. Delay Distortion

AUDIBLE EFFECTS OF PHASE DISTORTION. Quite aside from the effects on articulation, when speech from a system having phase distortion is compared with that from a system of negligible distortion, it is noticed that the distorted speech is accompanied by certain audible effects which appear to be extraneous to the speech and transient in character. These effects, which are due to components of different frequencies arriving at different times, are often termed "birdies" or "tweets," for delay distortion of the type shown above. Their noticeableness depends upon the amount of delay distortion and the frequency range in which it occurs. For speech, it was found that one section of the all-pass network, when associated with a 2400-cycle low-pass filter, had sufficiently small delay distortion so as to be just noticeable. This determination was made by alternately listening to speech from the system under two conditions: one, the filter alone; two, the

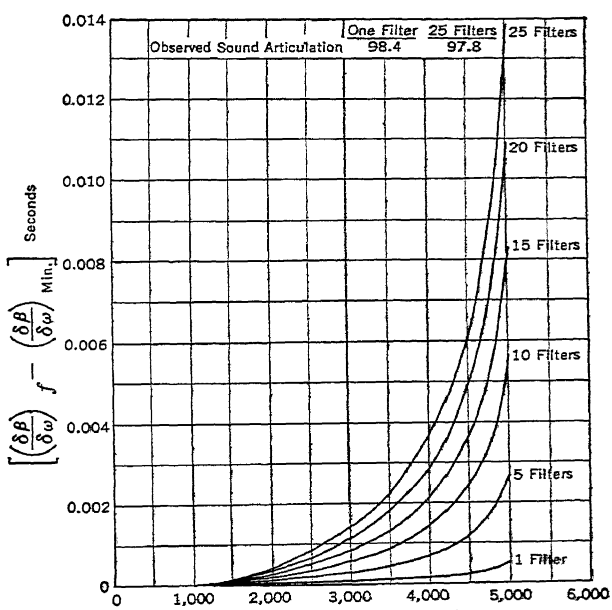

FIG. 15. Articulation and Delay Distortion for 5000-cycle Low-pass Filters

filter with the all-pass network. Judgments of which condition contained the network were correct about 50 per cent of the time and wrong about 50 per cent of the time for one section of the network. The total delay distortion at the cutoff frequency in this case, i.e., that due to the filter plus that due to one section of the network, was about 0.006 sec. When three sections were used the distortion was easily noticed.

Similar tests with the 5000-cycle low-pass filters indicated that some number between 5 and 10 filters in tandem would cause just-noticeable distortion and that the distortion was clearly noticeable for 20 filters in tandem. The amount of delay distortion at the cutoff frequency for 5 filters is about 0.003 sec, and for 10 filters about 0.006 sec.

The above figures depend somewhat upon the attenuation characteristic as the cutoff frequency is approached, small amounts of attenuation reducing the noticeability of the effects. The figures also vary somewhat with individuals, depending upon their experience and hearing characteristics.

Tests on piano reproduction when single notes were struck or when a passage of music was played indicated that the distortion caused by 25 of the 5000-cycle low-pass filters in tandem was not noticeable. As in speech, it would be expected that the noticeableness of the distortion would depend upon the frequency range in which it occurs. In general, the effects of delay distortion on music are very much less noticeable than on speech, which is probably due in part to the more sustained character of music.

EFFECTS OF ROOM REVERBERATION ON ARTICULATION. To determine the effects of room reverberation on articulation, the microphone of a system substantially

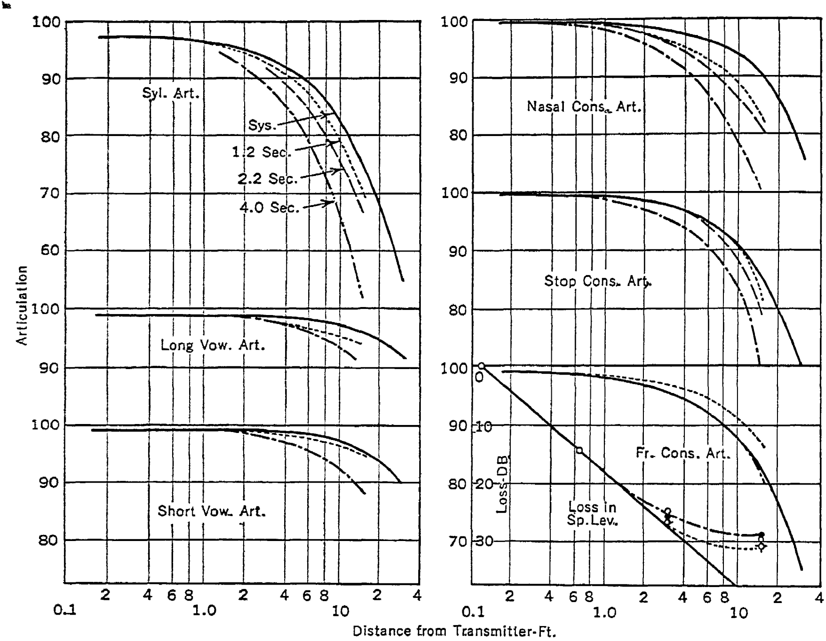

FIG. 16. Effect of Reverberation on Articulation

free of distortion was placed in a room having variable reverberation conditions. The room dimensions were 20 ft by 30 ft by 15 ft. The reverberation time was practically uniform over the important speech frequency range. The articulation tests were made under three conditions of reverberation, corresponding to the reverberation times 1.2, 2.2, and 4.0 sec, and for the following four distances between the diaphragm of the microphone and the lips of the speaker, 0.12 ft, 0.66 ft, 3.0 ft, and 15 ft. In all the tests, the speaker faced toward the microphone. Observers listened in another room, by means of head receivers, to the speech picked up by the microphone in the reverberant room. A volume indicator was used to measure the level of the speech from the microphone. The instrument measures, substantially, the phonetic power of the vowel sounds. The gain of the system between microphone and receiver was set so that the level of the speech received by the observers, for the close talking condition, was 74 db above threshold. The gain of the system was then kept constant for all tests. The loss in speech level vs. distance between microphone and speaker, and the articulation results, are shown in Fig. 16. The speech level decreased inversely as the square of the distance for distances up to 1 ft from the transmitter, but at the 15-ft distance the level was some 12 db greater than the level obtained by assuming the inverse square relation. The solid curves designated as "sys."

show articulation vs. distance between speaker and microphone, for the system alone. They are graphs of the data of Figs. 3 and 4, where level above threshold has been converted into distance between speaker and microphone. This was done by means of the solid curve showing loss in speech level vs. distance, and taking the level for zero loss as 74 db above threshold. This level is, of course, some 20 db less than the level the observer would have received if the speaker had spoken directly into his ear from a distance of 0.12 ft. A comparison of the curves indicates that the various sound groups were not uniformly attenuated by increasing the distance between speaker and microphone. For a given distance, the effect of increasing the reverberation time was always in the direction of decreasing the articulation, even though the received speech levels increased as the reverberation increased. For distances up to 15 ft, at least, the articulation was appreciably less for a reverberant room than it would be for one with perfectly absorbing walls.

15. AUDITORY PERSPECTIVE

Part of the emotional and esthetic appeal of sounds, when listened to directly with both ears, may be ascribed to the appreciation of their spatial character. When this property of sound waves is preserved in reproduction, the sounds are said to be reproduced in true auditory perspective. Ideally, there are two ways of accomplishing such reproduction. One is binaural reproduction, which aims to reproduce in the distant listener's ears, by means of head receivers, exact copies of the sound waves that would exist in his ears if he were listening directly. In this case, a complete system consisting of microphone, line, and receiver is used for each ear. The other method uses loudspeakers and aims to reproduce in the distant hall an exact copy of the pattern of sound vibration that exists in the original hall. In the limit, an infinite number of microphones and loudspeakers of infinitesimal dimensions would be needed. In a symposium on reproduction in auditory perspective the basic requirements for the production of orchestral music were discussed and a practical system designed to achieve auditory perspective was described (*Bell Sys. Tech. J.*, April 1934).

ACOUSTIC PROPERTIES OF ROOMS

By Vern O. Knudsen

The acoustic quality of nearly all communication systems, as radio, television, telephony, motion pictures, phonograph recording, hearing aids, and public-address and other sound-amplifying or -reproducing systems, is largely influenced by the acoustic properties of the rooms in which the sound to be transmitted or recorded is generated, and in which this sound is reproduced.

The following definitions pertinent to the acoustic properties of rooms have been selected from American Standard Acoustical Terminology—Z24.1–1942 (see *J. Acous. Soc. Am.*, Vol. 14, 84–110 [1942] for these and other pertinent definitions).

Effective Sound Pressure (P). The effective sound pressure at a point is the root mean square value of the instantaneous sound pressure over a complete cycle, at that point. The unit is the dyne per square centimeter.

Pressure Level.* The pressure level, in decibels, of a sound is 20 times the logarithm to the base 10 of the ratio of the pressure P of this sound to the reference pressure P_0. Unless otherwise specified, the reference pressure is understood to be 0.0002 dyne per sq cm.

* In discussing sound measurements made with pressure or velocity microphones, especially in inclosures involving normal modes of vibration or in sound fields containing standing waves, caution must be observed in using the terms "intensity" and "intensity level." Under such conditions the terms "pressure level" or "velocity level" are preferable since the relationship between the intensity and the pressure or velocity is generally unknown.

Velocity Level.* The velocity level, in decibels, of a sound is 20 times the logarithm to the base 10 of the ratio of the particle velocity of the sound to the reference particle velocity. Unless otherwise specified the reference particle velocity is understood to be 5×10^{-6} cm per sec effective value.

Sound Energy Density (E). Sound energy density is the sound energy per unit volume. The unit is the erg per cubic centimeter.

Sound Intensity * (I). The sound intensity of a sound field in a specified direction at a point is the sound energy transmitted per unit of time in the specified direction through a unit area normal to this direction at the point. The unit is the erg per second per square centimeter, but sound intensity may also be expressed in watts per square centimeter.

Intensity Level * (I_L). The intensity level, in decibels, of a sound is 10 times the logarithm to the base 10 of the ratio of the intensity I of this sound to the reference intensity I_0. Unless otherwise specified the reference intensity I_0 shall be 10^{-16} watt per sq cm.

Echo. An echo is a wave which has been reflected or otherwise returned with sufficient magnitude and delay to be perceived in some manner as a wave distinct from that directly transmitted.

Multiple Echo. A multiple echo is a succession of separately distinguishable echoes from a single source.

Flutter Echo. A flutter echo is a rapid succession of reflected pulses resulting from a single initial pulse. If the flutter echo is periodic and if the frequency is in the audible range it is called a musical echo.

Noise. Noise is any undesired sound.

Acoustic Reflectivity. The acoustic reflectivity of a surface not a generator is the ratio of the rate of flow of sound energy reflected from the surface, on the side of incidence, to the incident rate of flow. Unless otherwise specified, all possible directions of incident flow are assumed to be equally probable. Also, unless otherwise stated, the values given apply to a portion of an infinite surface, thus eliminating edge effects.

Acoustic Absorptivity. The acoustic absorptivity of a surface is equal to 1 minus the reflectivity of that surface. (Sometimes called *Sound-absorption Coefficient.*)

Sabin. The sabin is a unit of equivalent absorption; it is equal to the equivalent absorption of 1 sq ft of a surface of unity absorptivity, i.e., of 1 sq ft of surface which absorbs all incident sound energy.

Acoustic Transmittivity. The acoustic transmittivity of an interface or septum is the ratio of the rate of flow of transmitted sound energy to the rate of incident flow. Unless otherwise specified, all directions of incident flow are assumed to be equally probable.

Reverberation. Reverberation is the persistence of sound, due to repeated reflections.

Rate of Decay (of Sound Energy Density). The rate of decay of sound energy density is the time rate at which the sound energy density is decreasing at a given point and at a given time. The practical unit is the decibel per second.

Reverberation Time (T). The reverberation time for a given frequency is the time required for the average sound energy density, initially in a steady state, to decrease, after the source is stopped, to one-millionth of its initial value. The unit is the second.

Mean Free Path. The mean free path for sound waves in an inclosure is the average distance sound travels in the inclosure between successive reflections.

16. REQUIREMENTS FOR GOOD ACOUSTICS

In order that a room may have good acoustics it is necessary (1) that the sound be sufficiently loud in the room; (2) that the room be free from noise whether of internal or external origin; (3) that the room be free from echoes, "flutters," or other interfering reflections; (4) that the reflecting boundaries of the room be so disposed as to provide a nearly uniform distribution of sound energy throughout the room; (5) that the room be free from undesirable resonance; and (6) that the reverberation in the room be sufficiently reduced to avoid excessive overlapping or commingling of successive sounds of articulated speech or music, but that the room be sufficiently "live" at all frequencies to give a pleasing effect to either speech or music as judged by the average listener.

In order to attain these necessary conditions for good acoustics the architect and acoustical engineer must assume responsibility relating to the following: (1) the selection of the

* In discussing sound measurements made with pressure or velocity microphones, especially in inclosures involving normal modes of vibration or in sound fields containing standing waves, caution must be observed in using the terms "intensity" and "intensity level." Under such conditions the terms "pressure level" or "velocity level" are preferable since the relationship between the intensity and the pressure or velocity is generally unknown.

site; (2) the making of a noise survey in the proximity of the proposed site; (3) the selection of a general type of wall and ceiling construction which will insulate the building adequately against external noise and vibration; (4) the selection and arrangement of rooms which require acoustical designing; (5) the design of the rough sketches for all speech rooms, music rooms, recording or broadcasting rooms, based upon the requirements for the proper distribution of direct and of reflected sound; (6) the application of appropriate formulas and principles to the detailed design of shape, sound insulation, and sound absorption for all rooms which require acoustical designing; (7) the selection of materials which will satisfy the acoustical, structural, decorative, and economic requirements; (8) the supervision of all aspects of construction which will affect the outcome in acoustics, and especially the making of tests on such materials as acoustical plaster; and (9) the testing of the completed building with regard to the distribution of sound; freedom from echoes, sound foci, or interfering reflections; the optimal conditions of reverberation; and the adequacy of sound insulation. In general, the acoustic problem consists of the adequate reduction of noise and vibration, and the designing of interiors in which the voice or instrumentation is heard or recorded most satisfactorily. All the factors mentioned in this section relate to the problem of room acoustics. One of the most basic of these factors is the problem of the growth and decay of sound in a room or, more strictly, the transient and steady-state behavior of sound in that room. Before considering this problem, it will be helpful to describe briefly two possible approaches to this and related problems: one, geometric acoustics, and the other, wave acoustics.

17. GEOMETRIC AND WAVE ACOUSTICS

Geometric or "ray" acoustics, as applied to the acoustics of rooms, assumes that sound travels in rays, that its frequency remains unchanged during the transient state as well as the steady state, that the rays are reflected, with partial absorption and transmission, at each encounter with the boundaries of the room, and that after a number of successive reflections the sound in the room becomes diffuse (all directions of propagation being equally probable) and of uniform energy density throughout the room. Obviously, this oversimplifies the actual behavior of sound waves in the room, especially when the wavelengths of the sound, as is often the case, are not small compared with the dimensions of the room; it neglects entirely such important properties as the normal modes of vibration of the room, interference, and diffraction. In spite of these shortcomings, it leads to many principles and formulas by means of which the acoustical engineer or architect can design auditoriums with satisfactory acoustics.

Wave acoustics deals with sound as waves; it offers the only means of dealing rigorously with wave phenomena in bounded spaces, with interference, diffraction, normal modes of vibration, and with the influence of localized areas of absorptive material and of irregularities of the contours of the boundaries of the room on both the transient and steady states of the sound in the room. The difficulties in applying wave acoustics to rooms are so great that very little progress has been made until recently, and even now much remains to be done before it can be used effectively by the average architect or acoustical engineer.

Historically, the study of the acoustic properties of rooms began and has continued, very largely, on the assumption that geometric acoustics is adequate to cope, at least approximately, with the transient and steady-state behavior of sound waves in most rooms. Obviously, the methods of geometric acoustics furnished satisfactory approximations in rooms in which the ratio of the room dimensions to the wavelength of the sound is large and in which the sound distribution is thoroughly diffuse (the "ergodic" state), but in most rooms, and especially for sounds of low frequency, the more rigorous methods of wave acoustics, recently developed by Morse and Bolt, should be used so far as this is possible. (See Morse and Bolt, Sound Waves in Rooms, *Reviews of Modern Physics*, April 1944). These methods of wave acoustics already have explained many apparent anomalies in room acoustics, especially those relating to the absorptive properties of acoustic materials as used in different rooms. No one who is not familiar with these methods should undertake the design of a room in which good acoustics is a prime requirement. Unfortunately, the results of these studies are not yet sufficiently simplified to be used by the average engineer as the basis for making routine analyses of the acoustic properties of rooms. Fortunately, on the other hand, the approximate and much simpler methods of geometric acoustics, when used with an understanding of the consequences and modifications which wave acoustics entails, will be found to be satisfactory for making the routine calculations which govern the acoustic properties of most rooms, such as offices, restaurants, classrooms, and residential rooms. For the acoustic design of broadcasting and motion-picture studios, auditoriums, theaters, churches, music rooms, courtrooms, lecture rooms, and all other rooms in which high-quality speech and music are required, full use should be made of the methods of wave acoustics, as far as they are applicable.

For the present, the methods of geometric acoustics continue to be used by most engineers for designing or correcting the acoustic properties of rooms, and their methods probably will continue to be used for possibly another five to ten years, but they should be used only in the light of existing and advancing knowledge of wave acoustics. In the following treatment, based largely on geometric acoustics, the practical modifications which wave acoustics imposes or suggests will be considered, and those who use this handbook as a guide for planning for good acoustics should give similar consideration to the relevance of wave acoustics in modifying the calculations and conclusions based on geometric acoustics.

18. GROWTH AND DECAY OF SOUND IN ROOMS—GENERAL CONSIDERATIONS

The approximate theories in use today are based upon the assumptions that sound, originating at some point in a room, propagates rays of vibratory energy with a speed of about 1125 ft per sec, uniformly in all directions; that these rays are partially reflected by the boundaries of the room; and that even after the source of sound is stopped these rays persist with their original frequency but become feebler after each reflection until ultimately they become inaudible. In these approximate theories it is assumed that the sound energy persists in rays or bundles; that, during the decay, the sound energy in the room remains constant in these rays or bundles for a short interval of time, equal to the time required for a ray to travel the average distance between successive reflections, the *mean free path*, and that then the total sound energy in the room suddenly drops a certain amount determined by the "average" (usually the weighted arithmetical mean) acoustic absorptivity of the boundaries of the room; and that this process of absorption by discrete steps continues until all the sound energy is converted into heat.

Although most of the absorption takes place at the boundaries at low frequencies, the absorption in the air at frequencies above 5000 cycles may be greater than the absorption at the boundaries. If the source continues to generate sound at a constant rate, a condition of equilibrium will be reached in which the rate of supply of sound energy to the room is just equal to the rate of absorption by the air and the boundaries. If the source is then stopped the sound in the room will die away at a rate equal to the rate of absorption, which is determined principally by the size, the shape, and the boundaries of the room. Although this decay is strictly made up of the free, damped, normal modes of vibration of a three-dimensional continuum, the decay is approximately represented by the simplification described above, provided that the absorptive material is distributed throughout the boundaries of the room and especially that it is not concentrated on one or two walls of the room. (Walls, as here used, refers also to the floor and ceiling.)

According to this simplification, the time required for the intensity of the sound to be reduced a specified amount will depend upon (1) the number of reflections which occur per unit time, and (2) the amount of sound energy which is absorbed at each reflection. If the room is a large one there will be only a few reflections per second; and in addition, if but a little sound energy is absorbed at each reflection, it will require a relatively long time for the intensity of ordinary sound to be reduced to the threshold of audibility. Such a room will be excessively reverberant. On the other hand, if the room is small and the boundaries highly absorptive, the room will be free from reverberation. Since the average intensity of speech or music in a room is of the order of one million times the intensity which is just barely audible, and since the hard, rigid boundaries may reflect as much as 98 per cent of the incident sound energy, it is apparent that an appreciable time, amounting to several seconds in many instances, is necessary for the sounds of speech or music to be reduced to inaudibility.

Thus, consider a room having a mean free path of 51 ft. Since the velocity of sound at room temperature (20 deg cent) is approximately 1122 ft per sec, there will be in this room just 22 reflections each second. Hence, if the initial sound in this room has an intensity of one million threshold units, and if 98 per cent of the initial sound energy is reflected at each encounter with the boundaries, to reduce the sound energy to one-millionth of its initial amount would require n successive reflections, where n is given by $0.98^n = 0.000001$. Solving, n is 684; that is, it requires 684 successive reflections in this room for the sound energy to die away to inaudibility. Since 22 reflections occur each second in this room, the time required for the sound to die away to inaudibility is $684 \div 22$, or 31.1 sec; that is, the time of reverberation in this room is 31.1 sec. By a similar consideration it can be shown that if this same room were completely lined with a material that reflects 50 per cent of the incident sound energy the total number of reflections would be reduced to 19.9, and the time of reverberation would be of the order of 0.9 sec. These simple considerations neglect the absorption of sound in the air, which at high frequencies will greatly modify these calculations. This type of absorption will be considered later in this section.

The formulas to which such approximate theories lead are sufficiently valid for most practical purposes in rooms which are bounded by materials having the same coefficient of absorption. However, in rooms bounded by materials having widely different coefficients of absorption, the formulas approach validity only as the decadent sound in the room is made to approach a completely diffuse state. It should be clearly recognized therefore that the formulas which will now be presented must be used with *caution* and *understanding*, especially with reference to the *average* coefficient of absorption in rooms which are bounded partly by highly reflective and partly by highly absorptive materials.

19. REVERBERATION EQUATIONS

The early experiments of W. C. Sabine show that the time of reverberation in a room is proportional directly to the volume of the room and inversely to the total amount of absorption supplied by the boundaries of the room. Sabine was able to determine experimentally the constant of proportionality k between reverberation time T and the volume V divided by total absorption a. Thus,

$$T = \frac{kV}{a} \tag{1}$$

The value of k as determined experimentally by Sabine for a large number of rooms of different shapes and sizes, at normal room temperatures, is approximately 0.05 when V is in cubic feet and a is in sabins (British units) and 0.164 when V is in cubic meters and a is in square meters (metric units). A few years later, Franklin and also Jaeger obtained this same equation from theoretical considerations.

This equation was used for nearly 30 years for calculating the reverberation time of either contemplated or finished rooms. Even the fallacious conclusion to which the equation leads for a room with totally absorptive surfaces, namely, that $T = kV/S$ instead of zero (where S is the total surface area of the room), was overlooked or was not sufficiently disturbing to destroy confidence in its validity, until recently. The equation is satisfactory in practice for frequencies between about 200 and 1000 cycles in the large majority of rooms in which the absorptive material is distributed and in which the rate of decay of sound is slow; that is, the equation applies to "live rooms," provided the frequencies are high enough to be well above the fundamental resonant frequency of the room but not high enough to involve a consideration of the attenuation in the medium.

MODIFICATION OF THE REVERBERATION FORMULA. A more satisfactory reverberation formula can be obtained by recognizing that the decay of sound takes place *discontinuously*, at time intervals equal to the time required for sound to travel the mean free path. The mean free path is given for rooms of conventional shape as $4V/S$. Strictly it is dependent upon the shape of the room and the location of the source, so that the equation is not accurate for rooms of peculiar shape. Thus, for the usual location of the source of sound and for the first 25 successive reflections, the mean free path is $4.3V/S$ for a large church or cathedral of cruciform shape and is $3.7V/S$ for a room with large horizontal dimensions and a low ceiling, the usual shape for large office and work rooms.

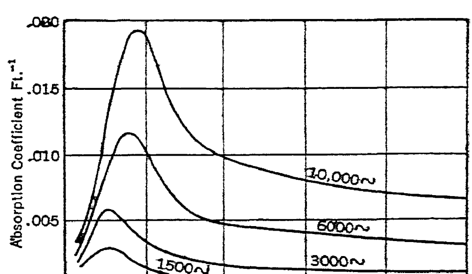

FIG. 1. Coefficients of Absorption of Sound in Air Containing Different Amounts of Water Vapor, for Frequencies of 1500, 3000, 6000, and 10,000 Cycles

Allowance must also be made for the absorption of sound in the air of the room, which is of considerable importance at the higher audible frequencies and especially in large rooms. The curves of Fig. 1 give the absorption coefficient m per foot for plane waves in air at 20 deg cent. It will be seen from the curves in Fig. 1 that m has a maximum for a certain concentration of water vapor, different for each frequency.

Based upon the inclusion of these factors and a mean free path of $4V/S$ the time of reverberation is

$$T = \frac{55.3V}{c[4mV - S \ln (1 - \bar{\alpha})]} \tag{2}$$

where c is the velocity of sound and $\bar{\alpha}$ is the arithmetic mean of the absorption coefficients of all the boundaries of the room.

At room temperature, 21 deg cent, $c = 1125$ ft per sec, so that for most working conditions

$$T = \frac{0.049V}{4mV - S \ln (1 - \bar{\alpha})} \tag{3}$$

in British units, or

$$T = \frac{0.161V}{4mV - S \ln (1 - \bar{\alpha})} \tag{4}$$

in metric units (see above). For frequencies below about 1000 cycles, m is so small that the first term in the denominator of eqs. (2), (3), or (4) can be neglected, that is, the absorption in the air is inappreciable; whereas, at high frequencies (above 5000 cycles), this term may become larger than the second (or surface absorption) term. At sufficiently high frequencies (above the audible range), the second term will become negligible, in which case the rate of decay and consequently the time of reverberation will be independent of the size of the room.

The foregoing reverberation formula, eq. (2), is sufficiently valid for practical purposes provided the sound in the room is thoroughly diffuse throughout the decay. This condition is realized for frequencies above about 250 cycles in all but very small rooms, provided all the boundaries of the room have approximately the same absorptivity, or provided suitable rotating paddles or "warble tones" are used to "mix" the sound in the room. Suitable precautions, such as those just mentioned, can be taken in making measurements in an acoustical laboratory, such as a reverberation chamber. In many rooms encountered in practice, the absorptive material may be concentrated on a single surface, as when a carpet, upholstered seats, and audience are all located on the floor, and the other surfaces in the room are highly reflective. In such rooms, especially if the opposite walls are parallel and not too far apart, the decay of sound will not conform to the approximately exponential decay predicted by eq. (2) but will consist, first, of a rapid rate of decay while the sound is relatively diffuse, and second, of a much slower rate of decay, made up largely of a horizontal flow of sound energy between the parallel and highly reflective walls, i.e., of modes of vibration which are directed at grazing incidence to the floor. The time of reverberation in such a room will be longer than that calculated by means of eq. (2), using an arithmetical mean for $\bar{\alpha}$.

This is borne out by some oscillograms of the rate of decay obtained in a small room, 8 ft by 8 ft by 9.5 ft (high), with the floor covered with a material having a rated absorption coefficient of 0.60 at 512 cycles and with the walls and ceiling finished with painted concrete. The first part of the decay (15 to 17 db) was relatively rapid, 95 to 100 db per sec. This was followed by a much slower decay, 38 to 40 db per sec. If the first part of the decay is used for calculating the time of reverberation T and the absorptivity of the floor material α, we obtain $T = 0.61$ sec and $\alpha = 0.55$. If the latter part is used, $T = 1.54$ sec and $\alpha = 0.22$. It will be noted that the first part of the decay, while the sound is relatively diffuse, yields a value for α which agrees fairly well with the rated value of 0.60 and therefore conforms reasonably well with the requirements of eq. (2), whereas the latter part of the decay, which is made up largely of the horizontal modes of vibration, is much slower than would be predicted by eq. (2). This is an extreme example of the inadequacy of eq. (2), which is based on geometric acoustics, to account for the true nature of the decay of sound in a room in which the absorptive material is concentrated on one wall (or floor or ceiling). Wave acoustics, on the other hand, accounts for the observed results very satisfactorily.

Fortunately, for the best acoustical quality in a room the absorptive material should be distributed on all surfaces of a room so that the rate of decay will be at least approximately the same in all directions, and under these circumstances eq. (2) will yield results which, as a rule, do not differ more than 10 per cent from the observed values. Furthermore, in very large rooms, as in theaters, school auditoriums, and churches, there is very little tendency for the reverberation to persist in two dimensions, even though most of the absorption is concentrated on the floor or on the floor and in the ceiling, (1) because the dimensions of the room are large compared with the wavelengths of the sound, and (2) because the architectural treatment of large rooms usually involves structural forms and ornamentations which tend to diffuse the sound during free decay.

In such rooms, provided there are no curved surfaces giving rise to concentrations of sound, the first 30 db (or more) of decay conforms very closely to eq. (2); and it is this portion of the decay that is pertinent to the acoustic quality of speech and music in rooms. Stated otherwise, the rate of decay after the first 30 db of decay is of little consequence, since in articulated speech or music such residual sounds will be so weak as to be completely masked by the primary (and much louder) sounds that follow. It is apparent, therefore, that eq. (2) is satisfactorily valid for the practical calculations of reverberations in most rooms. In many small rooms, such as are frequently used for radio broadcasting or for the recording of sound, it is important that the sound-absorptive materials be distributed quite uniformly throughout the room if eq. (2) is to be applicable. The true rate of decay of sound in small rooms is greatly dependent upon room resonance.

20. ROOM RESONANCE

A room is a resonant chamber, with resonant properties similar to those of a violin string, an organ pipe, or a diaphragm of a telephone receiver, except that in general the resonant properties of the room are much more complicated than those of one- or two-dimensional systems. Thus, if the dimensions of a rectangular room are l_1, l_2, and l_3, the "resonant" or normal frequencies ν for the room are given approximately by

$$\nu = \frac{c}{2}\left[\frac{l_1^2}{n_1^2} + \frac{l_2^2}{n_2^2} + \frac{l_3^2}{n_3^2}\right]^{1/2} \tag{5}$$

where c is the velocity of sound in the room, and n_1, n_2, and n_3 are order numbers having values of 0, 1, 2, 3, ... In a room where $l_1 = 8$ ft, $l_2 = 8$ ft, and $l_3 = 9.5$ ft, the gravest mode of vibration is given by $n_1 = n_2 = 0$ and $n_3 = 1$; that is, the room resonates as does an organ pipe, 9.5 ft long and stopped at both ends, when vibrating at its gravest mode. The wavelength of this gravest normal mode is 19 ft, and the frequency (assuming $c =$ 1125 ft per sec) is 59.2 cycles. Other resonant or normal frequencies, in ascending order, for this room, are 70.3, 92.8, 99.8, 116.0, 119.2 cycles, and continuing in a triply infinite series of frequencies corresponding to increasing values of the n's. When none of the n's is zero the resonant standing waves are *oblique*, and when one or two of the n's are zero the waves are *tangential*; that is, the waves move parallel and grazing to one or two, respectively, pairs of walls in the rectangular room.

The above-enumerated normal frequencies for the room under discussion have been observed, both by the "reinforcement" the room gives to steady tones of these frequencies, and by the transient decay of tones which have approximately these frequencies. Thus, Fig. 2 is a series of oscillograms showing the free decay of sound for this room when it is excited with tones having different "driving" frequencies between 90 and 101 cycles, as indicated above each oscillogram. When the room is excited with a frequency of 92.9 cycles, which corresponds closely to the normal mode having a frequency of 92.8 cycles, the free decay is made up almost exclusively of this one mode, and its decay rate is smooth and almost exactly exponential. Similarly, when the room is excited by any other frequency which differs only slightly from 92.8 cycles, the free decay is made up of this one mode, and the frequency during decay *is not the driving frequency* but is *always the frequency of this normal mode.* When the room is excited with a frequency of 96.7 cycles, which is about midway between the frequencies of the two modes of 92.8 and 99.8 cycles, the free decay is made up of these two normal modes, which are about equally excited, giving rise to the pronounced beats of about 7 per second, as expected, since the two natural frequencies differ by 7 cycles. When this same room was excited at a frequency of 118 cycles, the oscillogram of the free decay revealed the coexistence of beats at about 3.3 and 19.3 cycles, which no doubt arose from the simultaneous excitation of the three neighboring normal frequencies of 99.8, 116.0, and 119.2 cycles. No matter what frequency is used for exciting the room, the "reverberation" always consists of the free decay of one or more of the room's normal modes of vibration.

The foregoing results demonstrate that reverberation is not the persistence of *rays* of sound which continue, after the source is stopped, as rays of sound successively reflected back and forth in the room, but rather is the free decay of one or more (and usually many) modes of vibration. However, Strutt has shown that the formal law governing the free, damped vibration of the sound in a room approaches asymtotically the simple reverberation law of eq. (2) as the wavelength of the exciting sound becomes short in comparison with the wavelength of the gravest mode of vibration for the room. Thus, in a room (assuming the absorptive material to be fairly well distributed) having its longest dimension 10 ft, which is about the smallest room in which acoustics is a factor of importance, the wavelength of the gravest mode is 20 ft. In such a room, sound having a wavelength of one-tenth of that of the fundamental, namely, 2.0 ft, would be sufficiently short to conform reasonably well to eq. (2).

In other words, when the room is filled with sound having a wavelength shorter than 2.0 ft, that is, a frequency greater than about 560 cycles, the modes of vibration which are excited are so numerous and their frequencies so close together that the sound in the room is essentially diffuse and, therefore, the requirements are fulfilled for the approximate theories of reverberation described in the earlier paragraphs of this section, especially if

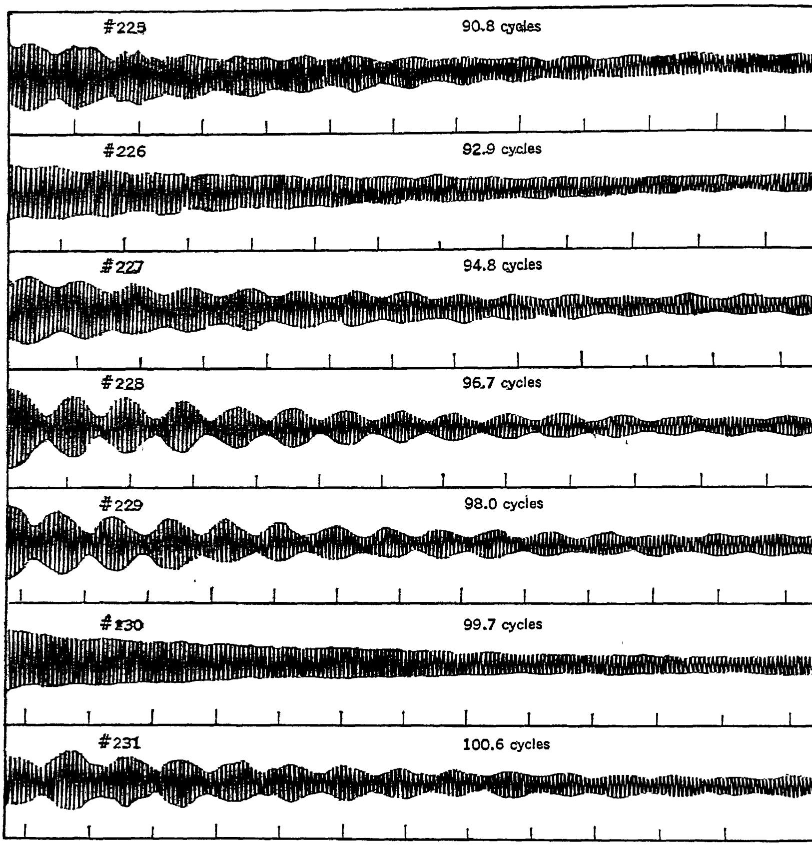

FIG. 2. Oscillograms of the Decay of Sound in a Small Rectangular Room, Showing that the Decay of Sound Consists of the Damped Free or Normal Vibrations of the Room

the absorptive material is distributed uniformly over the boundaries of the room or if some means are provided for mixing or diffusing the sound during the decay. In large rooms, such as concert halls, church or school auditoriums, and theaters, the lowest modes of vibration are usually in the subaudible range of frequencies, so that the elementary theory of reverberation applies with adequate rigor in such rooms for all frequencies above about 100 cycles, and the effects of room resonance usually can be neglected. (For further details consult M.J.O. Strutt, *Zeitschrift angew. Math. Mech.*; Knudsen, *J. Acous. Soc. Am.*, Vol. 4, 20–37 [1932]; and Morse and Bolt, *loc. cit.*)

REVERBERATION IN COUPLED SPACES. When two or more inclosures are coupled by means of openings such as open doors, passageways, or even thin partitions which are capable of transmitting an appreciable amount of sound, the reverberation in each inclosure is affected by the reverberatory properties of the other inclosure. Thus, most auditoriums of the theater type are divided into at least three coupled spaces—the stage, the main portion of the auditorium, and the space under the balcony. Even a long sound-recording studio, one end of which is reverberant and the other end non-reverberant, may be regarded as two coupled spaces. Office space is often divided into a number of coupled spaces; and a great complexity of coupled spaces often will be found in cathedrals, consisting of nave, transepts, choir, sanctuary, aisles, chapels, balconies, and organ chamber. If the mean free path can be determined for such coupled spaces, and if all surfaces have approximately the same absorption coefficients, the regular reverberation formula, using the appropriate value of k, will give the time of reverberation for the entire room. (See Knudsen, *Architectural Acoustics*, Chapter V.) But it is not always feasible to determine the mean free path for a complicated combination of coupled spaces, and it is very improbable that all surfaces will have even approximately the same coefficients of absorption. In many instances, therefore, it becomes necessary to consider the reverberation in each of the several coupled spaces, and to adjust the reverberation time in each space to the optimal condition.

Many rooms have poor acoustics because of failure to recognize the effect of coupled spaces. Thus, in many school auditoriums containing a balcony, it is common practice to install nearly all the absorptive material in the ceiling. In some auditoriums the walls under the balcony, the soffit of the balcony, and the floor under the balcony may be of hard, reflective materials, as hard plaster and concrete. If, in addition, the seats under the balcony are of the unupholstered type, the space under the balcony will be very reverberant although the space in the main part of the auditorium may be quite free from reverberation. During the growth or decay of sound in such an auditorium there is a transfer of energy between the two coupled spaces, with different rates of growth or decay in the two spaces. During the steady state the rate of transfer of sound from the *dead* space to the *live* one is equal to the rate of transfer in the opposite direction. During the very early stages of the decay these rates of transfer are nearly equal, but since the sound decays much more rapidly in the main part of the auditorium than it does under the balcony, there soon will be established an excess rate of flow from the live to the dead space, and the result is that the reverberation is prolonged in the main part of the auditorium as well as in the space under the balcony.

In order to overcome this undesirable condition it is necessary that the rates of decay in both spaces be nearly equal (or that the rate of decay in the smaller space under the balcony be greater than the rate of decay in the main part of the auditorium). This involves a determination of the reverberation in both spaces, which in turn necessitates the assignment of coefficients of absorption to the opening which couples the two spaces. It is not possible to assign precise coefficients to these openings. The coefficients will depend, in general, upon the size and shape of the opening, the depth under the balcony, and the amounts of absorption under the balcony and in the main part of the auditorium. But if both spaces have approximately the same rates of growth, as they should for good acoustics, the "effective coefficients" will be of the order of 0.40 to 0.80—nearer the lower limit for shallow recesses which contain a relatively small amount of absorption. Similar considerations apply to the stage opening which couples the stage and the main part of the auditorium.

Many theaters, churches, memorial halls, and other auditoriums are often coupled, by means of door openings or archways, to rooms or corridors which are excessively reverberant. In such auditoriums, even though the reverberation in the audience space has been adjusted to the proper value, there will be a "feedback" of reverberation from the adjacent reverberant rooms into the main auditorium. Thus, auditors in a theater who are seated near an opening to a reverberant corridor, foyer, or anteroom will be disturbed by the excessive reverberation in the adjacent room. It is advisable in all such cases either to close the openings or to use an adequate amount of absorption in all spaces which are coupled to the audience room. In general, such anterooms, foyers, or corridors, unless they are used for speech or music rooms, should be as non-reverberant as possible.

21. REVERBERATION AT DIFFERENT FREQUENCIES

Unless otherwise specified, it is generally understood that *the time of reverberation* refers to a pure tone of 512 cycles. Although the calculation of reverberation at a single frequency, as 512 cycles, will suffice to represent the reverberation in a room at other frequencies provided the absorptive material in the room has nearly the same absorptivity at all frequencies, or provided the variation in absorptivity is known, it is obvious that such is not the case if the absorptive material has widely different and undetermined absorptivities at different frequencies. Thus, an acoutical plaster, $^1/_4$ in. thick, applied to concrete or tile, may have coefficients of absorption of 0.06 at 128 cycles, 0.36 at 512 cycles, and 0.72 at 2048 cycles. If such plaster is applied to the entire inner surface of a room the reverberation time at 128 cycles would be at least six times as long as the reverberation time at 512 cycles, and the time at 2048 cycles would be less than one-half of the 512-cycle time. If the reverberation time in such a room is 1.25 sec at 512 cycles, it will be at least 7.5 sec at 128 cycles. To describe this room as one having a time of reverberation of 1.25 sec—which is regarded as close to the optimal time for good acoustics—certainly does not describe the reverberatory properties of the room; and such a room will be highly unsatisfactory. There will be complaints of excessive reverberation, and the room will be too reverberant for the bass notes of music, and even the low-frequency components of speech will be reverberant and overemphasized. On the other hand, the higher tones and harmonics in music will be suppressed owing to over-absorption at the high frequencies. Such rooms are particularly objectionable for recording or broadcasting purposes.

It is necessary therefore to specify and calculate the reverberation times for representative frequencies throughout the entire range used in speech and music. It will be found, however, that, if calculations are made at 128, 512, and 2048 cycles, the resulting times will give a satisfactory description of the reverberatory properties of the room. In recording and broadcasting studios it is desirable to consider frequencies as high as 8000 cycles.

In general, the reverberation time at 128 cycles should be slightly longer than the time at 512, and the reverberation time above 512 should remain nearly constant. (See Fig. 10, p. 12-75, for present recommended practice.) The success or failure in the acoustical design of rooms will depend upon the selection of absorptive materials which will give the proper reverberatory characteristic throughout the entire range of frequencies used in speech and music.

22. THE MEASUREMENT OF REVERBERATION AND ABSORPTION COEFFICIENTS

The reverberation time of a room, or the total absorption of the room, for rooms in which geometric acoustics will apply, can be determined by measuring either the rate of decay of sound or the time for the decay between known intensity limits. For determining the sound-absorptive coefficients of materials it is customary to make measurements of the rate of decay of the sound in a reverberant room first when the room contains a certain area of the acoustical material to be tested and again when the material is removed from the room. In order to approximate conditions which will justify the applicability of formulas based on geometric acoustics, it is better to distribute the absorptive material on three (non-parallel) walls rather than concentrate in one area on one wall. By means of eq. (3), the value of $\bar{\alpha}$, and consequently the total absorption $\bar{\alpha}S$, can be calculated. The absorption of the acoustical material in the room is assumed to be equal to the difference between the absorption of the room with the material in it and the absorption of the room with the material removed. This is equivalent to assuming that $\bar{\alpha}$ is the arithmetical mean of all absorptive surfaces in the room, an assumption which is justifiable provided the sound in the room is kept thoroughly diffuse during the steady state and the decay. Warble tones at least 100 cycles in breadth with a warble frequency of at least 4 or 5 per sec should be used for test tones below about 500 cycles, and, unless the room be bounded by diffuse reflectors, large rotating vanes should be used for test tones of all frequencies. The test tones should be pure.

When these precaustions are taken the rate of decay will conform satisfactorily to the theoretical rate, and, if the test area is as large as about 72 sq ft in a room having a volume about 5000 to 10,000 cu ft, the difference between the rates of decay with and without the acoustical material in the room will be large enough to yield coefficients of absorption accurate to about ± 0.05 for frequencies up to 2000 cycles. At higher frequencies the absorption in the air, which may change during the time required for the completion of the test, is so large a factor that errors of the order of ± 0.10 are unavoidable unless the reverberation room is carefully air-conditioned. Even with an air-conditioned room the accuracy is not satisfactory at frequencies above 4000 cycles, because the absorption in the air is such a large factor that the difference between the rates of decay with and without the acoustical material in the room is not appreciable unless the test area is greatly increased.

The rate of decay is measured by some type of reverberation meter which in general consists of (1) a suitable source of steady or warble tones, usually a vacuum-tube oscillator, an electrical low-pass filter, a power amplifier, and an electrodynamic loudspeaker; (2) a high-quality microphone and amplifier; (3) an electrical attenuator for varying the gain of the amplifier; and (4) either a recorder which registers continuously, on a moving paper chart or on a light-sensitive medium, a graphic record of the decay, or some type of indicator, usually a relay and chronograph, by means of which the rate of decay can be determined.

The Bell Telephone Laboratories, Inc., among others, have developed a high-speed level recorder which gives a response proportional to the logarithm of the actuating current, and the instrument is so adjusted that the record gives directly, when the paper tape is moving with constant speed, the rate of decay of the sound in decibels per second. If the decay follows the exponential law, the curves will be straight lines. However, since the decay consists of several contiguous frequencies (normal modes of vibration) in close proximity to the frequency of the exciting tone, there will be interference between these several frequencies (each of which decays exponentially) so that the resultant decay curve generally will be quite irregular. Typical decay curves obtained with this instrument in the reverberation room of the Bell Telephone Laboratories are reproduced in Fig. 3. As these

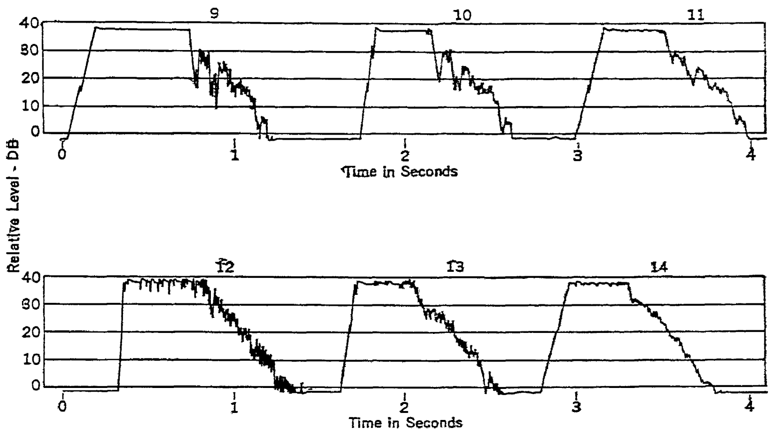

FIG. 3. Decay Curves Obtained with Bell Laboratories High-speed Level Recorder

records show, the decay is not strictly exponential but, except for minor fluctuations which can be attributed to the resonant or interfering phenomena discussed in article 20, the general trend of the decay conforms very satisfactorily to the exponential law, over a range of 40 db; and, if a straight line is fitted to the recorded curve of decay, the slope of this line will give the rate of decay with sufficient accuracy for practical purposes.

The curves labeled 9, 10, and 11 were made with a pure tone and a single microphone and with the recorder adjusted to "follow" maximal speeds of decay of 240, 120, and 60 db per sec, respectively. In 9, for example, the recorder is capable of following the actual decay much more closely than it is in 11, where only the slower variations of decay are recorded. The curves labeled 12, 13, and 14 were made at the same recorder speeds, respectively, but a warble tone was used instead of a single pure tone. The advantage of the warble tone for reverberation measurements is obvious from these decay curves.

In the chronographic type of reverberation meter, in use in many laboratories, it is customary to measure the time for a given drop in level, increasing the drop in steps of 5 or 10 db. A good meter of this type is the one developed by F. V. Hunt (*J. Acous. Soc. Am.*, Vol. 5, 127 [1933], and Vol. 8, 34 [1936]), which is almost automatic. As usual, the sound source is a warble tone oscillator. Several microphone positions throughout the room are used to insure a good average, and the reverberant sound thus detected and amplified is rectified, and rapid fluctuations are filtered out. An automatic timer turns off the source, always at the same phase of the sound wave, when the sound level in the room has reached a predetermined level, indicating the time for this decay. This is repeated 40 or more times, and the average value is used for plotting the decay curve. Figure 4 is a composite curve obtained by Hunt, showing the average decay for a warble tone of 1000 ± 200 cycles throughout a course of 80 db. By comparing the observed decay curve with the dashed straight line, it will be seen that the decay is satisfactorily exponential during the first 50 db of decay, the portion of the curve which should be used in making sound-absorption measurements. The non-linear decay from 50 to 80 db probably results from the more slowly damped tangential modes of vibration, which predominate during the latter stages of the decay.

A third method of measuring the decay rate is the oscillographic, illustrated in Fig. 2, which gives a detailed picture of the frequencies, as well as the intensity, throughout the course of the reverberation.

Reverberation measurements are useful not only for determining the coefficients of sound absorption of acoustical materials in a reverberation chamber but equally for determining the reverberatory properties of all rooms. In general, a reverberation meter should be capable of making measurements at all frequencies between about 128 and 4096 cycles and should reveal the detailed nature of the decay of the sound, especially during the first 30 to 40 db of the decay. In music rooms, recording or broadcasting rooms, and theaters, it is desirable to make measurements at frequencies as high as 8000 cycles.

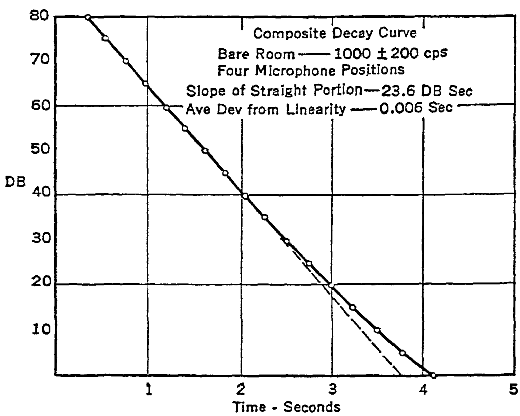

FIG. 4. Decay Curve, Based on Measurements of Average Time for a Given Drop in Level. (Hunt.)

For additional methods for measuring reverberation and absorption, consult Knudsen, *Architectural Acoustics*, Chapter VII; Sabine, *Acoustics and Architecture*, Chapter VI; Olson and Massa, *Applied Acoustics*, Chapter XII; and Beranek, *Acoustic Measurements*.

23. COEFFICIENTS OF SOUND ABSORPTION

In the following charts and tables there is given a fairly complete listing of the coefficients of sound absorption of the materials which are used in building construction, especially for acoustical purposes. Many of the same materials have been measured by different investigators, and the results are not always in good agreement. Such factors as actual differences in the samples, differences in the methods of measurement, differences in the size, shape, and location of the samples compared with the size and shape of the test rooms, the purity of the test tone used, and errors inherent in the use of reverberation methods and formulas based on geometric acoustics when wave and not geometric acoustics applies are probably responsible for this lack of agreement. Where large discrepancies have existed, certain liberties, guided by experience and the probable influence of wave acoustics, have been taken in averaging results.

Most of the materials manufactured by the leading acoustical concerns in the United States have been tested in the same laboratory by the same method; this facilitates comparison of different materials. The authority for these measurements is the Acoustical Manufacturers' Association; the tests were made at the Riverbank Laboratories. The authorities for the other measurements are listed in Table 1.

Much progress has been made in the development of acoustical materials during the past decade, and this progress will continue. Many improved and new materials will be described in subsequent issues of the *Bulletin of the Acoustical Materials Association*, which is published at frequent intervals. (These bulletins should be consulted; they can be obtained from the Acoustical Materials Association, 205 W. Monroe St., Chicago, Illinois.)

Table 1, on sound-absorption coefficients, includes considerable data concerning acoustical materials in addition to the coefficients of sound absorption, such as the *type* of the material, the nature of the *mounting*, the light reflection coefficient (usually as painted by the manufacturer), the weight per square foot of the material, and the unit size of the material. The numbers used to describe the *types* and *mountings* are those used by the Acoustical Materials Association. The legend for these numbers is given in the table.

In choosing materials for noise-reduction purposes, in offices, factories, restaurants, hospitals, etc., it is customary to rate the materials acoustically in terms of the arithmetic mean of the coefficient at 256, 512, 1024, and 2048 cycles. This average value is called the *noise-reduction factor*. It is better practice, however, to choose materials that have the absorption characteristics best adapted to the characteristics of the noise to be absorbed. It is especially important to avoid materials having very low absorption at the low frequencies for sounds which are made up predominently of low frequencies.

Table 1. Sound-absorption Coefficients

Types of Material:

I. Cast units composed of small uniform mineral particles and Portland cement.
II. Cast units having a surface composed of or resembling small uniform granules.
IV. Units having a mechanically perforated surface, backed with a sound-absorbent material.
V. Units mechanically perforated, the perforations extending into the sound-absorbent material.
VI. Units having a fissured surface.
VII. Compressed units composed of long wood fibers—surface not perforated.
VIII. Felted fiber or wood-pulp units—surface not perforated.

Types of Mounting:

1. Cemented to plaster board or other hard, rigid surface.
2. Nailed to 1 in. by 2 in. wood furring, 12 in. o.c.
3. Attached to metal supports applied to 1 in. by 2 in. wood furring.

The table contains absorption data on a number of mineral wool blankets, made up of wool of different densities, and of thicknesses varying from 1 to 3 in. It will be seen that by suitable choice of density and thickness it is possible to obtain a wide variety of absorption characteristics.

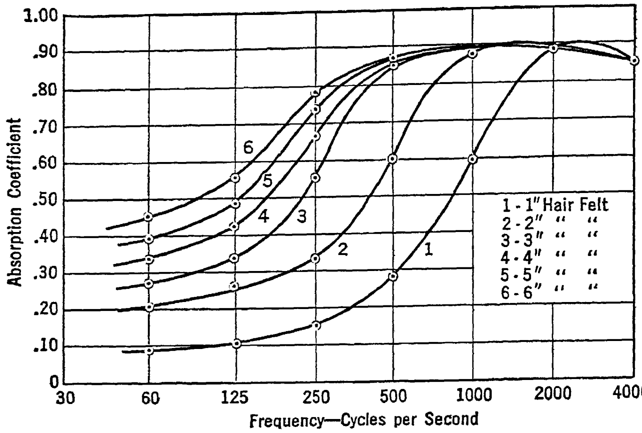

FIG. 5. Absorption of Different Thicknesses of Hair Felt. (Wente and Bedell.)

In Fig. 5 are shown the results of sound-absorption measurements of Wente and Bedell on hair felt of different thicknesses. The principal effect of increasing the thickness of a porous material is to increase the absorption at the low frequencies.

In Fig. 6 are shown the results of measurements at 512 cycles on different thicknesses of hair felt obtained in four different laboratories. These results show not only the effect of thickness but also the order of agreement of measurements made at different laboratories.

The manner of mounting acoustical materials influences their absorptivity. Most fibrous and porous materials increase in absorptivity, especially at frequencies below 500 cycles, as the thickness of the air space behind the material increases. Thus, fiber board

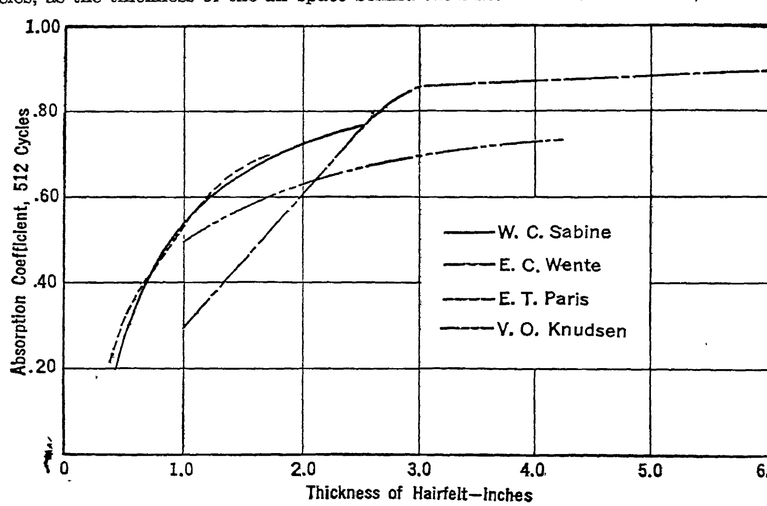

FIG. 6. Absorption of Hair Felt as Determined in Different Laboratories

and tiles, acoustical plaster, and similar materials, are more absorptive at low frequencies when furred out from a dense, rigid wall than when applied directly to the wall.

The absorptivities of such materials as acoustical plaster are dependent upon the composition as well as upon the manner of applying and drying. If too much binder material is used the plaster is not sufficiently porous; if an insufficient amount of binder is used the plaster does not set hard. Likewise, if the undercoats of plaster are too wet (or "green"), the binder material forms an impenetrable film at the surface, whereas if the undercoats are too dry the binder material is absorbed by the undercoats, and the plaster will crumble. In order to obtain good results with acoustical plaster it must be applied by competent plasterers in strict conformity with the specifications of responsible manufacturers.

The absorptivity of acoustical plaster or fiber board may be ruined by decoration with oil or water paint, varnish, distemper, or other materials which will close the surface pores. Viscous or heavy paints which *bridge over* or close the surface pores must be avoided. Such materials as thin aniline dyes, gasoline or kerosene stains, thin lacquer sprays, or dry paint dusted on with a pounce bag are satisfactory means of decoration without impairing the absorptive properties of plaster or fiber board. Certain commercial materials containing large holes, or materials covered with a perforated facing, may be decorated with lead or oil or any other kind of paint, provided the paint does not bridge over the holes.

In order to facilitate convenient use of the table the materials have been grouped as follows: acoustical tiles, boards, and sheets; acoustical plasters and sprayed-on plastic materials; mineral wool, Fiberglas blankets, and acoustical felts; set materials for use in motion-picture studios; hangings, floor coverings, and miscellaneous materials; hard plasters, masonry, wood, and other standard building materials; and audience, individual persons, chairs, and other objects. The tabulation in each group of materials is arranged in alphabetical order.

24. PRACTICAL CONSIDERATIONS OF SOUND-ABSORPTIVE MATERIALS

In making a choice of absorptive materials a number of other factors must be considered besides the coefficients of sound absorption. Good acoustics is only one of many qualities which should be secured in every building. Thus, besides absorption coefficients, it is necessary to consider such factors as the following: structural strength; decorative possibilities; adaptability to the surface available for, or requiring, absorptive treatment; maintenance; sanitation; ease of application; fire hazard; absorption of water; attraction for vermin; "fool-proofness"; durability; and cost. Each room requires a certain amount of sound absorption; certain surfaces in some rooms require highly absorptive treatment. These two conditions usually limit the choice of absorbents to materials having coefficients within certain specified limits. As a rule, however, many materials having coefficients within these limits will be available. This allows considerable freedom in the selection of materials which will be satisfactory not only acoustically but also for the other requirements. For a detailed discussion of the choice of sound-absorptive materials consult any standard textbook on architectural acoustics (as Knudsen and Harris, *Acoustical Designing in Architecture*).

SOUND INSULATION

By Vern O. Knudsen

25. NOISE MEASUREMENTS

During recent years, acoustical engineers and civic authorities have become increasingly aware of the problems associated with the measurement and abatement of noise. One of the prime requirements for good acoustics in every room is absence of noise, i.e., *unwanted sound*. In the design of theaters, music rooms, churches, schools, office and industrial buildings, hotels, apartment houses, and studios for the recording or broadcasting of sound, it is necessary that the designing architect or engineer know (1) the amount and kind of the noise against which he is to provide insulation, and (2) the amount of noise which can be tolerated in different types of buildings. The difference between the magnitudes of (1) and (2) gives the amount of sound insulation which should be provided in the building. As discussed in article 5 of this section the magnitudes of noises vary over a wide range.

The magnitude and character of steady sounds can be represented by plotting the intensity level (per cycle or for a specified band width) as a function of the sound frequency. In Fig. 1, the intensity level per octave, i.e., the intensity levels as measured in octave bands, for a number of ordinary sounds are plotted for the important audio-frequency range of 50 to 10,000 cycles. Traffic noise will be seen to have its predominant intensity at low frequencies; the noise from typewriters, on the other hand, is greatest at high frequencies. Such characteristics of noise should be considered in the problems of sound insulation and noise reduction in building design.

Most measurements of noise, of interest in building design, have been made with commercial sound-level meters which measure the overall sound level in decibels rather than the intensity level as a function of the frequency. The latter should be used whenever available, but the sound level corresponds roughly with the *sensation* of the sound and provides a convenient numerical scale for comparing the levels of different sounds. Thus, Fig. 2 gives the average sound levels, in decibels, as measured with a sound-level meter, for a large number of locations in or near buildings.

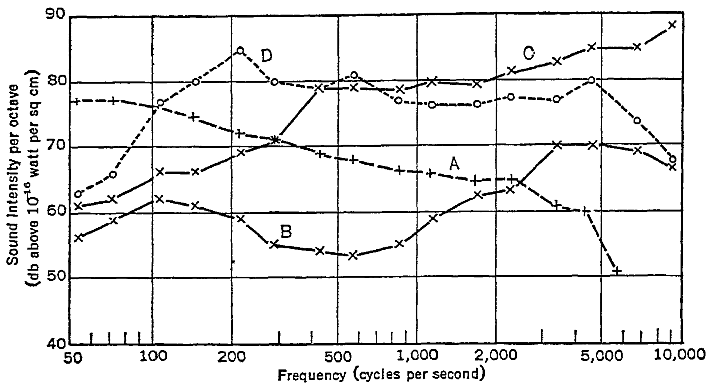

FIG. 1. Sound Spectra of Some Typical Noises. (Fleming and Allen.) (British Crown Copyright reserved. Reproduced by permission of the Controller of His Britannic Majesty's Stationery Office.)

Examples of Noise Analysis

A—Traffic noise. Average of miscellaneous vehicles passing at about 20 ft.
B—Typists' room. Two typewriters in operation.
C—Woodwork shop. 14-in. circular saw.
D—Woodwork shop. Planing machine.

If a sound wave completely modulates the pressure of the air at sea level, i.e., if the instantaneous pressure varies from 0 to 2 atmospheres, the intensity level would be 194 db. This represents an upper possible limit for the intensity of sounds, a limit which is not far above that actually attained with the Victory Siren (a large air stream modulated with a "chopper"), which was used in New York City and other American cities as an air-raid alarm during World War II. Most of the other entries in Fig. 2 are self-explanatory. The standard deviations are given for a number of measurements; these were made by Bell Telephone Laboratories (D. F. Seacord, *J. Acous. Soc. Am.*, Vol. 12, 183) at more than 600 locations in four different cities. The measurements in the private hospital room (made by the author with a continuous recorder) revealed sound levels of 50 to 58 db during 80 per cent of the time from 5:00 P.M. to 7:00 P.M.; at 9:00 P.M. the level had dropped 2 or 3 db. In the corridors of this same hospital, levels of 65 to 75 db were common; there were peak levels of 78 db from the closing of elevator doors 55 ft away from the sound-level recorder, and 90 db from coughing 40 ft away.

26. ACCEPTABLE NOISE LEVELS IN DIFFERENT BUILDINGS

Although it is not customary for building codes to specify the allowable noise in different types of buildings, and opinions differ considerably as to tolerable noise levels, the following table gives approximate loudness levels which will be, in general, highly satisfactory:

	Decibels
Radio, recording and television studios	25 to 30
Hospitals	35 to 40
Music rooms	30 to 35
Apartments, hotels, and homes	35 to 45
Theaters, churches, auditoriums, classrooms, and libraries	30 to 40
Private offices and conference rooms	35 to 45
Large public offices, banking rooms, stores, etc.	45 to 55
Restaurants	50 to 55
Factories	45 to 80

Special conditions or circumstances, such as past experience, other near-by noises, and costs, may alter the acceptable noise levels, but the levels given in the table are recommended for purposes of building design. As will be seen by comparing these values with those given in Fig. 2 the acceptable values given in the table are somewhat lower than

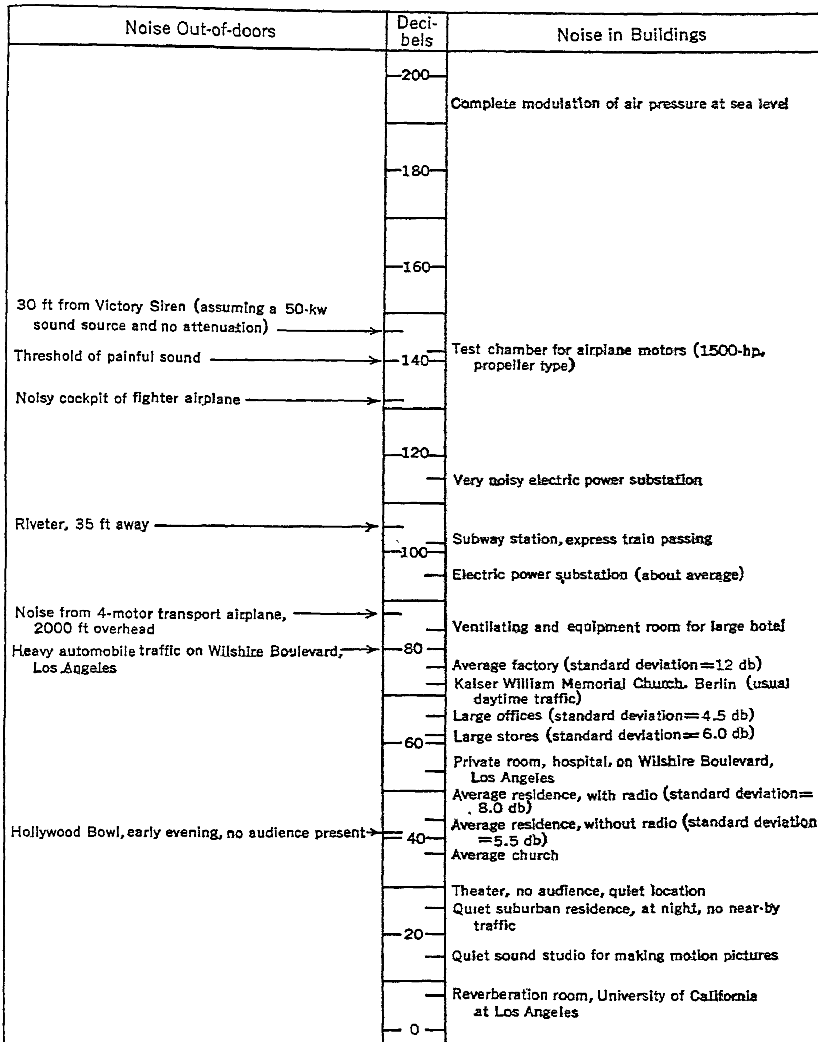

FIG. 2. Sound Levels in or Near Buildings

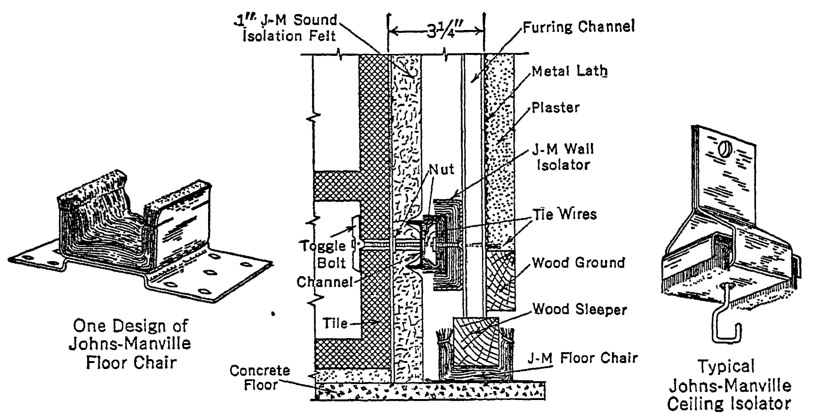
those that prevail in existing buildings. The average loudness level in the private hospital room, for example, is 54 db, which is some 15 to 20 db greater than the level proposed in the table. Since the outside traffic noise adjacent to this hospital has an average level, when traffic is heavy, of 80 db, and since the average tolerable level for a hospital is 37 db, the building should be designed for sound insulation in such a manner as will provide an overall noise reduction 80–37 db, i.e., 43 db. Part of the required noise reduction can be accomplished by a proper "setback" of the building and, in some instances, by dense planting of evergreen shrubs and trees between the street and the building; another part, by the use of sound-absorptive materials within the building; but most of the reduction can be accomplished only by proper sound insulation of the building itself.

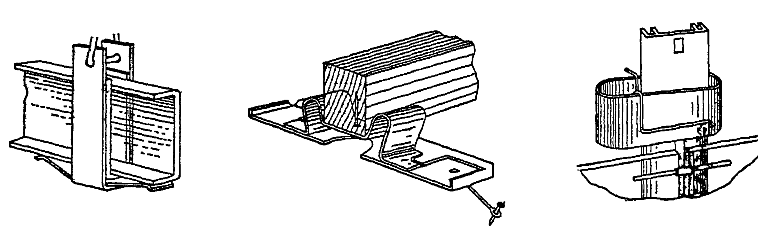
27. FUNDAMENTAL PRINCIPLES OF SOUND INSULATION

Nearly every building is subject to the annoyance of noises which have their origin in adjacent rooms or outside. It is possible to design buildings in such a manner as to exclude effectively both these types of annoying noises. The principal means whereby such noises enter a building are the following:

1. By means of openings, as windows, cracks around doors, ventilating ducts, or any other openings that will admit a free flow of air.
2. By means of refraction or transmission through partitions. This is analogous to the refraction or transmission of light from air to water, or between any other two dissimilar media.
3. By means of the conduction of sound through solids. For example, "impact sounds," such as footfalls, hammering on walls or floors, or the moving of furniture on hardwood floors, are conducted through the dense and rigid structural members of a building.
4. By means of the diaphragm action of walls which communicate sound from one side of a partition to the other side.



Typical Johns-Manville Wall Isolating Treatment



As Used by United States Gypsum Co.

Fig. 3. Flexible Cushions, Supports and Connectors

The refraction or transmission of sound from one medium to another, as from air to plaster or stone, is an almost negligible factor in building construction—not more than about one-millionth of the intensity of the incident wave in air can penetrate a material like brick or stone.

The transmission of sound through openings, on the other hand, is often the means by which sound is most readily transmitted from one portion of a building to another. This means of transmission often limits the amount of sound insulation which can be obtained in buildings, especially in hotels and apartments where the insulation is determined by such unavoidable openings as may be incidental to the use of windows and doors. Under such circumstances it would be futile to provide a relatively high insulation through the separating walls or partitions. Even very small openings, such as cracks around doors or around imperfectly fitting windows, are effective in transmitting a considerable amount of sound.

The transmission of sound through ventilating ducts often becomes a troublesome problem. There are three types of sound-transmission which must be controlled: (1) the noise from the fans, motors, and other air-conditioning equipment which is transmitted through the ducts and into the room; (2) the noise from an adjacent room which is transmitted from opening to opening, often through a short and highly conductive section of duct; and (3) the noise from adjacent rooms or outside which may be transmitted through the walls of the duct and thence through the ducts and into the room. The noise from the ventilating equipment room can be reduced suitably by (1) the selection of slow-speed, quietly operating equipment; (2) treating the walls and ceiling of the equipment room with highly absorptive material; and (3) introducing acoustical attenuation within the ducts, which can be accomplished by using very long ducts of small cross-sectional area and by lining the ducts with highly absorptive material, or by introducing other acoustical filters in the ducts.

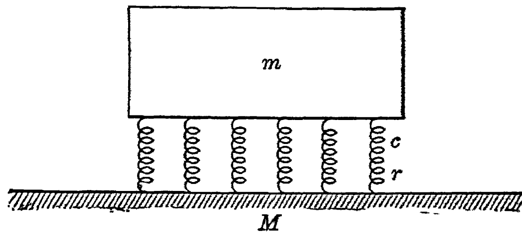


FIG. 4. Effective Method for Insulation of Vibration

Solid-borne sound travels through the structural members of a building with but very little attenuation. The compressional wave in a solid is often communicated to large surfaces, as the walls or floor of a room, and these large surfaces are made to vibrate like the sounding board of a piano. In this way a large portion of the solid-borne sound may be radiated into a room. Many solid-borne sounds can be controlled by the carpeting of floors; by the wrapping of pipes—especially where they touch the frame of the building—with flexible, porous materials, as hair felt; or by the proper mounting of machinery on flexible or elastic supports, so that the natural frequency of the machinery mounted on its flexible support will be low in comparison with the frequencies which are to be insulated. One of the most effective methods of eliminating these solid-borne sounds is to introduce discontinuities in the paths of the conducted sounds. These discontinuities should consist of materials which differ largely in elasticity and density from the solid structure of the building. For example, it is possible to suspend the ceiling by means of flexible supports; it is possible to build up inner walls in a room which are fastened to the monolithic frame by means of flexible ties; and it is possible to float the floor of the room upon flexible pads of cork or felt or other elastic material. In Fig. 3 are shown two types of flexible cushions, supports, and connectors which are effective for insulating solid-borne vibrations in buildings. Figure 3 also shows some constructional details for insulating solid-borne sound in buildings.

Figure 4 shows a simple method of insulating any object, as a part of a building or a piece of equipment, from earth, building, or machinery vibration. The problem consists of insulating a mass m from another object of mass M by means of a flexible support which has certain elastic and damping properties. Figure 5 is the electric circuit equivalent

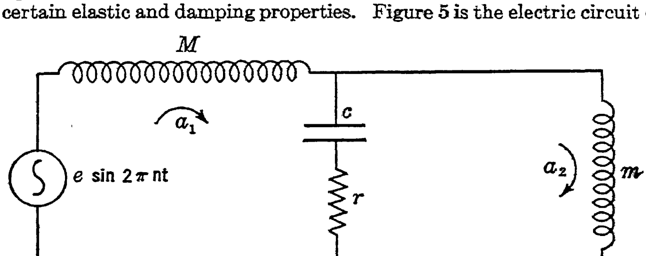

FIG. 5. Electric Circuit Equivalent of Fig. 4

of Fig. 4. This circuit implies that, when M is set into forced periodic vibration, these vibrations are communicated to m principally by means of the elastic coupling between M and m, although the internal damping or resistance r of the system also contributes to the coupling. If a_1 and a_2 represent the amplitudes of vibration set up in M and m, respectively, n the frequency, and c the compliance, then

$$\frac{a_2}{a_1} = \sqrt{\frac{r^2 + (1/4\pi^2n^2c^2)}{r^2 + [2\pi mn - (1/2\pi nc)]^2}} \tag{1}$$

This equation has been tested experimentally for both supported and suspended systems and is in good agreement with the observed results. The equation is useful for calculating the insulation value of different types of flexible supports. For values of n which are small compared with the natural or free vibration of m upon its elastic support, a_2/a_1 will be equal to unity; that is, m and M vibrate with the same amplitude. At the resonant frequency, a_2/a_1 is greater than unity, or the *insulating* support actually amplifies the motion imparted to m. However, at frequencies greater than $\frac{1}{\pi}\sqrt{mc}$ the value of a_2/a_1 becomes less than unity, and it approaches the value $r/2\pi nm$ at frequencies which are high compared with the natural or resonant frequency. In general, both m and c should be as large as possible if m is to be well insulated from the vibrations in M; that is, the support should be very elastic and loaded as heavily as possible (see also article 30).

In Table 1 are given the values of the compliance c and the resistance r of a number of materials which are used for the insulation of vibration. Beside these materials there are a number of patented devices, similar to those shown in Fig. 3, which are very effective. (See *Sound Transmission in Buildings*, by Fitzmaurice and Allen, His Majesty's Stationery Office, London [1939], and *Modern Theory and Practice in Building Design*, by Fleming and Allen, The Institution, London [1945].)

Table 1. Compliance and Resistance Data for Typical Specimens of Flexible Materials

The compliance and resistance given in the table are for specimens 1 in. thick and 1 sq cm in cross-section.

Material	Description of Material	Approximate Upper Safe Loading, lb per sq in.	Compliance, c, cm per dyne	Resistance, r, absolute units
Corkboard	1.10 lb per board ft	12	0.25×10^{-6}	0.15×10^5
Corkboard	0.70 lb per board ft	8	0.50×10^{-6}	0.25×10^5
Flax-li-num	1.35 lb per board ft	4–6	0.60×10^{-6}	0.50×10^5
Celotex	Insulating board	12	0.18×10^{-6}	
Insulite	Insulating board	15	0.16×10^{-6}	
Masonite	Insulating board	15	0.12×10^{-6}	
Sponge rubber	25 lb per cu ft	1–3	3.0×10^{-6}	
Soft India rubber	55 lb per cu ft	3–6	1.2×10^{-6}	
Hair felt	10 lb per cu ft	1–2	1.5×10^{-6}	

In the choice of materials for the insulation of vibration or solid-borne sound, it is necessary to give consideration to the safe amount of loading the material will withstand without breaking down or without being compressed to the extent that its compliance is reduced beyond required limits. It also is important to select a material that will have a long life and that will not continue to compress or settle under the load which it supports. For example, if ordinary insulation cork is loaded as much as 20 or 30 lb per sq in., the material will continue to compress indefinitely, and at the same time will become less and less compliant, until ultimately it not only loses its insulation value but also allows an amount of settling which cannot be tolerated. For example, a specimen of 1-in. insulation cork (0.70 lb per board ft), under a load of 20 lb per sq in., settled 0.04 in. during the first 24 hours, 0.02 in. during the next 24 hours, and 0.11 in. during the first 5 months it was under compression. The same specimens, under a load of 10 lb per sq in., settled only 0.01 in. during the first 24 hours, 0.005 in. during the next 24 hours, and only 0.03 in. during the first 5 months. In general, the most satisfactory material will be one that has a high compliance and very little tendency to settle under the influence of the load and that tends to return to its initial condition when the load is removed. Hair felt, cork, and rubber seem to be the best available materials that meet these requirements, although all these materials continue to settle, and become less and less compliant, as they become older. Flexible steel supports and clips, such as those shown in Fig. 3, do not have these defects and are proving to be very satisfactory not only for the insulation of walls, floors, and ceilings but also for insulating all sorts of equipment from the floor or the rigid frame of the building.

INSULATION OF SOUND BY POROUS MATERIALS. The insulation of sound by porous materials is accomplished principally by viscous losses within the capillary pores within the material and by the vibration of the component parts of the material. Figure 6 shows the transmission coefficients at different frequencies for one, two, three, and four layers of hair felt having a density of 12 lb per cu ft. These results show that, approximately, the logarithm of the energy reduction, or the reduction in decibels, of sound transmitted through porous materials is proportional to the thickness of the material. The results also show that porous materials, if used by themselves, do not provide a very high degree of sound insulation unless the insulating blanket or partition is very thick. Thus, at 700 cycles, the coefficient of transmission for four layers of hair felt—each layer is 0.58 in. thick—is about 0.01; that is, a sound wave of 700 cycles would be attenuated only 20 db in passing through 2.32 in. of hair felt. However, when such materials are used properly in conjunction with rigid partitions, they may contribute a considerable amount to the total insulation supplied by a wall structure. One of the most effective ways in which such materials may be used for the insulation of sound is by suspending or supporting the porous blanket in an air space between two rigid partitions.

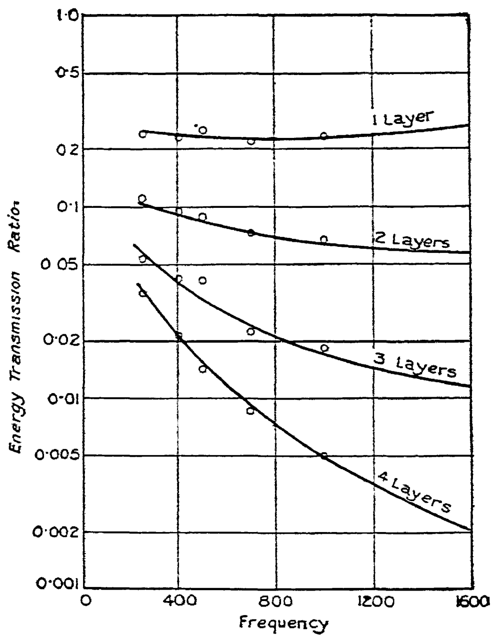

Fig. 6. Transmission Coefficient for One, Two, Three, and Four Layers of Hair Felt. (Davis and Littler.)

INSULATION OF SOUND BY RIGID PARTITIONS. Sound is transmitted through rigid partitions principally by the forced vibration of the wall; that is, the entire partition is forced into vibration by the pressure variations of the incident sound wave. The transmission coefficient τ for a heavy partition, as masonry or concrete, for normally incident sound, is given, approximately, by

$$\frac{1}{\tau} = 1 + \frac{1}{4}\left(\frac{\rho_1 c_1}{\rho c}\right)^2 \sin^2 k_1 l \quad (2)$$

where ρ_1 and c_1 are the density and sound velocity in the partition, ρ and c the corresponding density and velocity in the air, $k_1 = 2\pi/\lambda_1$, where λ_1 is the wavelength of the sound in the partition and l is the thickness of the panel. The transmission loss in decibels ($10 \log_{10} 1/\tau$) for a 9-in. brick wall, as calculated by eq. (2), is about 50 db at 100 cycles and rises almost uniformly with frequency to 78 db at 4000 cycles, and then drops to a minimum at 8000 cycles (which is zero according to eq. [2] but actually is of the order of 50 db because of dissipation within the partition). At frequencies below about 100 cycles, the resonant properties of the partition are of considerable influence; the transmission loss (T.L.) at these low frequencies may be much less than that calculated by eq. (2). The observed T.L. for heavy masonry partitions, even at 100 to 4000 cycles, is some 10 to 15 db less than that calculated from eq. (2), but the equation is useful for predicting the influence on T.L. of such factors as the wavelength of the sound and the mass and thickness of the partition.

For most rigid walls in buildings, as concrete, brick, clay or gypsum tile, wood or metal studs plastered on one or both sides, and even glass or metal panels, eq. (2) can be further simplified so that, approximately, for frequencies of 100 to 4000 cycles,

$$\frac{1}{\tau} = \left(\frac{1}{4}\right)\left(\frac{k^2 m^2}{\rho^2}\right) \quad (3)$$

where $k = 2\pi/\lambda$ (λ is the wavelength of the sound in air); and m is the effective mass per unit area of the wall, which is of the order of 0.2 to 1 times the actual mass per unit area. The mass reaction of rigid walls is thus the dominant factor affecting sound transmission; the sound is transmitted largely by the diaphragmlike vibration of the wall, the wall responding to the alternating force of the impinging sound wave much as a rigid piston would.

In thin flexible panels, the stiffness, the internal damping, the size of the panel, and the manner in which it is clamped around the edges all contribute to the total amount of vibration which will be imparted to the partition, and therefore all these factors contribute to the insulation value of such walls. However, these factors are effective principally at low frequencies; the mass is the predominant factor throughout most of the audio-frequency range in determining the insulation value of nearly all rigid panels and partitions encountered in practice. In Fig. 7 is given a summary of the measured insulation value of many rigid panels having weights varying from 2 lb per sq ft up to 100 lb per sq ft. There is a nearly linear relation between the average T.L. and the logarithm of the weight per square foot of the partition. (The average T.L. is the arithmetical mean of the measured transmission losses at 128, 256, 512, 1024, and 2048 cycles.)

Whereas the insulation value of porous materials is proportional approximately to the thickness of the material, the insulation value of a rigid material increases only as the logarithm of the thickness. Because of the slow increase in insulation with increased mass or thickness of a rigid partition, it is not always feasible to secure a high insulation by merely increasing the thickness of the wall. Thus, it would be necessary to increase the thickness of a concrete wall to nearly 4 ft in order to give the wall an insulation of 60 db.

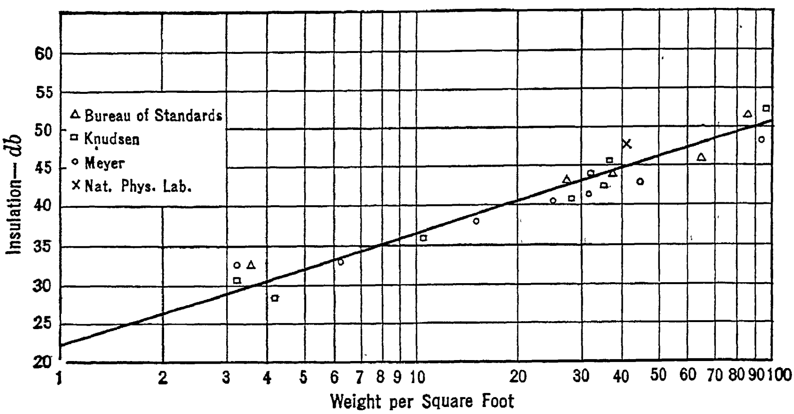

FIG. 7. Transmission Loss in db for Rigid Single Partitions

When walls of high insulation are required, it is more feasible and economical to employ special structures which combine the two principles of sound insulation just described: namely, absorption losses in porous-flexible materials, and inertial losses in massive partitions. Thus, two or three rigid and relatively thin partitions separated from each other by felts or blankets can easily be composed in such a manner as to give an insulation of 60 or even 70 db. The insulation value of many special forms of construction employing these and other principles will be found in the tables in the next section. (See also references given on p. 12-75.)

28. COEFFICIENTS OF SOUND TRANSMISSION

The coefficient of sound transmission of a panel is the ratio of the transmitted to the incident sound energy. One of the most satisfactory methods for measuring the coefficients of different materials is to make measurements of the sound intensity on both sides of a test panel placed between two rooms which are so constructed that no sound is transmitted from one room to the other except through the test panel. Thus, suppose the average intensity near the panel in the source room to be I_1 and the average intensity in the test room to be I_2. Then the rate of flow of sound energy against the test panel in the source room will be I_1A, where A is the area of the test panel. The rate at which energy will be transmitted through the panel into the test room will be $I_1A\tau$, where τ is the transmission coefficient for the panel. The product $I_1A\tau$ is then the rate of emission of sound energy in the test room. Hence, when equilibrium is established, this rate of emission of sound energy will be equal to the rate of absorption of sound in the test room, which is equal to I_2a, where a_2 is the total absorption of the test room. Hence,

$$\tau = \frac{I_2a_2}{I_1A} \tag{4}$$

The coefficient of transmission thus involves not only the intensities on the two sides of the panel but also the area of the panel and the total amount of absorption in the test room.

* Reduction factors from the Bureau of Standards, for the most part, are for the following frequency bands: 150 to 157, 250 to 285, 500 to 547, 1000 to 1070, and 2000 to 2175 cycles. The data for the several frequency bands are recorded under the frequencies to which the frequency bands most nearly correspond.

† For frequencies of 300, 500, and 1000 cycles.

‡ Average value from 128 to 2048 cycles.

§ Berg and Holtsmark's reduction factors are for frequency bands of 100–200, 200–400, 400–800, 800–1600, and 1600–3200 cycles. Their values are recorded under 128, 256, 512, 1024, and 2048 cycles, respectively.

Authority: (1) Bureau of Standards, (2) V. O. Knudsen, (3) P. E. Sabine, (4) Davis and Littler, (5) Berg and Holtsmark, and (6) National Physical Laboratory.

For other methods of measuring transmission coefficients see Knudsen, *Architectural Acoustics*, Chapter XI.

The results of sound-insulation measurements obtained in different laboratories are grouped in Table 2. Each group contains the data for materials or partitions having a number of properties in common. The data in each group have been arranged so as to keep together those from each laboratory, which is necessary since the results on the same panel tested in different laboratories are not always in good agreement. The data from most laboratories give what has been called the *reduction factor* for the panel or partition tested. This *reduction factor* is usually the ratio of the intensities of sound on both sides of the test panel, or, in decibels, is 10 times the logarithm of this ratio. Since the transmission coefficient depends upon the size of the panel and the amount of absorption in the test room, as is shown by eq. (4), the reduction factors published by several laboratories (before about 1935) do not agree with the T.L., which in decibels is $10 \log_{10} 1/\tau$. The compiler has made an attempt to adjust the data from different laboratories in such a manner as to give comparable ratings for all the materials and partitions listed in the tables.

In the table, the data given under "Reduction Factors in Decibels" are the results published by the authors. The data given in the last two columns in the table give the compiler's estimate of the probable average value of the T.L., and the probable average value of the transmission coefficient τ. The *reduction factors* at the different frequencies are useful since they describe the insulation value of the panel or partition at these frequencies. This is often an important matter in the selection of materials or partitions for sound insulation. For example, partitions which have a relatively low insulation value in the frequency range from 500 to 1000 cycles would not be suitable for the insulation of traffic noise and of most noises met in buildings, since most such noises contain a relatively large amount of sound energy in this frequency range. (See Fig. 1.) For this reason, the panels which show the highest values of T.L. may not supply the greatest amount of sound insulation for all types of noise. It is necessary, in determining the best type of partition for each problem which arises in sound insulation, to give consideration to the reduction factors at the different frequencies as well as to the average value of T.L. or τ.

Partitions which possess outstanding merit with regard to both insulation value and practicability are designated by bold-face type in the column which gives the name and description of the partition.*

29. PRACTICAL CONSIDERATIONS IN THE SELECTION OF MATERIALS AND TYPES OF STRUCTURE FOR INSULATION IN BUILDINGS

Since errors as large as 3 or 4 db are inherent in many of the data on sound insulation, small differences in the tabulated results of the preceding article should not be regarded as having much significance. A consideration of the tabulated data suggests the following generalizations concerning the insulative properties of different building materials and partitions:

1. The insulation value of rigid masonry or monolithic partitions increases directly as the logarithm of the weight per square foot of wall section—so that the rate of increase of insulation with increased weight is relatively slow for partitions which are heavier than, say, 30 or 40 lb per sq ft. As a consequence, it is often in the interest of both insulation and economy to substitute two or more light-weight partitions, or specially composed partitions, for heavy masonry partitions. There are many occasions in building practice where this may be done with a gain in insulation, with a reduction in the dead load of the building, and at a reduced cost. However, for thin partitions, where the dead load is not a serious problem, dense rigid panels such as plastered brick or solid tile provide a satisfactory means of obtaining a T.L. of about 40 to 45 db.

2. Lime plaster on wood lath and wood studs gives better insulation than an equal thickness of gypsum plaster on wood lath and wood studs. Sabine reports an advantage of about 9 db for lime plaster as compared with gypsum plaster, and the Bureau of Standards reports an even greater difference. Wood stud and plaster partitions rate slightly higher than channel iron and plaster.

3. Wood partitions, with tongue-and-groove joints, provide more insulation than masonry partitions of the same weight or thickness. (The development of cracks in wood partitions, however, will greatly reduce their insulation value.)

* More extensive tables on sound-insulation data will be found in Knudsen's *Architectural Acoustics*, Glover's *Practical Acoustics for the Constructor*, Constable and Ashton, Sound Insulation of Single and Complex Partitions, *Philosophical Mag.*, Vol. 23, 161–181 (1937), and Knudsen and Harris, *Acoustical Designing in Architecture* (1949).

4. Double partitions seem to offer the most feasible means of obtaining high insulation at a reasonable cost and reasonable dead load. The separate partitions should be as completely insulated from each other as possible, as the introduction of structural ties between the separate partitions tends to convert the two partitions into a single rigid one and thus greatly reduces the insulation. The suspension of a blanket or fiber board between double partitions or between the wood studs or channel irons in staggered stud partitions is often

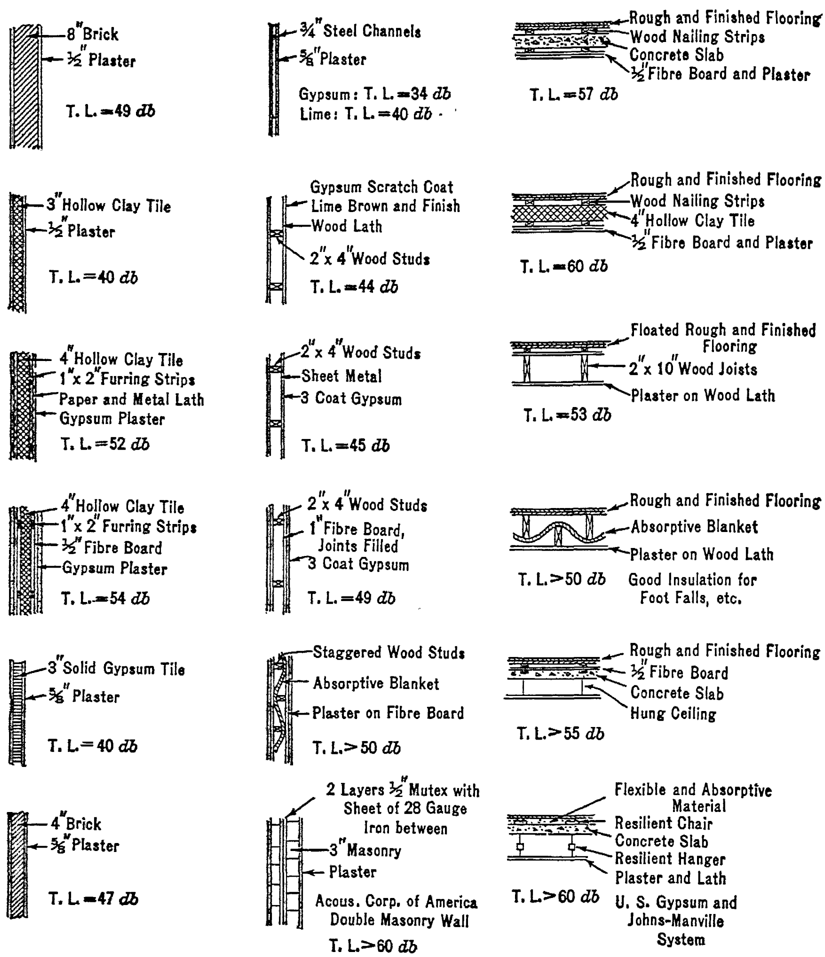

FIG. 8. Recommended Types of Structure for Sound Insulation

an aid to insulation. The addition of any absorptive material in the air space between double partitions contributes considerably to sound insulation unless the absorptive material makes a rigid or semirigid *bridge* between the two partitions, in which case it may be worse than nothing. Thus, the addition of cinders, pumice, or other rigid-porous materials between structurally separated partitions will sometimes reduce the overall insulation.

A number of satisfactory types of construction for obtaining wall partitions having a T.L. greater than 40 db and floor and ceiling partitions having a T.L. greater than 50 db are indicated in Fig. 8. These methods of construction will meet most of the requirements for sound insulation that will arise in connection with the design of buildings. The average T.L. is given for each partition. (See also references given on pp. 12-67 and 12-75.)

30. CALCULATION OF INSULATION IN BUILDING DESIGN

From a simple consideration of the transmission of sound through the boundaries of a room it can be shown that the *noise-reduction factor* for a room (the number of decibels the intensity of the sound is reduced by transmission through the boundaries) is given by

$$\text{Noise-reduction factor} = 10 \log_{10} \frac{a}{T} \tag{5}$$

where a is the total absorption of the room, and $T = \tau_1 A_1 + \tau_2 A_2 + \tau_3 A_3 + \ldots$ is the total transmittance for the boundaries of the room. τ_1, τ_2, and τ_3 are the coefficients of transmission of the different parts of the boundaries of the room, and A_1, A_2, and A_3 are the corresponding areas of these boundaries.

In order to illustrate the use of eq. (5) a typical calculation will be made for determining the noise-reduction factor of a small studio.

Volume of room = 50,000 cu ft.
Total absorption in room, including audience = 2400 sabins.

Description of Walls, Ceiling, Windows, and Doors; and the Transmittance through These Surfaces

Material	Area, A, sq ft	τ	τA
4-in. concrete slab ceiling plus 1/2 in. acoustical material	2500	0.000025	0.0625
8-in. brick walls plus 1/2 in. acoustical material	4500	.0000080	.0360
3/16-in. glass windows, closed	400	.00110	.440
1 1/2-in. hardwood doors, good closure	100	.00031	.031
Total transmittance (T)	....	....	0.5695

Therefore

$$\frac{a}{T} = \frac{I_1}{I_2} = \frac{2400}{0.5695} = 4210$$

and

$$10 \log_{10} 4210 = 36.2 \text{ db}$$

That is, the noise-reduction factor, or the effective insulation which the room provides against outside noise, is 36.2 db. Thus, if the studio is located where the outside noise is at a level of 60 db, the level of the noise which reaches the studio will be 60 − 36.2 or 23.8 db. It will be noted that most of the transmitted noise is that which comes through the glass windows, and that therefore the noise-reduction factor can be increased considerably by means of double windows or by dispensing with the windows.

ACOUSTIC DESIGN OF AUDITORIUMS

By Vern O. Knudsen

31. THE HEARING OF SPEECH IN AUDITORIUMS

Four principal factors affect the hearing of speech in auditoriums: the shape of the room, the loudness of the speech which reaches the listeners, the reverberation characteristics of the room, and the amount of noise in the room. If average speech is loud and distinct, and entirely free from the interfering effects of noise and reverberation, the percentage articulation for the average listener will be 96, that is, 96 out of 100 meaningless monosyllabic speech sounds will be heard correctly.

In an equation for calculating the percentage articulation for a room it will be necessary to introduce reduction or distortion factors due to (1) the shape of the room, (2) inadequate loudness, (3) excessive reverberation, and (4) extraneous noise. It is possible to represent approximately the percentage articulation in any room by the equation

$$\text{Percentage articulation} = 96 k_s k_l k_r k_n \tag{1}$$

where k_s = the reduction factor due to the shape of the room.
k_l = the reduction factor due to the inadequate loudness of speech.
k_r = the reduction factor due to the excess of reverberation in the room.
k_n = the reduction factor due to the extraneous noise in the room.

In the ideal room each of these factors will be equal to unity, so that the percentage articulation under such conditions would be 96 per cent.

Experimental data have been obtained by means of which it is possible to determine the appropriate values of these four factors for any auditorium, although considerable research remains to be done before accurate values of k_s are known. When these factors are determined for a certain auditorium and substituted in eq. (1) the resulting product gives the probable average percentage articulation in that auditorium.

It is admittedly only an approximation to represent these factors by single numbers. For example, the reverberation is described not by a single number but by a curve giving the times of reverberation at different frequencies. However, if one takes the time of reverberation for a tone of 512 cycles, one will have a fairly reliable index for representing the condition of reverberation in a room, especially if the reverberation time does not vary too widely at different frequencies. Such a single index is very useful for rating the acoustical quality of rooms. In problems of design, on the other hand, consideration should be given to the reverberation throughout the entire range of frequencies. Similarly, the noise spectrum in the room and the shape of the room cannot be represented rigorously by single numbers. However, in the rectangular room of conventional shape it is not only admissible to use a single factor to represent the effect of shape on articulation, but the factor k_s will not deviate appreciably from unity.

The four factors which affect the hearing of speech in rooms will now be considered separately.

SHAPE. It is not only necessary to avoid shapes which will produce acoustical defects, such as echoes, flutters, sound foci, interfering effects, and "whispering gallery" effects, but it is of prime importance to design shapes which will facilitate the most advantageous flow of sound energy to all auditors in the room.

There are three outstanding forms which should never be tolerated: (1) those which will produce a pronounced focusing of sound, thus giving an excessive concentration of sound in some places and a scarcity of sound in other places; (2) those which will produce excessive delays between the sound which reaches the auditors by a direct path from the source and that which reaches the auditors by reflection from the ceiling or walls; and (3) those in which the sound reaching the auditors travels a relatively long distance, at grazing incidence, over a highly absorptive surface. The sound which comes by the reflected paths always has to travel a greater distance than that which comes by the direct path, and if the difference in these path lengths is as great as 65 ft the reflected sound will be delayed to the extent that it is heard as a separate sound; that is, the delayed sound produces an echo. Even when the reflected sound is delayed as much as 50 ft it unites with the direct sound sufficiently out of phase to produce a masking or *blurring* interference. Figure 1 exhibits a characteristic defect which results from the use of concave surfaces.

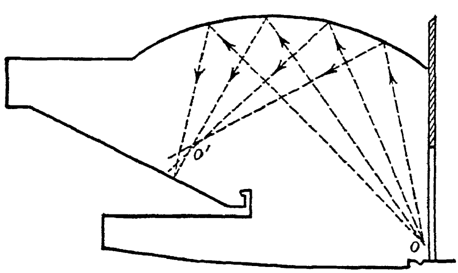

Fig. 1. Reflection of Sound from a Domed Ceiling

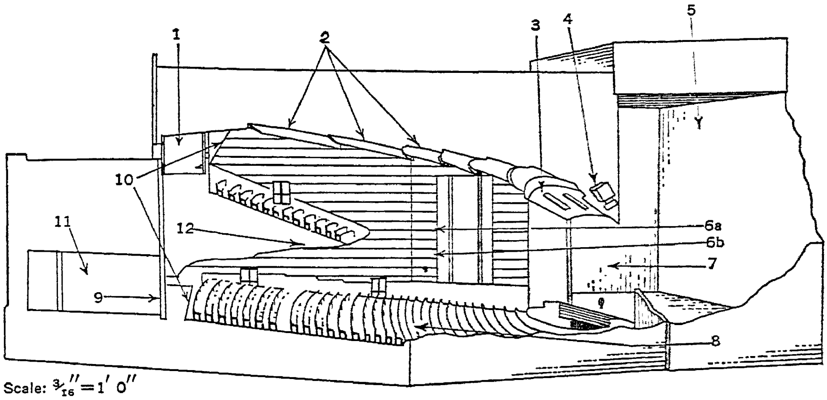
Figure 2 shows a longitudinal section of a cut-away model of an auditorium which is not only free from concentrations, dead spots, and interfering reflections but also is so shaped as to give a nearly uniform distribution of diffusely reflected sound to all parts of the auditorium, with a slight preference for the more remote parts.

In many auditoriums, and even in some sound-recording studios, it may be difficult or even impossible to avoid large and therefore troublesome differences of path between the direct and reflected sound. In such instances it is advisable to break up the surfaces producing these delayed reflections by introducing coffers, beams, pilasters, or other irregularities in contour. A number of rooms, highly acclaimed for their good acoustics, have been designed with walls and ceiling deliberately covered with polycylindrical sound diffusers. Figure 3 is a typical example. In rooms where public-address systems are required, the architect will have greater freedom in designing the shape and size of the room.

Both speech and music rooms should be designed so that the auditors receive a relatively large amount of sound which travels directly from the source or from reflectors located sufficiently near the source so that this reflected sound is nearly in phase with the direct sound. The stage, pulpit, platform, choir loft, or other location for the speaker or performer should be well elevated above the audience and provided with large, reflective



Scale: $\frac{3}{16}'' = 1'\ 0''$

1. Acoustically treated projection booth with sound amplification equipment and controls for sound monitoring.
2. Ceiling planes reflect sound to all parts of the auditorium.
3. Three-channel public address system to reproduce stage sound in "auditory perspective".
4. High-fidelity speakers: bass-compensated dynamic speaker for low tones; high frequency directional horns for high tones.
5. Backstage treated with acoustical plaster to reduce "stage echoes".
6. Acoustic treatment on walls: over-all distribution in alternate bands of (a) acoustic tile and (b) hardwall plaster.
7. Proscenium splays. horn-like shape of stage opening projects sound to audience.
8. Upholstered seats: absorption value of each seat equivalent to that of a person's clothing.
9. Double doors to foyer insulate against external noises.
10. Slanting rear walls on main floor and balcony reflect sound down toward rear seats.
11. Acoustically treated foyer to reduce external noises.
12. Streamlined balcony improves flow of sound to rear seats.

FIG. 2. Cut-away Model of the High School Auditorium for Whittier, California. (William Harrison, Architect.)

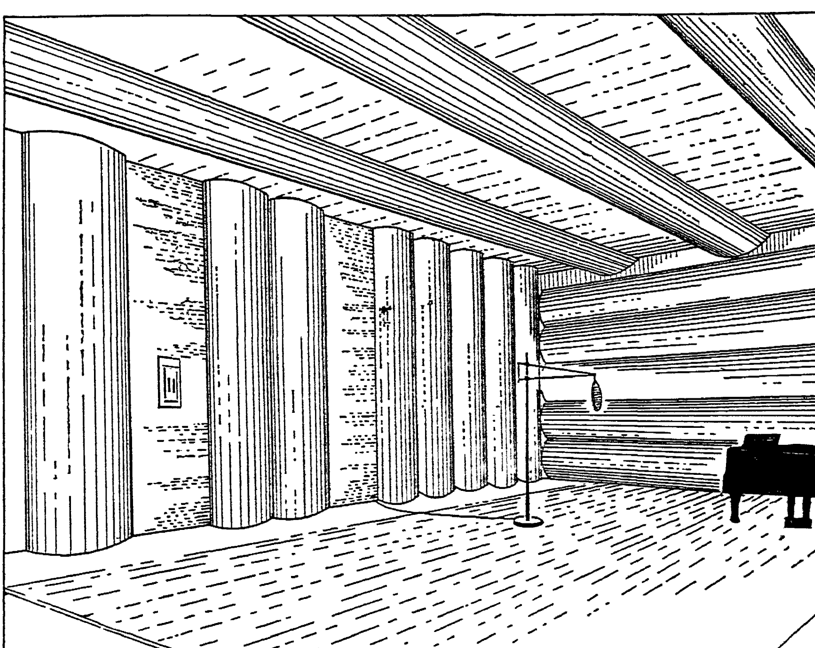


FIG. 3. Polycylindrical Sound Diffusers in an RCA Disk Recording Studio in New York. (Volkmann.)

surfaces located behind, above, and on both sides of the position where the sound originates. In addition, especially in large rooms, the floor should rise progressively toward the rear of the room, or the room should be designed with one or more balconies, so that all auditors obtain an abundance of direct or beneficially reflected sound—the path length of the reflected sound should not exceed that of the direct sound by more than 50 ft, and preferably less than that, so that the reflected sound will reinforce, and not interfere with, the direct sound. Long rooms with level floors, with a low platform or no platform at all, and with a highly absorptive ceiling, are especially poor speech rooms, since much of the sound reaching the auditors in such rooms travels at near grazing incidence over the highly absorptive audience and also along the absorptive ceiling. (See Fig. 4.) The intensity of free progressive sound waves propagated over such surfaces has been found to diminish as the inverse fourth power of the distance from the sound source. Properly designed reflective surfaces, large compared with the wavelength of the sound, will largely compensate for such excessive losses and will insure adequate loudness of unamplified speech for rooms having volumes of less than about 50,000 cu ft. For larger rooms it is necessary to amplify the speech with a suitable public-address system.

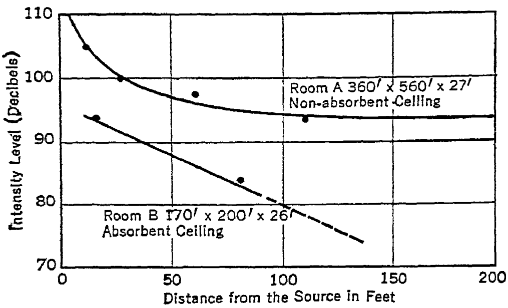

FIG. 4. Variation of Intensity of Sound with Distance from Source in Large Rooms with Absorbent and Non-absorbent Ceilings, Showing the Excessive Decrease in Level Which Occurs When Sound Travels over or along an Absorptive Surface

For further details regarding shape of rooms consult Bagenal and Wood, *Planning for Good Acoustics;* Knudsen and Harris, *Acoustical Designing in Architecture;* and the current and bound volumes of the *Journal of the Acoustical Society of America.*

NOISE. The curve in Fig. 5, obtained empirically, gives the value of the noise-reduction factor k_n for different amounts of noise. The abscissa is the ratio of the sound level of the noise, in decibels, to that of the speech, also in decibels. Thus, when the noise

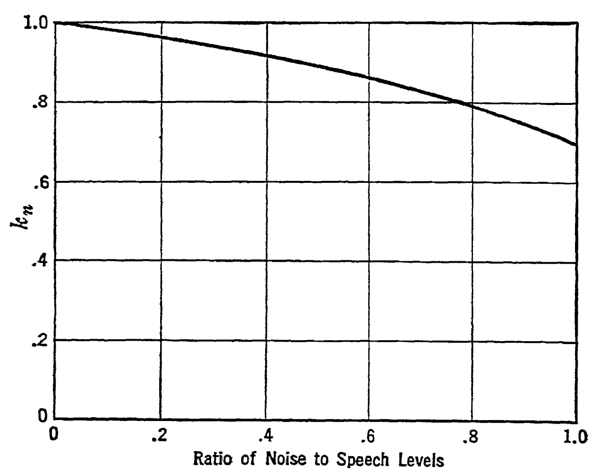

FIG. 5. Effect of Noise on the Hearing of Speech

is at the same level as the speech, the abscissa is 1.0. Although the value of k_n given in these curves is only an approximation, based upon a limited number of measurements, experience has indicated that it is useful in problems of design or correction.

LOUDNESS. The curve of Fig. 3, p. 12-31, gives the percentage articulation for speech as a function of the sound level of speech, as determined by Fletcher and Steinberg. Thus, the optimal sound level of speech, in quiet surroundings, is 70 db above threshold, and for levels below 40 db the articulation drops off rapidly. The loudness reduction factor k_l to be used in eq. (1) is obtained by dividing the percentage articulation by 96. The curve in Fig. 6 gives the average speech power, in microwatts, of the average speaker in rooms of different size. By means of this curve, and the amount of absorption in the

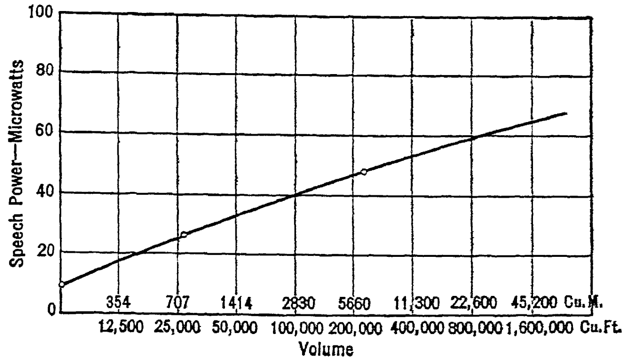

FIG. 6. Average Speech Power of Speakers in Rooms of Different Sizes

room, it is possible to calculate the average sound level of speech for any auditorium, and then from Fig. 3, p. 12-31, to calculate the appropriate value of k_l. In Table 1 are given values of k_l for rooms of different size and different times of reverberation.

Table 1. Values of k_l for Use in Eq. (1)

Time of Reverberation, sec	Volume of Room, cu ft							
	12,500	25,000	50,000	100,000	200,000	400,000	800,000	1,600,000
0.50	0.96	0.94	0.92	0.90	0.88	0.85	0.81	0.76
0.75	.97	.95	.93	.91	.89	.87	.84	.80
1.00	.97	.96	.94	.92	.90	.88	.86	.82
1.25	.97	.96	.95	.93	.91	.89	.87	.83

8.00	.99	.99	.98	.97	.96	.95	.94	.92

REVERBERATION. The curve shown in Fig. 7, empirically determined, gives the value of k_r, the reverberation reduction factor, for different times of reverberation at 512 cycles. This curve is based upon the results of speech articulation data obtained in four-

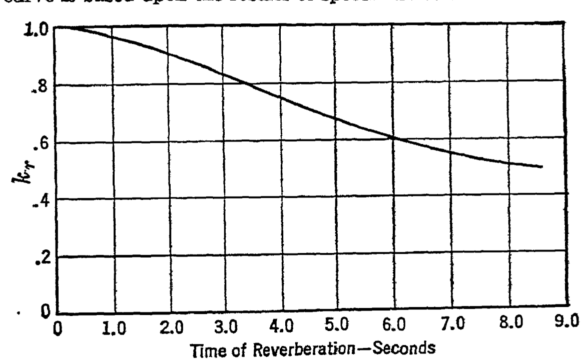

FIG. 7. Effect of Reverberation on Hearing of Speech

teen different auditoriums having times of reverberation varying from less than 1 sec up to more than 8 sec. It is seen that k_r decreases almost uniformly as the time of reverberation increases from 1 to about 6 sec. The abscissa in this curve gives the reverberation time at 512 cycles. In general, the time of reverberation at 128 cycles should be about 25 to 50 per cent longer than it is at 512 cycles, and the reverberation time should remain approximately constant at frequencies above 512 cycles, increasing slightly for frequencies above 2048 cycles.

COMBINED EFFECTS OF LOUDNESS AND REVERBERATION. Since the addition of absorption to a room diminishes the loudness of speech as produced by the average speaker, it is reasonable to assume that there will be an optimal time of reverberation for speech rooms. This optimal time will be attained when a further reduction in the reverberation will concurrently reduce the loudness of speech to the extent that the impairment produced by the diminished loudness will just compensate for the improvement occasioned by the reduction of the reverberation. The curves shown in Fig. 8 were calculated by means of eq. (1), using the appropriate values of the loudness-reduction and reverberation-reduction factors. These curves give approximately the average percentage articulation

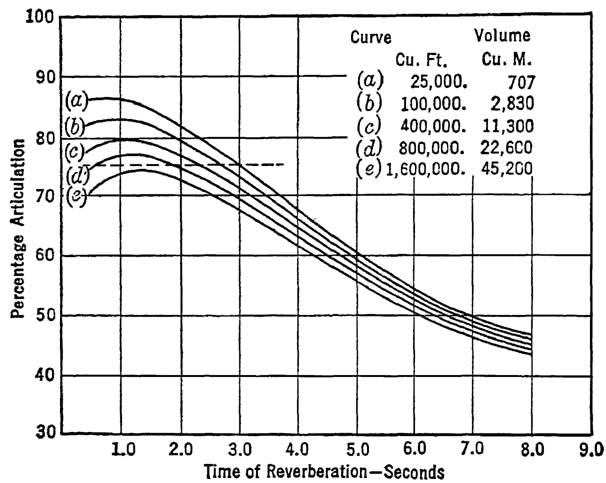

FIG. 8. Percentage Articulation Curves for Rooms of Different Sizes and Different Times of Reverberation

which will obtain in rooms of different sizes and different times of reverberation, for the average speaker, without artificial amplification. If an articulation of 75 per cent is regarded as the minimal for satisfactory hearing (see also article 29), it is apparent that the average speaker will not be heard satisfactorily in an auditorium larger than about 1,000,000 cu ft, no matter what condition of reverberation has been provided for the room. Also, in an auditorium having a volume of 100,000 cu ft the time of reverberation should not exceed 2.70 sec. The curves in Fig. 8 are based upon the assumption that the noise level has been reduced to 30 db, an unusually quiet room, and that $k_s = 1.0$. The need for artificial amplification of speech in large rooms is apparent; amplification should be provided in all rooms larger than about 50,000 cu ft, and even in smaller rooms when considerable noise is present.

The curves in Fig. 8 apply to the average speaker. Speakers with weak voices will not be heard so well, as is indicated by the curves, and speakers with loud voices will be heard better.

In all the curves in Fig. 8 it will be seen that the articulation is a maximum for a particular time of reverberation, and that this optimal time of reverberation increases with the size of the room, a fact which is well established by experience. Furthermore, the percentage articulation in Fig. 8 is the average value; in general, the articulation diminishes progressively with the increase of distance from the speaker.

32. MUSIC ROOMS

The reverberatory properties of a room are of even greater significance for music than they are for speech. The acoustical properties of a music room are no less important than those of the musical instrument to be played in that room; indeed, the room and instrument together comprise a coupled system, and it is this combined system that the ear or microphone "hears." The resonant frequencies of a room, considered in article 20, depend on the dimensions of the room; their intensities and their rates of growth and decay are largely influenced by the distribution of the absorptive and reflective materials over the boundaries of the room.

A music room should be so dimensioned, shaped, and treated with absorptive and reflective materials as to support and enhance the rich quality of the individual tones and harmonies of music, and to join together these separate tones and harmonies so that they coalesce into a continuously flowing melody. The best music rooms, like the best violins, are those which are free from prominent resonances and which have a relatively uniform steady-state response throughout the entire frequency range. Rooms in which the ratio of height, width, and length is approximately 2 : 4 : 5, and in which furred-out wood paneling and wood flooring on wood joists comprise most of the interior boundaries, are found to meet these conditions and usually are highly acclaimed by both performers and listeners. The use of non-parallel pairs of opposite walls, of polycylindrical diffusers of wood veneer, similar to those illustrated in Fig. 3, and of "patches" of absorptive materials distributed over walls and ceiling so as to give an ergodic diffusion of sound has given good results.

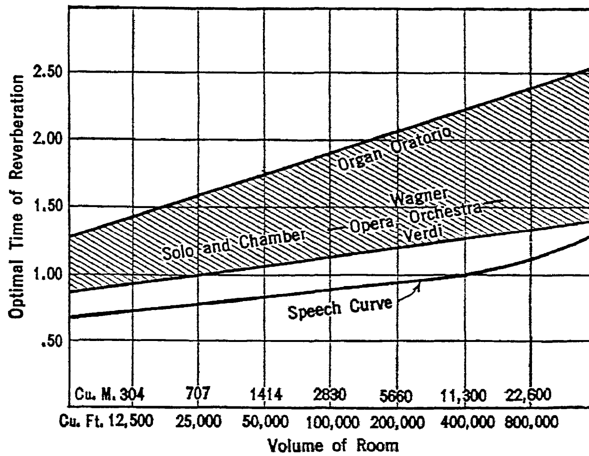

FIG. 9. Optimal Reverberation Times for Speech and Music Rooms

The design of music rooms should always be guided by the principles of wave acoustics. However, the optimal reverberation characteristics can be best calculated by means of the approximate formulas of geometric acoustics, such as eq. (3) of article 19.

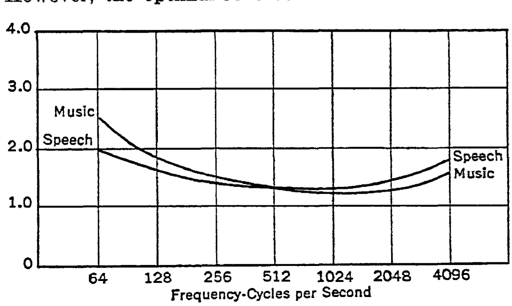

FIG. 10. Optimal Reverberation Times at Different Frequencies, for Speech and for Music, When the Optimal Reverberation Time at 512 Cycles Is 1.3 Seconds. Similar curves should be used when the optimal time at 512 cycles differs from 1.3 seconds.

The optimal reverberation time for music rooms depends not only on the size of the room but also on the type of music to be performed in the room. The ideal arrangement should provide for adjustable reverberation so that the optimal reverberatory properties can be readily obtained for all musical performances for which the room is designed.

The chart in Fig. 9 shows the optimal times of reverberation for both speech rooms and music rooms. This chart applies for a frequency of 512 cycles. As for speech, the reverberation time at 128 cycles should be approximately 25 to 50 per cent longer than the time for 512 cycles; the reverberation time should remain approximately constant for frequencies between 512 and 2048 cycles, and should increase slightly for frequencies above 2048 cycles (see Fig. 10).

Experience has shown that the most satisfactory reverberation time for radio broadcasting or sound-recording studios is about two-thirds to three-fourths of the accepted time for speech or music rooms (see also Section 16, Sound-reproduction Systems).

33. PRACTICAL PROCEDURE FOR OBTAINING GOOD ACOUSTICS IN BUILDINGS

The procedure for obtaining good acoustics in buildings begins with the selection of the site and ends with the furnishing, testing, and maintaining of the building. The necessary steps, approximately in chronological order, are as follows:

1. *Selection of a suitable site* (sound studios, theaters, schools, churches, and hospitals, especially, should be located in quiet surroundings).
2. *Noise survey*, at the proposed site, to determine the amount of insulation required to reduce the noise level in the building to a satisfactory point.
3. *Insulation against outside noise*, which includes not only the selection of the proper sound-insulative and sound-absorptive constructions but also the proper arrangement of rooms, corridors, entrances, windows, landscaping, and other appurtenances of the building.
4. *Design of the shape of the room* (shapes should be designed which not only will avoid such acoustical defects as echoes, interfering reflections, room flutter, and sound foci, but also will facilitate the most advantageous flow of diffuse sound energy to all auditors in the room, and at the same time will preserve or even enhance the natural beauty of speech and music).
5. *Control of the noise within the building*, including solid-borne as well as air-borne noise and vibration.
6. *Selection and distribution of the absorptive and reflective materials to provide the optimal conditions for both steady-state and transient sounds throughout the room*, a problem which deserves special study and careful planning, and one which involves, besides the acoustical characteristics of the materials, such properties as structural strength, decorative possibilities, adaptability to the surfaces available for, or requiring, absorptive treatment, maintenance, sanitation, ease of application, fire hazard, absorption of water, attraction for vermin, "fool-proofness," durability, and cost.
7. *Supervision of the installation of acoustical materials* (especially necessary for the application of acoustical plaster—in large buildings it is advisable to require the plastering contractor to prepare a small room for test and approval before the plaster is used in other parts of the building).
8. *Installation of high-quality amplifying equipment under the supervision of a competent engineer* is necessary in all large auditoriums; even in rooms seating as few as 200 or 300 persons it will be found that many speakers have weak voices that require amplification.
9. *Inspection of the finished building* should include tests to determine whether the sound insulation, the sound absorption, and the other acoustical properties have been satisfactorily attained.
10. *Maintenance instructions, preferably in writing, should be left with the building manager*, indicating (*a*) how the acoustical materials can or cannot be cleaned or redecorated, (*b*) which furnishings in the building are essential to good acoustics, and (*c*) how the humidity of large speech and music rooms should be maintained in order to avoid excessive absorption of high-pitched sounds.

The foregoing steps, or their equivalent, if carefully executed, will lead to good acoustics. Developments in modern theories of room acoustics, supplemented by additional empirical data, will contribute to more reliable criteria than are now available for determining the best acoustical shape of a room and the most favorable distribution of absorptive and reflective materials throughout the room; but if proper use is made of what is now known there need be no anxiety respecting the outcome in the acoustics of buildings—the outcome will be good.

SECTION 13

ELECTROMECHANICAL-ACOUSTIC DEVICES

ELECTROMECHANICAL-ACOUSTIC DEVICES

EFFECTS OF THE ACOUSTIC MEDIUM

By Hugh S. Knowles

"An electroacoustic transducer is a transducer which is actuated by power from an electrical system and supplies power to an acoustic system, or vice versa." (I.R.E. Standards.)

The theory of operation of electroacoustic transducers is an extension of the theory of electromechanical transducers, in which account is taken of the reaction of the fluid, or acoustic medium, on the diaphragm. (See Section 5, article 33.)

1. PHYSICAL PROPERTIES OF COMMON ACOUSTIC MEDIA

The velocity of a sound of small (infinitesimal) wave amplitude depends on the elasticity and density of the fluid. The velocity of propagation, c, of a sound wave is

$$c = \sqrt{\frac{k}{\rho}} = \sqrt{\frac{\gamma p_0}{\rho}} \quad \text{cm sec}^{-1} \tag{1}$$

where k is the volume modulus of elasticity, ρ is the density in grams cm^{-3}, γ is the ratio of the specific heat at constant pressure to that at constant volume, and p_0 is the static pressure of the fluid.

The characteristic impedance, z_0 (also sometimes called surge impedance or acoustic resistance), of the medium is

$$z_0 = \sqrt{k\rho} = \rho c \quad \text{mechanical ohms cm}^{-2} \tag{2}$$

1. Air. The density, ρ, at 20 deg cent and $p_0 = 760$ mm ($\doteq 10^6$ dynes cm^{-2}) is 0.001205 gram cm^{-3}; $\gamma \doteq 1.41$, giving

$$c \doteq 33{,}060 + 61\theta \quad \text{cm sec}^{-1} \tag{3}$$

where θ is the temperature in degrees centigrade. Also the radiation resistance of air is

$$z_0 = 42.8 - 0.079\theta = 41.2 \quad \text{mechanical ohms cm}^{-2} \text{ at 20 deg C} \tag{4}$$

The pressure level, L_p, in decibels is

$$L_p = 20 \log_{10} \frac{p}{p_0} = 74 + 20 \log_{10} p \tag{5}$$

where p is the pressure and p_0 the reference pressure of 0.0002 dyne cm^{-2}. The intensity, I, in the direction of propagation, of a plane or spherical "free" (i.e., no reflections) sound wave is

$$I = \frac{p^2}{\rho c} = 2.42 \times 10^{-9} p^2 \quad \text{watt cm}^{-2} \tag{6}$$

where p is the rms sound pressure in dynes cm^{-2}.

2. Hydrogen. The density, ρ, of hydrogen at 0 deg cent and at $p_0 = 760$ mm is approximately 0.00009 gram cm^{-3}. The velocity $c \doteq 1.26 \times 10^5$ cm sec^{-1}, from which $z_0 = 11$ mechanical ohms cm^{-2}.

3. Water. The density, ρ, of water is $= 1.0$ gram cm^{-3}. The value of c at 20 deg cent $= 1.46 \times 10^5$ cm sec^{-1}, from which $z_0 = 1.46 \times 10^5$ mechanical ohms cm^{-2}.

REACTION OF ACOUSTIC MEDIUM ON A DIAPHRAGM. The audible frequency range of sounds covers roughly 10 octaves. Even the more important range from 80 to 8000 cycles covers nearly 7 octaves, giving a wavelength range of roughly 428 cm (14.1 ft) to 4.28 cm (1.69 in.). Radiation, diffraction, and reflection phenomena which depend on the relative length of the sound wave and the linear dimensions of the radiator, or collector, therefore differ greatly in different portions of the wavelength range, and hence simplifying assumptions can ordinarily be made only over restricted frequency ranges.

2. MECHANICAL IMPEDANCE TO MOTION OF SOME SIMPLE ACOUSTIC RADIATORS

The impedance to motion of a diaphragm is altered by its contact with the acoustic medium or fluid. If the diaphragm has an effective area S and a mechanical impedance z_m, its total effective mechanical impedance is $z_{mf} = z_m + z_f$, where z_f is the fluid impedance (see also Section 5, article 33).

SOURCE RADIATING PLANE SOUND WAVES. The impedance per unit area in contact with the fluid is the characteristic impedance of the medium, and the total increase in mechanical impedance to motion of a radiator of effective area, S, resulting from contact with the fluid medium, is

$$z_f = r_f = z_0 S \tag{7}$$

or $\doteq 41.2 \times S$ mechanical ohms in the case of air. At any frequency, the radiated acoustic power is

$$P_f = \dot{s}^2 r_f 10^{-7} \tag{8}$$

or $4.12 \times 10^{-6}\dot{s}^2 \times$ watts in the case of air ($\dot{s}$ is the velocity of the radiator element).

PULSATING SPHERE RADIATING SPHERICAL SOUND WAVES INTO AN UNLIMITED ACOUSTIC MEDIUM. A pulsating sphere is one in which the surface vibrates or pulsates with small amplitude and uniform velocity in a radial direction. At any frequency the impedance per unit area in mechanical ohms is

$$z_A' = r_A' + jx_A' = \rho c\left(1 + \frac{1}{jkR}\right)^{-1} = \rho c\,\frac{k^2R^2}{1 + k^2R^2} + j\omega\,\frac{\rho R}{1 + k^2R^2} \tag{9}$$

where $k = 2\pi/\lambda = \omega/c = 2\pi f/c$, where λ is the length of the emitted sound wave, and R is the radius of the sphere in centimeters. This leads to an equivalent circuit of parallel mass and resistance elements of values (for the whole surface) $m_f = 4\pi\rho R^3$ grams and $r_f = 4\pi R^2 \rho c$ mechanical ohms.

Graphical plots of r_A' and x_A' are given in Fig. 1. The imaginary or reactance term is in phase with the acceleration and is an inertia or mass reactance term.

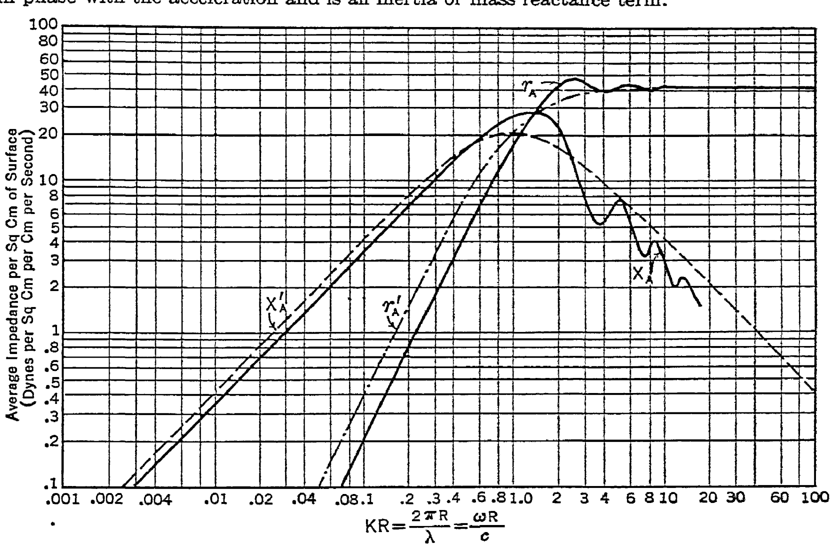

FIG. 1. Air Resistance and Reactance per Unit Area on One Side of a Pulsating Sphere of Radius R (r'_A and x'_A) and on One Side of a Circular Piston of Radius R (r_A and x_A) in an Infinite Baffle

The fluid increases the impedance to motion of the spherical surface or diaphragm by an amount $z_f = Sz_A'$. At any frequency the radiated acoustic power is $P_f = \dot{s}^2 r_f \times 10^{-7}$ watt.

Special Case of a "Point" Source ($R \doteq 0$). When the length of the sound wave is large in comparison with the radius of the sphere ($\lambda \gg R$ and $k^2R^2 \ll 1$),

$$z_f \doteq 4\pi\rho R^4 \frac{\omega^2}{c} + j\omega 4\pi\rho R^3 \quad \text{mechanical ohms} \tag{10}$$

CIRCULAR RIGID DIAPHRAGM OR "PISTON" reciprocating or vibrating sinusoidally in a (perfect-fitting) cylindrical hole, in an infinite plane wall or baffle, and radiating into an unlimited fluid ("semi-infinite" medium) on each side of the baffle, is another configuration of interest. (R is the radius in centimeters.)

The impedance per unit area is not constant over the surface in this case, but since the radiator is assumed rigid an average value may be taken. At any frequency the impedance in mechanical ohms cm^{-2} is given by $z_A = r_A + jx_A$ as plotted in Fig. 1.

Since the imaginary term is in phase with the acceleration, it is a mass reactance term. The increase in mechanical impedance to motion of a piston, $z_f = r_f + jx_f = S(r_A + jx_A)$, which results from an air "load" may be obtained directly from these curves by multiplying the ordinate for any value of kR by the area of the piston. When the fluid is air, piston radiators are usually operated with fluid on both sides of the baffle. Both sides of the piston must then be considered, in which case $S = 2\pi R^2$. The total apparent increase in mass of the piston is $m_f = Sx_A/\omega$. At any frequency, the radiated acoustic power is $P_f = \dot{s}^2 r_f \times 10^{-7}$ watt.

Special Case of a "Point" Source ($R \doteq 0$). When the length of the sound wave is large in comparison with the radius of the piston, the impedance per unit area is

$$z_A \doteq \frac{\rho R^2\omega^2}{2c} + j\omega\frac{8}{3\pi}\rho R \tag{11}$$

Reference to Fig. 1 will show that, for small values of kR, $x_A \gg r_A$, so that $z_A \doteq jx_A$. That is, the increase in impedance to motion of the piston, which results from contact with the fluid, is largely reactive. At this low-frequency condition the radiation impedance of the piston may be represented by an equivalent circuit of parallel mass and resistance elements of values $8\rho R^3/3$ grams and $(128/9\pi^2)\pi R^2\rho c$ mechanical ohms respectively. The values are $0.00656d^3$ grams and $301d^2$ mechanical ohms, d being the piston diameter in inches.

It has been found experimentally that when a conventional rigid conical diaphragm loudspeaker is used S is approximately the area of the "base," or large end, of the cone; also, that the usual magnetic structure changes the radiation from the rear surface of the cone by a negligible amount at low frequencies.

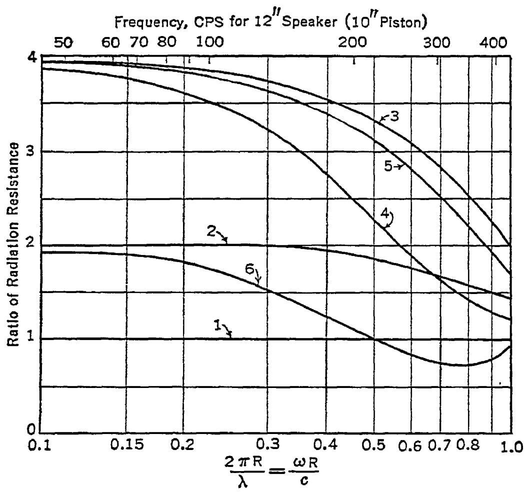

FIG. 2. Ratio of Total Radiation Resistance of a Piston, Vibrating in the Presence of Others, to the Radiation Resistance of a Single Piston. Curve 1, single piston. Curve 2, each of two tangent pistons. Curve 3, each of four tangent pistons in square array. Curve 4, each outer, and Curve 5, each inner, piston of four tangent pistons in a straight line. Curve 6, each of two pistons with centers three diameters apart. All pistons have equal velocities (both magnitude and phase) and equal diameters, and vibrate in an infinite plane baffle.

MULTIPLE PISTONS. When more than one piston radiates into a common region in the medium any one position experiences not only the force on its surface arising from its own vibration but additional forces due to the vibration of the other pistons. The resultant force is the vector sum of the individual forces. The magnitude and phase of each force depend on the diameter, velocity, and frequency of vibration of the piston giving rise to the force and upon its distance from the reference piston. The ratio of the resultant force on any piston, to its velocity, is the total fluid or radiation impedance and comprises the self-impedance due to its own vibration, discussed above, and the mutual impedances due to the vibration of the other pistons. From Fig. 2 it will be seen that the real part of the total impedance increases as the distance between the pistons decreases and their number and hence total area increase. When the pistons are close together, vibrate with equal amplitude, and are separated by a small fraction of a wavelength, they approximate a single piston equal in area to the combined area of the individual pistons. It may also be seen that as the separation and frequency are increased the phase of the force arising from the vibration of the other piston is retarded and may give rise to a component out of phase with the velocity of the reference piston which lowers the radiation or fluid resistance below the value the reference piston would have alone. This occurs in curve 6, Fig. 2, for values of $\omega R/c$ greater than 0.5.

ENCLOSED BACK PISTON. Same as preceding case but with small enclosure to suppress radiation from one side of a diaphragm, or to add stiffness to the vibrating system.

The fluid impedance at the external surface corresponds to the preceding case (note that $S = \pi R^2$).

If the dimensions of the enclosure are larger than the diameter of the piston the enclosure adds approximately the same effective mass per unit area, m_A, as the unlimited fluid medium. Therefore, the effective area used in calculating the total effective fluid mass is $S = 2\pi R^2$, that is, $m_f = 2\pi R^2 m_A$.

If the length of the radiated sound wave is roughly four or more times the maximum linear dimension of the enclosure, uniform adiabatic compression of the fluid occurs. The enclosure then increases the stiffness (see Section 5, article 33) per unit area of the mechanical system by an amount

$$s_A = \frac{\rho c^2 S}{V_0} \quad \text{cm dyne}^{-1}\,\text{cm}^{-2} \qquad (12)$$

(V_0 is the volume of the enclosure). The total increase in stiffness, s_f, due to the fluid, is Ss_A.

The enclosure does not approximate a constant stiffness when the length of the sound wave is less than four times the maximum linear dimension of the enclosure.

If the purpose of the enclosure is to provide a "sink" to absorb back side radiation, absorbing material is usually placed in the enclosure. This increases the effective resistance of the vibrating system. The absorption coefficient of the material used is normally high enough at the high resonant frequencies of the enclosure to make the enclosure approximate a semi-infinite medium.

3. HORNS

"A horn is an acoustic transducer consisting of a tube of varying sectional area."

The proper use of a horn as the radiating portion of a loudspeaker leads to better control of the response, efficiency, and directional characteristics. In addition these characteristics may be controlled almost independently of one another.

The total radiation response of a horn considered as an acoustical circuit element is determined largely by its throat impedance as a function of frequency. In all well-designed horns, transmission losses are minimized, so that the energy output is closely equal to the input.

The rigorous calculation of the throat impedance is possible for but very few useful horn contours, and so approximate methods are used. The low-frequency region is of greatest interest to the horn designer, as all horns have a high-frequency throat mechanical impedance which approaches a constant resistance that is the same (per unit area) for all horns. Experiment reveals that the low-frequency wave fronts in the horn are smoothly curved surfaces (Fig. 3); by expressing this mathematically there results a pressure wave equation in which the only space variable is the axial distance. For convenience, all horn-design work is usually referred to a straight axis horn of circular cross-section, as in Fig. 3.

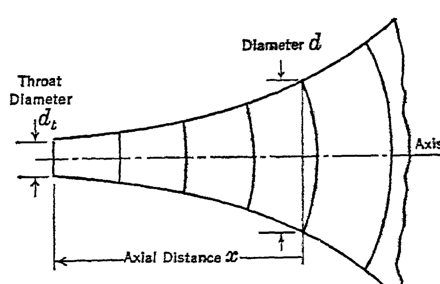

FIG. 3. Low-frequency Wave Fronts in Long Straight Axis Horn of Circular Cross-section

The question arises as to what types of horns have this kind of simplified behavior. Starting from the experimental data it is observed that the "chords" (the diameter, d, in Fig. 3) for the wave fronts are approximately proportional to the square root of the area of the wave front, provided that the expansion of the horn is not too rapid. If the sound pressure is assumed to decrease steadily as the horn expands, modified by the change of phase down the horn, this assumption may be expressed analytically and inserted into the pressure wave equation together with the relation between d and the area of wave front. This leads to a relation between d and x, the axial distance, which when solved yields

$$d = d_t[\cosh(x/x_0) + T \sinh(x/x_0)] \tag{13}$$

Here d_t is the diameter at the throat; x_0 is a reference distance fixing the rate of taper of the horn, and is related to the cutoff frequency f_c by $f_c = c/2\pi x_0$; and T is a parameter by which a particular horn contour is selected. The names "catenoidal horns" and "Salmon horns" have been suggested for this family, the latter after the person who first described their characteristics.

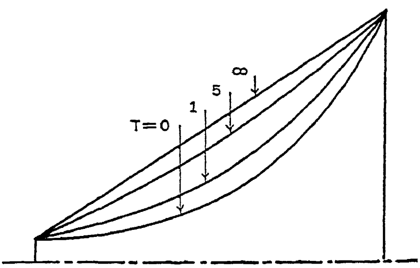

FIG. 4. Contours of Horns of Eq. (13) for $T = 0$, 1, 5, and ∞

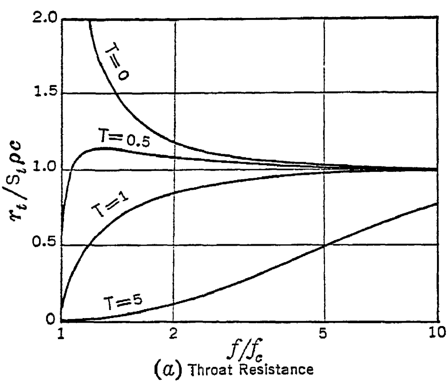
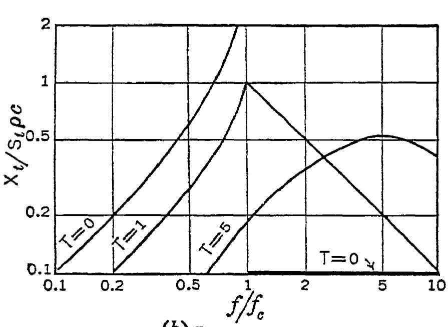
The family is the most general one consistent with the simplifying assumptions made; for $T = 1$ there results the familiar exponential horn $d = d_t \exp(x/x_0)$, while for $T = \infty$ there results, by a limiting process, the conical horn. At $T = 0$, $d = d_t \cosh(x/x_0)$, which may be termed the cosh horn. Since this family includes the most widely used horn contours, it will be taken as a basis of discussion. Contours for $T = 0$, 1, 5, and ∞ are shown in Fig. 4.

The low-frequency throat impedance of all practical horns shows considerable variation with frequency due to reflections from the mouth. Hence it is common engineering practice to state as the throat impedance that for the infinite horn (outgoing wave only); in practice the actual impedance varies about the infinite horn value as a mean, or trend, which is approached as reflections from the mouth are decreased. When the mechanical throat impedance is evaluated for the horns of eq. (13) there results

$$Z_t = r_t + jx_t$$
$$= S_t\rho c\left\{\frac{[1 - (f_c/f)^2]^{1/2} + j(Tf_c/f)}{1 - (1 - T^2)(f_c/f)^2}\right\}, \tag{14}$$



(a) Throat Resistance



(b) Throat Reactance

FIG. 5. Throat Impedance of Infinite Horns of Eq. (13). The f_c in the abscissa is the cut-off frequency.

where S_t is the throat area; ρc is the characteristic impedance of the medium; the cutoff frequency $f_c = c/2\pi x_0$, c being the velocity of a free sound wave. An examination of eq. (14) reveals that r_t is zero for $f < f_c$ (for the infinite horn), so that below f_c the impedance is entirely reactive. Figure 5 shows $r_t/S_t\rho c$ and $x_t/S_t\rho c$ as functions of f/f_c for $T = 0$, 0.5, 1, and 5. The equivalent circuit of the mechanical impedance of eq. (14) is as shown in Fig. 6; note that the parallel elements are simple; only m_t varies with T, and only r_t varies with f.

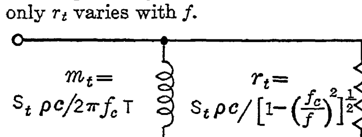


FIG. 6. Equivalent Circuit of Throat of Horns of Eq. (13). Negligible reflection from mouth.

The selection of the optimum member of the above family of horns cannot be considered apart from the loudspeaker unit or other source out of which the horn is to work, as both form a fairly tightly coupled system. The essential mechanical elements are shown in Fig. 7 for a moving-coil driving unit as discussed in article 6.

The electrical system consists of a generator of constant emf, e, and total electrical impedance, r_e, which is here assumed resistive and equal to the generator resistance proper plus the blocked resistance of the voice coil. The resulting force input to the circuit of Fig. 7 is thus $\beta le/r_e$, which is fairly constant for horn loudspeakers. As seen from the mechanical mesh, the electrical side also contributes a "source impedance" $r_1 = (\beta l)^2/r_e$ which is as constant as the force. In these expressions β is the magnetic flux density in the gap and l is the conductor length.

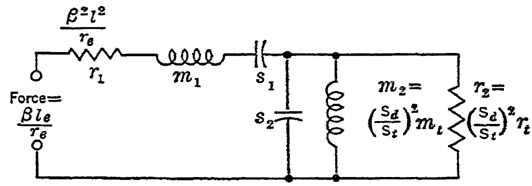

FIG. 7. Approximate Equivalent Circuit of Typical Horn Loudspeaker. $(S_d/S_t)^2$ is the impedance ratio of the fluid transformer formed by the areas S_d and S_t.

In the purely mechanical system m_1 is the mass of the loudspeaker motor, and s_1 its stiffness, which may include air trapped back of the diaphragm. The stiffness of the air s_2, of volume V, between diaphragm and horn throat (the sound chamber), is equal to $\rho c^2 S_d^2/V$ when referred to the diaphragm area S_d. Because S_d is usually different from S_t the horn throat elements of Fig. 6 appear at the diaphragm multiplied by the fluid transformer impedance ratio $(S_d/S_t)^2$, which is controlled by the horn.

The configuration of the circuit is that of a band-pass filter; however, this is not a satisfactory basis of design, as only a half section is present. In practice a flat response is not always the desired goal, and so the elements are chosen with a particular application in mind. Usually the unloaded resonant frequency, $f_1 = \frac{1}{2\pi}\left(\frac{s_1}{m_1}\right)^{1/2}$, of the motor is placed below the midband, while the other resonant frequency, $f_2 = \frac{1}{2\pi}\left(\frac{s_2}{m_2}\right)^{1/2}$, is placed above. The bandwidth is fixed largely by s_2/s_1; thus the sound-chamber volume and hence the clearance to the diaphragm should be as small as possible for a wide band. The horn influences this by controlling m_2 through the parameter T, permitting f_2 to be properly placed, with a suitable s_2.

The sound chamber, which may be regarded as a part of the horn just as a transformer is often associated with a loudspeaker, serves to reduce the effect of m_1 at high frequencies by the $m_1 - s_2$ resonance. Similarly at low frequencies the $m_2 - s_1$ resonance, as influenced by the value of T, may produce a rise in response. This reactance annulling permits good low-frequency response to be obtained by placing the horn cutoff frequency, f_c, below f_1, the resonant frequency of the $m_1 - s_1$ combination.

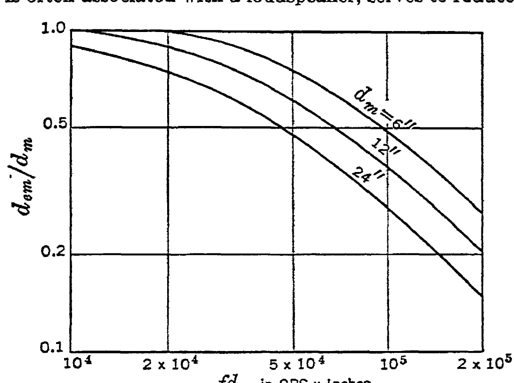

FIG. 8. Approximate Relation between Effective Mouth Diameter and Frequency for Exponential Horn

The termination r_2 is usually close to r_1 to obtain approximate matching in the mid-response region, thus governing the maximum efficiency. This involves the proper relation between horn-throat area and useful magnetic energy in the air gap. When $r_1 \doteq r_2$, variations in horn-throat impedance due to mouth reflections have a minimum effect on the radiated power. These reflections are minimized also when the product of mouth diameter in inches and cutoff frequency in cps is greater than 4000; this product may be made as little as 2000 if $r_2 \doteq r_1$.

Since diaphragms are often called on to radiate energy at wavelengths for which destructive interference may take place across the diaphragm, it is usual to remove the radiation by one or more annular slots so placed that phase effects are minimized. The annular passages may then be constricted in average diameter until the circular horn section is reached.

The directional properties of a horn are largely determined by the mouth geometry, particularly the diameter and slope. As frequency is increased, there is reached a value at which the emergent sound is so directional that the wave does not "touch" the mouth portion at all. Thus the effective mouth diameter decreases as the frequency is raised, and in some designs the polar response pattern becomes almost independent of frequency. Data reported in the literature may be presented in the form of equivalent mouth diameter as a function of frequency. In Fig. 8 this is shown for one group of measurements on exponential horns; the curves are rough approximations and should be taken as indicating only the trends. The ratio (d_{em}/d_m) is that of equivalent and actual mouth diameters.

In general, the steeper the mouth slope, the less directional the horn; but, if this generalization is carried too far, the violence done to the wave fronts appears as a rough response characteristic. The directional effect of horns is not too serious in practical applications, for often this property is useful in reducing acoustic feedback and improving the sound level in a desired localized region. When uniform radiation over a large solid angle is required, multicell horns are commonly used. Often the shape of the horn may be altered so as to provide improved distribution, and this frequently results in a more uniform space-response variation.

LOUDSPEAKERS AND TELEPHONE RECEIVERS

By Hugh S. Knowles

A loudspeaker is an electroacoustic transducer actuated by energy from an electrical system and radiating energy into an acoustical system, the spectral composition of the energy in the two systems being substantially equivalent. Loudspeakers may be classified as to type of radiator or radiating system, type of motor, and reversibility.

4. ACOUSTIC RADIATORS

DIAPHRAGMS. The transformation of electrical into acoustical energy is usually accomplished by electrically actuating a surface or diaphragm in contact with air, or some other fluid, causing it to move and set the adjacent air particles in motion. (See, however, article 9.) When the resulting radiation is into a large solid angle the radiation resistance, or real part of the fluid impedance, is low when the length of the radiated wave substantially exceeds the diameter of the radiator. The diaphragm serves to couple the air, which has low impedance per unit area, to a motor having a relatively high mechanical impedance, when connected to its source of electrical energy, viewed from the diaphragm.

The low radiation resistance is unfortunate both because of the problem of obtaining efficient energy transfer and because large diaphragm amplitudes are required to radiate appreciable power at low frequencies. Figure 1 shows the peak diaphragm amplitude, or half the total diaphragm displacement, required of several piston sizes to radiate 1 watt. One-tenth this amplitude is required to radiate 10 milliwatts. These curves cover the frequency range in which the radiation resistance is proportional to the square of the frequency and to the fourth power of the piston radius.

Most diaphragms are conical in shape and, if rigid, displace the same amount of air for the same amplitude as would a flat piston having a diameter equal to the diameter of the base of the cone. At low frequencies the base diameter of the cone is therefore taken as the equivalent piston diameter.

The size of the usual conical diaphragm, frequently called a cone, is limited by the need for increasing its mass per unit area as the area is increased in order to maintain adequate stiffness. It is customary to make the diaphragm thickness vary almost directly with the diaphragm diameter. This largely offsets the improved resistance-reactance ratio of the fluid impedance.

The conical diaphragm may be thought of as a conical transmission surface in which there are both radial and circumferential waves. At low frequencies only the radial wave need be considered. The flexible annular support or "surround" provides a termination for the base or large diameter of the conical surface. The flexural phase velocity of the radial wave in the diaphragm and the impedance of the termination are such that the effective length is one-quarter wave at 600 to 1000 cps in large diaphragms (16-in. to 10-in. "pistons") and at 1000 to 2000 cps in small diaphragms (8-in. to 2-in. "pistons"). Below this frequency all parts of the cone move in phase although the amplitude is not substantially uniform except at lower frequencies where the radial length is a small fraction of a wavelength. If the annular support behaves as a non-linear stiffness over the required amplitude range, as it frequently does, the diaphragm may flex in a complicated way even at low frequencies.

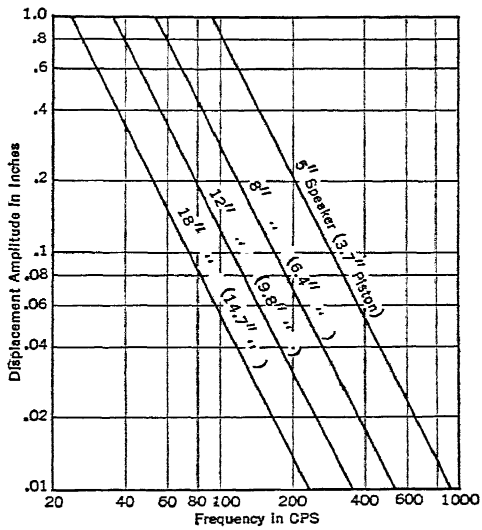

FIG. 1. Displacement of Piston from Equilibrium Position Required to Radiate 1 Watt. The total displacement is twice the value given. (If both sides radiate, divide by $\sqrt{2}$.)

Wave transmission in the diaphragm is desirable because it results in a more favorable high-frequency driving point impedance into which the motor is coupled. It also results in a broader high-frequency directional pattern than would obtain if the diaphragm were a rigid piston. When maximum loudness is required, a diaphragm made of materials having low internal dissipation such as pressed or calendered paper and a low-resistance flexible annular termination is used. When a smoother response-frequency curve is desired with reduced transient distortion and the reduced loudness can be tolerated, a "soft" more blotterlike material with higher flexural resistance is employed, sometimes with a dissipative termination of leather, felt, cloth, or a dissipative elastomer. The modes of vibration of the diaphragm are also influenced by cone angle, lumped masses and compliances (usually annular beads or corrugations), impregnants, etc. Because of the complex behavior of diaphragms most design work is largely empirical.

To reduce the mass per unit area and yet obtain the benefit of a large radiating area multiple diaphragms are frequently used. If all the diaphragms vibrate in phase and with the same amplitude the average radiation impedance seen by the array will correspond to that of a single diaphragm of equal area. (See p. 5-66.) By properly orienting the speakers the spatial radiation pattern, at high frequencies, may be improved.

In addition to the common right circular cone shape two others are sometimes used. The conoidal or "curvilinear" is used when an increase in radiation above 5000 cps is wanted at the expense of the 2000–5000 cycle region. The elliptical shape is sometimes used when space requirements limit one dimension of the cone. Unfortunately the limited dimension is usually the vertical one, resulting in the major or long axis of the ellipse being mounted horizontally. Contrary to popular belief this leads to a narrow horizontal and wide vertical high-frequency directional pattern as predicted from theoretical considerations. In spite of the appeal of its shape the oval or elliptical diaphragm has had limited acceptance because it is more difficult to fabricate, its response is more difficult to adjust, it has less radiation resistance in the middle-frequency range than a circular diaphragm of identical area, and its asymmetrical support leads to cone and moving-coil distortion which necessitate larger air-gap clearances for a comparable safety factor.

Over the frequency range in which the fluid mass, m_f, is substantially constant most conical diaphragms behave as a rigid piston of mass m_m. If the flexible centering members supporting each end of a conical diaphragm are linear (displacement proportional to force), their stiffnesses may be combined into an equivalent stiffness s_m or equivalent compliance C_m.

HORNS. The radiation from a horn may be considered as originating at the mouth, with the remainder of the horn serving to "match" the mouth and throat terminating impedances. For this purpose it is important that the walls be relatively non-porous and non-vibratile.

The theory has been developed on the basis of a straight axis horn of circular cross-section, with no reflections from the mouth. One common departure from these idealized conditions is in the shape of the axis. It may be bent, as in the low-frequency horns used in theater systems, or it may be folded, as in re-entrant public-address horns. The contour of the boundary at the changes in the direction of the axis must usually be selected empirically because of the complex manner in which the wave front executes the change in direction. The contour must also be selected so as to avoid exciting transverse modes of vibration of the air. This requires smoothly and symmetrically changing contours, and careful attention to the symmetry of the driving diaphragms with respect to the throat of the horn.

In practice, the cross-sectional area may be circular, rectangular, or annular, the last two corresponding to the theater and public-address horns mentioned above. In these horns the lateral dimensions are chosen to retain the same area-axial distance relation as in the circular (reference) horn.

The effect of mouth reflections may be minimized by proper attention to the horn driver unit (see article 3). Advantage may be taken of reflections to load the horn unit at frequencies near cutoff for which the radiation resistance is normally low.

5. EFFICIENCY

The total power dissipated by the mechanical system is

$$P_{mf} = \dot{s}^2 r_{mf} = \dot{s}^2 (r_m + r_f) = \frac{I^2 z_{12}^2}{z_{22}^2}(r_m + r_f) \qquad (1)$$

in which r_m and r_f are the mechanical and fluid resistances, I is the current in the electric mesh and z_{22} is the total self-impedance of the mechanical system, and the electrical and mechanical meshes are numbered 1 and 2 respectively. (See Section 5, article 33 and eqs. [4*a*] to 5[*b*] below.)

Energy Efficiency. The ratio of acoustic power (or energy) output to electric power (or energy) input is called the energy or conversion efficiency and corresponds to the definition of efficiency commonly used for most transducers other than electroacoustic ones. This efficiency is

$$\eta_e = \frac{z_{12}^2 r_f}{z_{22}^2 r_{mc} + z_{12}^2 r_f} \qquad (2)$$

where r_{mc} is the blocked resistance of the system.

System Efficiency. Because both the modulus and phase angle of the normal input impedance of the speaker vary with frequency, the speaker in general absorbs less power from the source than an ideal load or transducer would. Since this inability of the transducer to absorb maximum power limits the useful power output of the source, it in effect reduces the "efficiency" of the transducer.

To take this property into account, the ratio of the acoustic power output to the electric power input which the source would supply if connected to an ideal transducer is defined as the system or absolute efficiency. If the source is a vacuum tube or generator whose internal impedance is a pure resistance, r_g, it supplies maximum power to a resistance of equal value, and the system efficiency is

$$\eta_s = \left| \frac{4 r_g z_{12}^2 r_f}{(z_{11} + z_M)^2 z_{22}^2} \right| \qquad (3)$$

where $z_M = z_{12}^2/z_{22}$, the other quantities are as defined above, and the vertical lines indicate that the absolute value is to be taken.

6. MOVING-CONDUCTOR SPEAKERS

"A *magnetic speaker* is a loud speaker in which the mechanical forces result from magnetic reactions."

"A *moving-conductor speaker* is a magnetic speaker in which the mechanical forces result from magnetic reactions between the field of the moving conductor and the steady applied field. (This is sometimes called a dynamic speaker.)" This classification includes moving-coil or electrodynamic (sometimes called "dynamic") and ribbon or "band" speakers. Cross-sections of two typical moving-coil speakers are shown in Fig. 2.

The mechanical circuit may be considered a series circuit with the elements m_{mf}, C_{mf}, and r_{mf}, which include the fluid impedance. In general the circuit elements are functions of frequency.

The actuating force on the conductor is βli dynes, where β is the flux density in gausses, l the conductor length in centimeters, and i the instantaneous current in abamperes (amperes × 10). If the electrical circuit, including the moving coil and generator, has a total series inductance L_e, capacitance C_e, and resistance r_e, and the generator an instantaneous open-circuit voltage e, the instantaneous "force" equations are

$$L_e\ddot{q} + r_e\dot{q} + \frac{q}{C_e} + \beta l\dot{s} = e \qquad (4a)$$

$$m_{mf}\ddot{s} + r_{mf}\dot{s} + \frac{s}{C_{mf}} - \beta l\dot{q} = 0 \qquad (4b)$$

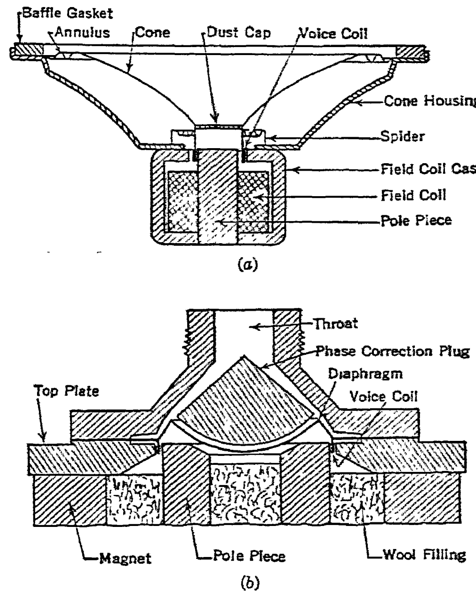

FIG. 2. Moving-coil Speakers. (a) Direct radiator type; (b) horn type.

The further assumption is made in these equations that β is a constant, independent of s, that $\dot{q}$ does not alter the magnetic field, and that there is negligible mutual impedance between the moving coil and the "field" coil which provides the static field. If β is supplied by a permanent magnet, a constant flux source is approximated which is little altered by $\dot{q}$. The performance of moving-coil speakers depends on β and not on whether this is supplied by a permanent magnet or an electromagnet.

If $e = E \sin \omega t$, the steady-state solution of eqs. (4) is

$$E = z_{12}\dot{s} + z_{11}I \qquad (5a)$$

$$0 = z_{22}\dot{s} - z_{12}I \qquad (5b)$$

where E, I, and $\dot{s}$ are the rms steady-state voltage, current, and velocity, and $z_{12} = \beta l$ is the force factor. "The force factor of an electroacoustic transducer is a measure of the coupling between its electrical and mechanical systems. It is the ratio of the open-circuit force or voltage in the secondary system to the current or velocity in the primary system." Equations (5) give

$$I = \frac{Ez_{22}}{z_{11}z_{22} + z_{12}^2} \qquad (6a)$$

$$\dot{s} = \frac{Ez_{12}}{z_{11}z_{22} + z_{12}^2} \qquad (6b)$$

DIRECT RADIATOR OR HORNLESS SPEAKER. These are the commonly used electrodynamic speakers which are designed to radiate as efficiently as possible into a solid angle of the order of 2π("semi-infinite medium"). They are used in baffles or cabinets when response at low frequencies is required but space limitations prevent the use of a horn or "directional baffle" to improve the efficiency. The radiated sound energy is $\dot{s}^2 r_f$, where $\dot{s}$ is given in eq. (6b) and r_f is Sr_A, with r_A from Fig. 1, p. 13-03, provided the mounting approximates an infinite baffle at the frequency considered. In the low and low middle frequencies, the fluid resistance is proportional to the square of the frequency. Therefore, if $\dot{s}^2 r_f$ is to be approximately constant, the velocity $\dot{s}$ must vary inversely with frequency. From eq. (6b) it may be seen that, when the applied frequency is appreciably higher than the resonant frequency of the mechanical system, $\dot{s}$ is largely a function of z_{12} and z_{22}. Since z_{12} is approximately a constant, and $z_{22} \doteq \omega m_{mf}$, $\dot{s}$ varies inversely with ω particularly if z_{12} is small. The radiated acoustic power is therefore approximately independent of frequency. In this frequency range the system efficiency, η_s, is approximately

$$\eta_s \doteq \frac{2 \times 10^{-9} \alpha E C}{(m/d^2)^2} \tag{7}$$

where α is the ratio of actual conductor volume to air-gap volume, V (product of gap length, mean perimeter, and coil winding length);

$$E = \frac{\bar{B}^2 V}{8\pi} \doteq \text{gap energy (ergs)}$$

$\bar{B}$ is the average flux density in volume V (gauss); C is the conductivity of the conductor with respect to copper; m is the effective motor mass (voice coil, cone, fluid mass) (gram); and d is the effective piston diameter (inches).

When the velocity of the diaphragm is largely limited by the mass reactance of the mechanical system and varies (roughly) inversely with frequency, the device is said to have "inertia control." To obtain uniform response, the natural frequency is placed near the lowest frequency to be transmitted. In 12-in. speakers this resonant frequency is of the order of 75 cps. At very low frequencies, either the stiffness reactance or the mechanical resistance limits the velocity, and the response decreases even if the speaker is operated in an infinite baffle. In the middle frequency range, the normal impedance and, therefore, the force on the mechanical circuit are fairly constant. In general the damping is less than "critical" or the value required to give the shortest transient response. See "Transient Response," Section 5, articles 13 and 15.

Figure 3 indicates the result of varying βl (or z_{12}) on the pressure measured in the sound field. Since the speaker directivity is almost independent of frequency in this range, the ordinates are proportional to the total radiated acoustic power. These curves show that

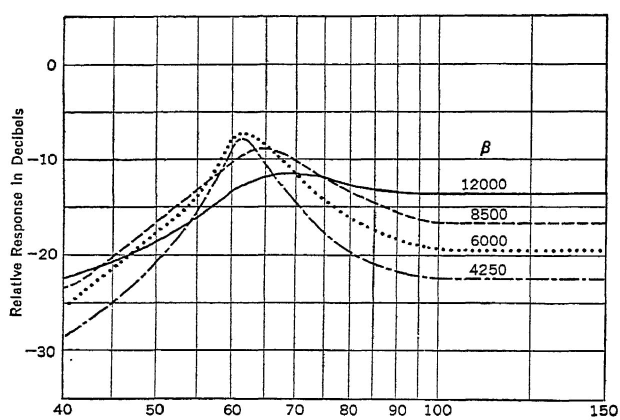

FIG. 3. Variation in Acoustic Pressure with Flux Density, or Force Factor. (Measurements were made on the axis, 10 feet from a direct radiator moving conductor speaker.)

speakers having large force factors or values of z_{12} and high efficiency in the middle frequency range have relatively less response near the resonant frequency of the mechanical circuit. Increasing the flux density and force factor increases the energy efficiency but decreases the system efficiency near resonance. Because the maximum peak powers in speech and music (see Section 12, articles 10 and 11) occur in the middle frequency range, it is important that the speaker have high efficiency in this range, and the better speakers have high force factors, which also reduce the transient distortion of the speaker.

Direct radiator speakers normally reach their maximum efficiency in the low middle frequency range, except when the effective baffle size is large so that the resonant frequency is radiated effectively. In that case, if z_{12} is small the maximum system efficiency may occur at the frequency of mechanical resonance. The normal impedance is resistive, or largely so, in either case. (See Fig. 4.)

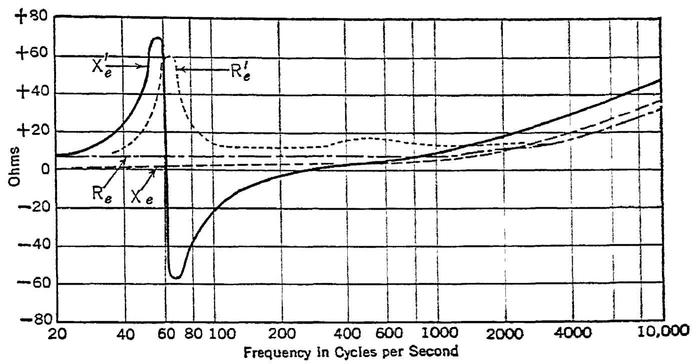

FIG. 4. Blocked and Normal (Primed) Resistance and Reactance of Moving-coil Direct-radiator Speaker in Ohms

The system efficiencies in the middle frequency range vary from roughly 1 to 20 per cent in commercial direct radiator speakers. The energy efficiency values are slightly higher in the middle frequency range and exceed 90 per cent at the mechanical resonant frequency in some designs.

ENCLOSURES. Direct radiator speakers are often placed in enclosures to contain and control the radiation from the rear surface of the diaphragm. If the enclosure is complete, that is, has no vents, it is sometimes called a "total enclosure" (see Enclosed Back Piston, article 1). The rear radiation may be put to use by permitting it to escape from the enclosure after first modifying it in phase and magnitude by a suitable acoustic network. When the vents, or ports, which radiate the energy from the rear of the diaphragm are close to the front surface of the diaphragm, the mutual impedance is high. In this case the phase of the rear radiation is critical but gives rise to maximum radiation when it is properly controlled (see article 2).

When the length of the radiated wave is large compared with the enclosure dimensions the acoustic parameters may be considered "lumped." A single cavity enclosure with a port may then be considered to add a compliance corresponding to that seen by the diaphragm with the port blocked or covered, which is in series with the speaker compliance. The enclosure compliance is shunted by the effective mass and radiation resistance of the port. The latter values are those referred to the speaker diaphragm. The frequency of the two resulting low-frequency modes may be computed very approximately by neglecting the mutual reactance term arising from the coupling of the external radiating surfaces of the diaphragm and port through the mutual fluid impedance. The real part of this mutual impedance must, however, be included in any accurate calculation of the total radiated power.

The vented enclosure may be used to maintain uniform radiation down to lower frequencies than those radiated effectively by a total enclosure of identical volume, or it may be used to provide a rise in the radiation near the cutoff frequency of the unvented enclosure. In practice it is common to provide a compromise between these two by so choosing the speaker and enclosure parameters that the resulting two modes of the simple structure described above occur approximately one-half octave below and above the mode of the speaker and enclosure with blocked port. The augmented low-frequency radiation is obtained with substantially reduced non-linear distortion since most of the radiation is from the port, which need have no variable or non-linear parameters, and the diaphragm displacement is appreciably reduced.

The rear of the diaphragm is sometimes coupled to a highly absorbent line approximately one-quarter wave long near the cutoff frequency of the acoustical system. The line absorption should be low in the frequency interval in which the line is between three-quarters and one wave long and increase rapidly above the upper frequency of this interval to suppress radiation which would otherwise be out of phase with the front radiation. When the line is one-quarter and three-quarter wave long it serves as an impedance inverter, thereby raising the impedance seen by the diaphragm and reducing its amplitude for a given total radiation.

HORN-TYPE MOVING-COIL (OR CONDUCTOR) SPEAKERS. To increase the fluid resistance, r_f, a horn may be used to couple the diaphragm to the acoustic medium. Because of their greater throat resistance at low frequencies for a given size, hyperbolic-exponential horns with $T \leq 1$ (see article 3) are normally used.

In the case of horn units the normal (electrical) impedance can be made quite uniform (see Fig. 5) so that the force on the diaphragm is approximately constant if the source voltage and impedance are constant.

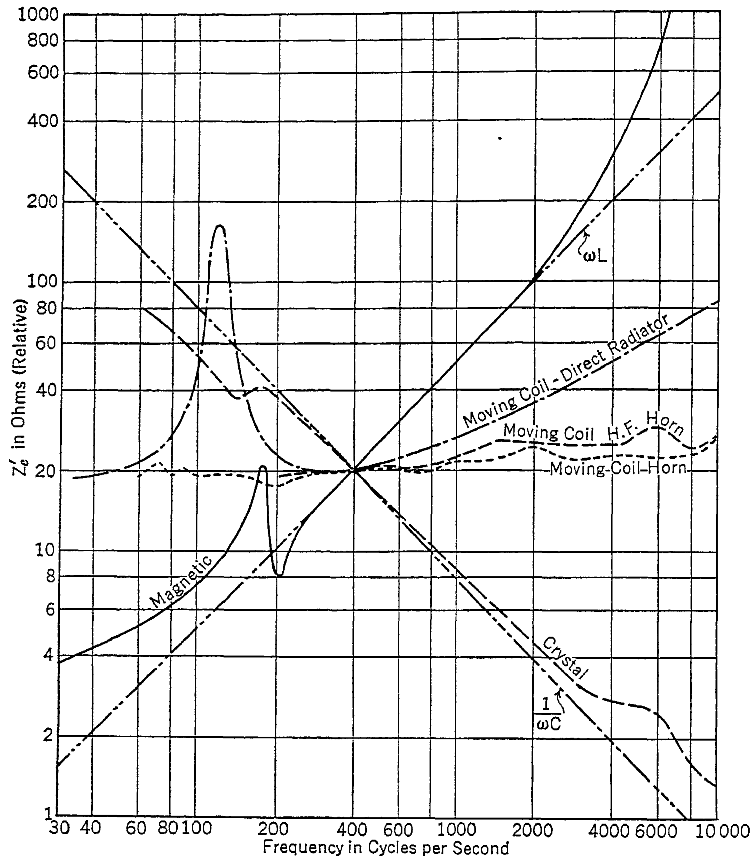

FIG. 5. Relative Scalar Normal Impedances of Typical Loud Speakers. (All arbitrarily adjusted to have the same impedance at 400 cps. Reactance of an inductance and capacitance plotted for comparison.)

The diaphragm is made to resonate an octave or two above the horn cutoff frequency. The stiffness reactance of the diaphragm assembly then reduces the effect of the mass reactance of the horn near its cutoff frequency. At high frequencies, the stiffness of the sound chamber may be made to reduce the effect of the mass reactance of the diaphragm. The fluid resistance is adjusted to the desired value by proper choice of the ratio (S_d/S_t). These factors make possible the design of a horn having uniform response over an extended frequency range.

At low frequencies, irregularities in response result from the variation in throat impedance of a horn of finite length. The resonant frequencies of the horn near its cutoff frequency also give rise to transient distortion. By using a horn unit having a large force factor, and by proper choice of the other elements, the steady-state variation in response and the transient distortion may be made negligible.

At high frequencies destructive interference occurs in the sound chamber since its dimensions are of the order of magnitude of the length of the sound wave. The horn throat is therefore sometimes so constructed that the difference in path length from different parts of the diaphragm to the throat is a minimum. The use of a phase equalizing plug for this purpose is shown in the horn unit of Fig. 2. At very high frequencies the diaphragm no longer behaves as a rigid piston, and this alters the response of the unit.

The minimum compliance of the sound chamber is limited by its minimum volume, V_0. This volume must be adequate to provide ample mechanical clearance at low frequencies, where the diaphragm amplitude is a maximum, and to limit the distortion which results from "finite" sound pressures.

7. MAGNETIC-ARMATURE SPEAKERS

"A magnetic-armature speaker is a magnetic speaker whose operation involves the vibration of the ferromagnetic circuit. (This is sometimes called an electromagnetic speaker.)" Numerous magnetic-armature designs have been proposed. The principle of operation of this type of speaker is analogous to that of moving-conductor speakers, and equations for the latter apply to this type if the appropriate value of z_{12} is used. They differ principally in the fact that the conductor does not move, which permits the use of a large conductor volume. In practice, high loudness efficiencies can be obtained in a limited frequency range with a magnet having moderate magnetomotive force. The efficiency at very high frequencies is normally poor because of losses in the armature. The very low-frequency response is limited by the stiffness required to give adequate armature stability. The current displacement curve is linear over a very limited range and gives rise to appreciable amplitude distortion.

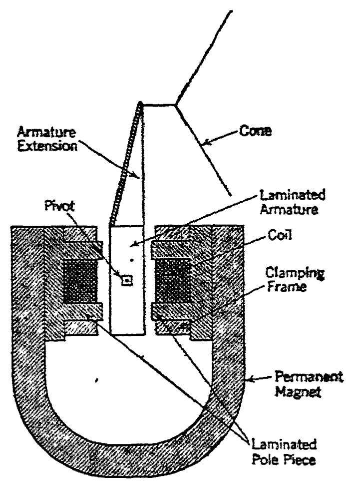

FIG. 6. Balanced Armature Speaker

BALANCED-ARMATURE MAGNETIC SPEAKER. A cross-sectional view of a unit of this type is shown in Fig. 6. The speech current flows through the stationary coil which surrounds the armature. It increases the effective flux through two (diagonally located) gaps and decreases it in the other two gaps. The steady flux, ϕ_0, is increased and decreased by an amount $\phi = 4\pi Ni/\mathcal{R}$ gausses, where N is the number of turns on the coil, i is the current through the coil in abamperes, and $\mathcal{R}$ is the effective reluctance of the alternating flux path.

The total effective force on the armature, acting at the magnetic force center, is

$$F = \frac{2(\phi_0 + \phi)^2}{8\pi A} - \frac{2(\phi_0 - \phi)^2}{8\pi A} = \frac{4\phi_0 NI}{\mathcal{R}A} = \frac{4\beta_0 NI}{\mathcal{R}} \tag{8}$$

where F is the rms force in dynes and A is the effective area in square centimeters at each gap and β_0 is the steady or undisturbed flux density. For small amplitudes the reluctance of the alternating flux path is approximately constant, since most of the reluctance is in the gap, and the reluctance of the permanent magnet path is large.

The assumption is usually made that all the elements of the circuits and the force factor are constant. This is approximated only when the amplitude is small. When the armature is in the undisturbed center position, it is in a state of unstable equilibrium. The application of a force results in a force tending to increase the displacement. This property is called negative stiffness or compliance. (See Section 5, article 30.) It here results from the fact that the torque on the armature is proportional to the square of the flux density. Therefore, it increases more rapidly at the tip that is approaching one magnet tip than it decreases at the tip that is receding from the other magnet tip. Since the force varies with the square of the flux density, and the density varies almost inversely with distance between the armature and magnet tip, the stiffness can be considered a constant only for small displacements. The positive value of C_m is, therefore, the difference between the positive diaphragm (and fluid, if any) compliance and the negative compliance. Stability of the system requires that the rate of change of force with displacement be less than the coefficient of stiffness. The further assumption is made that the lever arm has infinite stiffness. In practice, resonances of this arm play a large part in modifying the mechanical impedance at high frequencies.

The steady-state solution for this speaker is the same as that of eqs. (5) and (6). In this case $z_{12} = 4\beta_0 N/\mathcal{R}$; for the more exact theory z_{12} is considered complex.

The principle of operation is analogous to that of the moving-conductor speaker. Equations for the latter apply if the above value of z_{12} is substituted. A large conductor volume is normally used to increase the force factor. This makes the inductance of the electrical circuit much higher than in moving-coil speakers. For this reason, the normal impedance varies over wide limits. The normal impedance is proportional to frequency over much of the frequency range, as shown in Fig. 5. The rise in impedance above the value predicted on this basis at the high-frequency end, in this particular speaker, was due to electrical resonance. The speaker was of the high-impedance type, and the inductance and distributed capacitance resonated at the high-frequency end. This is normally the case in high-impedance speakers of this type, and its effect must be included in any complete performance analysis.

BIPOLAR MAGNETIC-ARMATURE SPEAKER. This type of speaker consists of a steel diaphragm mounted near the two ends of a U magnet. The speech current flows through the stationary coils which surround the two pole pieces. If the current through the two coils, connected in series, is $I \sin \omega t$, and the coils have N turns, the alternating flux is $\phi = \dfrac{4\pi NI \sin \omega t}{\mathcal{R}}$, where I is the maximum value of the current in abamperes, and $\mathcal{R}$ is the effective reluctance of the alternating flux path.

The total effective force F acting at the magnetic force center is

$$F = \frac{2(\phi_0 + \phi)^2}{8\pi A} = \frac{\phi_0^2}{4\pi A} + \frac{2\phi_0 NI \sin \omega t}{\mathcal{R}A} + \frac{2\pi N^2 I^2}{\mathcal{R}^2 A} - \frac{2\pi N^2 I^2 \cos 2\omega t}{\mathcal{R}^2 A} \tag{9}$$

The first term on the right is a constant force; the second is the useful component which is proportional to ϕ_0 and to the signal current. The last two terms are distortion terms and are minimized by making $\phi_0 \gg \phi$.

The force factor $z_{12} = 2\beta_0 N/\mathcal{R}$. The more exact theory includes the case in which z_{12} is complex.

The principle of operation is analogous to that of the balanced-armature magnetic and moving-conductor speakers. The equations for these speakers apply to the bipolar magnetic armature if the value of z_{12} given above is used.

8. CONDENSER SPEAKERS

"A condenser speaker is a loud speaker in which the mechanical forces result from electrostatic reactions." Speakers of this type have a movable conducting electrode which serves as the diaphragm and is mounted close to a perforated fixed electrode or between two perforated fixed electrodes.

TWO-ELECTRODE CONDENSER LOUDSPEAKER WITH MECHANICAL CIRCUIT HAVING ONE DEGREE OF FREEDOM. One speaker of this type has a movable and a fixed electrode separated by a thin dielectric as shown in Fig. 7. The force of attraction between the electrodes as the charge varies provides the actuating force for the movable electrode which is used as the diaphragm.

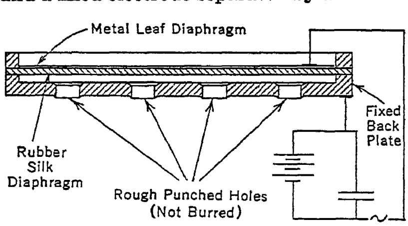

FIG. 7. Condenser Speaker

The equations for a system of this type are developed in Section 5, article 32. The steady-state equations for a single sine-wave applied voltage are:

$$E = z_{11} I + z_{12} \dot{s} \tag{10a}$$

$$0 = z_{12} I + z_{22} \dot{s} \tag{10b}$$

where $z_{12} = \dfrac{jq_0}{\omega C_0 d_0} = \dfrac{jE_0}{\omega d_0}$. The force factor therefore varies directly with the polarizing voltage, E_0, and inversely with the frequency and no-signal separation of the electrodes, d_0. The minimum value of the separation is determined by the maximum low-frequency amplitude, and it must be large in comparison with the amplitude if non-linear distortion is to be avoided.

$$I = \frac{Ez_{22}}{z_{11}z_{22} - z_{12}^2} \tag{11a}$$

$$\dot{s} = \frac{-Ez_{12}}{z_{11}z_{22} - z_{12}^2} \tag{11b}$$

The radiated acoustic power is $\dot{s}^2 r_f \times 10^{-7}$ watt, where $\dot{s}$ is given by eq. (11b) and r_f by article 2. The diaphragm does not move as a piston. Therefore, a generalized velocity based on the type of deformation here obtained must be used.

Because the blocked impedance of the speaker is that of a capacitance, C_0, the normal impedance varies inversely with frequency over much of the frequency range. Therefore, uniform response and high efficiency are difficult to obtain. The impedance of the electrical circuit is sometimes altered to improve the response.

9. PNEUMATIC SPEAKERS

"A pneumatic speaker is a loudspeaker in which the acoustic output results from variations of an air stream." It is of the irreversible or relay type. The definition of efficiency for reversible speakers is not used in this case, since the efficiency, as defined for them, can exceed 100 per cent because no account is taken of the power used to compress the air. Any type of loudspeaker motor may be used to drive a very light balanced valve which modulates an air stream.

These units permit the generation of large acoustic powers. The valve and valve parts give rise to spurious noises that are difficult to eliminate. When large acoustic outputs are generated, there is appreciable "finite" amplitude distortion in the types that have been made.

10. TELEPHONE RECEIVERS (EARPHONES)

Telephone receivers are so constructed that they operate directly into the ear cavity. The fluid impedance of the ear cavity varies appreciably from ear to ear, particularly at high frequencies. If there is no fluid leak between the ear "cap" of the receiver, which held in contact with the ear, and the ear, the fluid impedance is approximately that of a 6-cm^3 cavity at frequencies in the middle and lower frequency ranges. At high frequencies, the ear cavity resonates and the fluid resistance of the cavity increases. If there is a fluid leak between the ear cap and ear, the fluid resistance of this leak must be considered at low frequencies where it tends to reduce the pressure in the cavity.

It has been found that a good compromise design for most ears is one in which the diaphragm displacement is independent of frequency. At low frequencies this gives constant pressure in the ear cavity if there is no fluid leak. Since the magnitude of the reactance of the ear impedance substantially exceeds the resistance below 1000 cps, the power supplied to the ear and the efficiency, as defined for other transducers, are not satisfactory performance criteria. The pressure squared, produced at the end of a non-dissipative cavity or "coupler," per unit power available from an ideally terminated source, is a common performance criterion. A 6-cc coupler is used for ear cap or external earphones and a 2-cc coupler for insert receivers which are placed in the outer ear canal and thereby reduce the volume of the cavity between the receiver and the eardrum.

MOVING-CONDUCTOR TELEPHONE RECEIVERS. Both moving-coil and ribbon telephone receivers are in use. The construction of one type of moving-coil receiver is similar to that of the microphone shown in Fig. 3, p. 13-24. The values of the circuit elements differ from those used in the microphone, in order to give as nearly as possible constant diaphragm amplitude at all frequencies with a constant-voltage source.

If the mechanical circuit consists only of the stiffness and resistance of the diaphragm, and the combined mass of the diaphragm and moving coil, its "force" equations are given by eqs. (6). The displacement $s = \dot{s}/j\omega$, where $\dot{s}$ is given by eqs. (6). Since z_{12} is a constant, if z_{11} is made approximately constant, z_{22} must vary inversely with frequency for the diaphragm displacement to be independent of frequency. This requires that the diaphragm have stiffness reactance over the range of uniform response. This is obtained by placing the resonant frequency of the diaphragm near the maximum frequency to be transmitted. Under these conditions the normal impedance of the receiver is fairly uniform below the frequencies near the resonant frequency of the diaphragm. The force is therefore nearly constant. The displacement of the diaphragm is small, and hence the efficiency of the receiver is poor when the resonant frequency and stiffness are high. It is also difficult in practice to obtain very high resonant frequencies.

To improve the efficiency and yet maintain uniform response, additional mechanical circuits are sometimes coupled to the diaphragm. The resonant frequency of the diaphragm itself is lowered, and the value of the mechanical elements is chosen to give uniform diaphragm displacement.

If the mechanical impedance is large in comparison with the ear cavity impedance, the latter may be neglected. In general, it may be neglected only for approximate calculations. The impedance of the fluid between the diaphragm and the ear cap must also be considered in any complete analysis.

MAGNETIC-ARMATURE TELEPHONE RECEIVER. The theory of operation corresponds to that of magnetic-armature loudspeakers given above. The first center moving mode of vibration of the magnetic diaphragm in the early type of telephone receiver occurs near 1000 cps. Near this frequency, the amplitude is large and the pressure in the ear cavity is large. Below this resonance region, the diaphragm has approximately constant stiffness or compliance, and the amplitude is fairly uniform. At frequencies above the resonant region, the displacement decreases and goes through a series of decreasing maxima at higher modes of vibration. In more recent types there is a thin film of air at the back of the diaphragm which is coupled to an auxiliary acoustical network. The parameters are chosen to give uniform pressure at the bottom of the test cavity or coupler up to 3000 cps in telephone hand sets and up to 4000 cps in some military types.

PIEZOELECTRIC TELEPHONE RECEIVERS. The high frequency at which the fundamental mechanical resonant frequency of a small Rochelle salt crystal occurs permits its use as a motor or motor and diaphragm in a telephone receiver. The large variation in normal impedance with frequency makes the response more dependent on the source impedance than it is when the normal impedance is constant.

11. PERFORMANCE AND TESTS

One criterion of the excellence of a complete sound-transmission system is its ability to produce the same space-pressure-time pattern at the ears of the listener that would be experienced if he were immersed in the sound field in the region of the original sound. This can be achieved with substantially complete realism in a binaural system in which two transmission links couple two properly mounted pressure microphones to two broadband telephone receivers placed on the ears of the listener.

In practice there is a growing tendency to apply a second criterion, namely the ability of a system to provide reproduction which is judged to be pleasant by a jury selected on the basis of scientific sampling of the public or the ultimate listening group. This second criterion has grown in importance for a number of reasons. One is that most listeners prefer loudspeakers to headphones, thus introducing complex effects due to coupling the loudspeaker to the ears of the listener via the listening room. Probably the most important reason for choosing pleasantness as the criterion of excellence is that radio and phonograph systems have in large measure attained the stature of an art medium in their own right. This has led to extensive work on the design of new types of studios and the development of new pickup techniques, all intended to please the listener in his home.

Though the complete test of a speaker is a complicated process, all the objective measurements have as their goal a satisfactory correlation between their results and those of properly conducted listening tests. Thus the ear becomes the final arbiter of the excellence of a sound system.

For discussing the aural performance it is desirable to use terms descriptive of the frequency ranges and of certain characteristics of the reproduced sound. As a group these terms constitute the imagery by which sound systems are described. They relate principally to two important frequency regions: 400 to 800 cps, which contains most of the energy of speech and music; and 2000 to 3000 cps, where the energy components contribute most strongly to the loudness. The first region is located in what most listeners classify as the low middles. A speaker with normal low middles is said to have "body," while an excess is "muddy," and a deficiency sounds "thin." When the second range, in the lower highs, is normal, reproduced sound is "crisp"; an excess introduces "bite" and is "brilliant"; a deficiency reduces articulation and loudness and, if no extreme highs are present to provide "spit," may yield a "mellow" speaker.

The whole range is conveniently divided into the very low frequencies, below 100 cps, lows from 100 to 250 cps, lower middle from 250 to 800 cps, upper middles from 800 to 2000 cps, lower highs from 2000 to 4400 cps, middle highs from 4400 to 8000 cps, and extreme highs above 8000 cps. The boundaries are quite arbitrary and will depend on the auditor, listening environment, and program material.

OBJECTIVE PERFORMANCE CRITERIA. Loudspeaker performance is determined to a large extent by the response, efficiency, directivity, distortion, power capacity, and impedance. The relative importance of these and other less important performance criteria depends on the application involved.

The response is that characteristic of the acoustic output, expressed as a function of frequency, to which a particular aural effect is closely proportional. The type of response will depend on the use to which the speaker is put. For speakers used outdoors or for very directional speakers the free space axial sound pressure level, as a function of frequency, is used and is called the sound pressure response.

For use indoors the sound pressure level is determined by the total acoustic power radiated and by the shape, size, and acoustical impedance of the room and its contents. Thus the effect of the speaker alone is approximated by the total radiation, usually ascertained by integration of the sound pressure measured in free space at fixed radius vector and variable angle. The total radiation response is modified by the "room response" to produce the desired effect on the ear, and it is often helpful to measure the rms average sound pressure in a room which is representative for the intended applications of the speaker. This mean pressure (corresponding to the mean energy density) response has good correlation with the aural effect when the measuring room is also that used for listening.

In Fig. 8 are shown the sound pressure, total radiation, and mean energy density response curves for a direct radiator speaker in a finite baffle. The excess of high frequencies

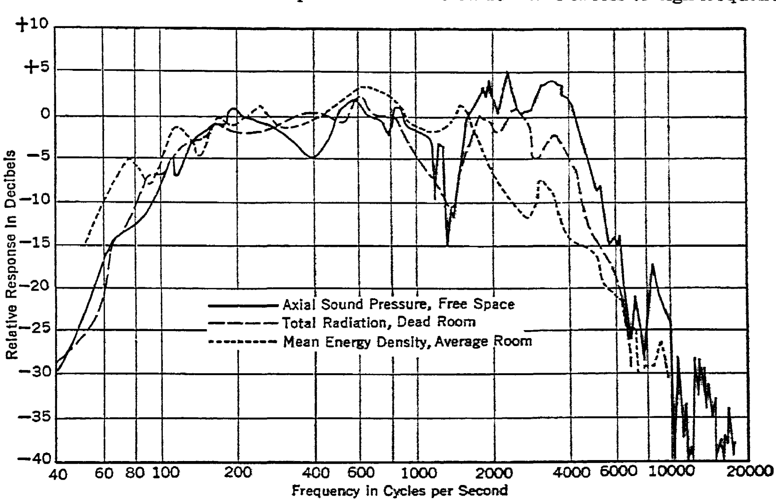

FIG. 8. Three Types of Response-frequency Curves for a Direct Radiator Speaker in a Finite Baffle

in the pressure response is due to directionality, and the difference between the second and third is due to the "response" of the room.

The system efficiency of speakers has been discussed in article 5. The loudness efficiency of two speakers is compared using a generator of constant emf and impedance, attenuation being inserted in the amplifier for the louder speaker. This judgment is usually the first of any listening test. It is becoming standard practice to test speakers with a source whose internal impedance is equal to its rated load impedance. The basis of stating the input to the speaker is conveniently the maximum power that may be taken from such a source, and it is called the power available to the speaker.

The series of sound pressure-frequency response curves run at various azimuths depict the directional characteristics of the speaker. Another clue to the directivity is obtained by comparing the sound pressure and total radiation response curves (see Fig. 8). When the wavelength is long compared to the size of the radiator, the radiation is uniform, and the curves should coincide. The differences at higher frequencies then indicate the magnitude of the directional effects.

If the listener's ear is relied on completely to select speakers having high loudness and (apparent) bass and treble response, there usually result speakers having large amounts of non-linear, transient, and frequency response distortion. The need for quantitative tests is indicated by Fig. 9, which shows the non-linear distortion in the sound pressure of a typical 12-in. speaker mounted in an 8 by 8 ft baffle. The speaker has an equivalent piston diameter of 10 in., a high force factor, and a voice coil $^7/_{16}$ in. long moving in a gap with a $^3/_8$-in. top plate.

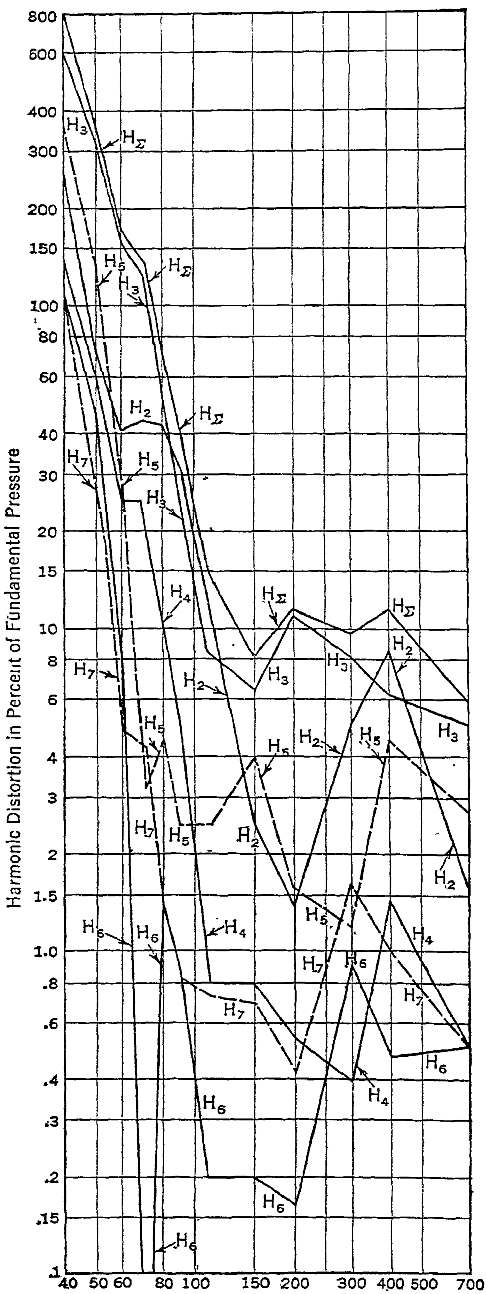

FIG. 9. Steady-state Non-linear Distortion in Moving-coil Direct Radiator Speaker

The curves are typical of commercial direct radiator speakers. Approximately half the distortion at low frequencies is due to the non-linear force displacement curves of the diaphragms. The remainder is due to the non-linear average-flux-displacement curves of the driving mechanism.

Since these curves are representative of commercial practice they are of interest in indicating the amount of distortion the untrained listener will tolerate. Speakers designed to give less distortion for a given cost will have less loudness efficiency, and less apparent bass response.

Distortion curves of horns show distortion of the same order in the middle frequency range. About a third of an octave above the theoretical cutoff frequency, the distortion begins to rise, and below cutoff usually considerably exceeds the distortion for direct radiator speakers. This distortion largely accounts for the horn's sounding as if it radiated effectively below its cutoff frequency.

For a more complete discussion of testing methods see the references in the bibliography marked "tests."

Another measure of distortion is the intermodulation of two signals of non-harmonic frequencies producing inharmonic modulation products. Because the annoyance of this type of distortion is extremely high, much smaller amounts may be tolerated than with non-linear distortion. Though the technique is not yet standardized, a useful procedure is to fix a low-frequency signal at a large value while a variable high-frequency scanning signal of much smaller value is applied through a linear combining circuit. A plot of the sound pressure due to the scanning signal and that due to the modulation products affords a means of assessing the audibility of the modulation products. It is important that this be done as a continuous function of frequency in order not to miss regions of large distortion. This is shown in Fig. 10 for an experimental direct radiator speaker with a 12-db difference between power available for low- and high-frequency signals.

The power rating of a loudspeaker is intended to provide the user with a yardstick by which he may set operating conditions to insure trouble-free life at any input up to the maximum. While this rating may be limited by distortion, thermal overload, or mechanical overload, the latter two are usually controlling. Thus the power rating usually sets a limit above which mechanical failure may be expected to occur. In one method of specifying this power, a saturating signal of a variety of program material is supplied to an amplifier of adjustable saturation power, used as the source. The rating power is that below which failure will not occur within, say, 100 hours for at least 90 per cent of a group of speakers. Thus the rating is essentially in terms of an amplifier whose output will be safely handled. In another method of rating, the amplifier has a much greater rating power than the speaker and is supplied a synthetic signal, such as noise, warble tone, or multitone. These have reasonably constant spectral composition and peak-to-rms ratio, and the power is increased until the 100-hour failure point is reached. Though neither method is yet standardized, it is nevertheless the intent of both to provide a realistic and useful value.

A final important characteristic of a speaker is its impedance. Both modulus and angle usually exhibit considerable variation with frequency, and the problem is to connect this load to a resistive source of essentially constant impedance. When properly connected, the source is able to deliver to the load the maximum program energy consistent with distortion requirements. In practice this "connection" impedance is selected by the manufacturer on the basis of his listening tests and experience. It may be called the rating impedance of the speaker, and it indicates the tap on the amplifier output to which the speaker should be connected. It is not necessarily the value at 400 cps, or the minimum in direct radiator speakers. Besides its use in determining speaker connections, the rating impedance is often used as the generator resistance in speaker tests.

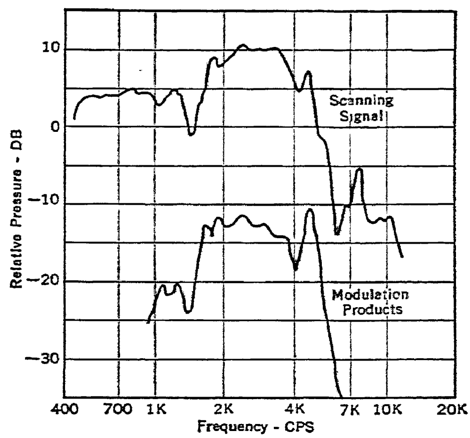

FIG. 10. Modulation Products for Experimental 12-in. Direct-radiator Speaker in Infinite Baffle. Available power input, 100 cps fixed, 16 watts; scanning signal, 1 watt.

MICROPHONES

By Hugh S. Knowles

A microphone is an electroacoustic transducer actuated by energy from an acoustical system and delivering energy to an electrical system, the spectral composition of the energy in the two systems being substantially equivalent. They may be classified as to reversibility, type of generator, acoustical quantity to which the output is proportional, and type of directional characteristic.

Reversible microphones are those that are also capable of converting electrical into acoustical energy, and they include moving-conductor (ribbon and moving-coil), variable-capacitance (condenser), variable-reluctance (moving-iron) and piezoelectric (crystal) generator types. The most important irreversible microphone is the carbon (variable-resistance) type.

Reversible microphones may be treated analytically by the same equations used for the corresponding loudspeakers, provided that the emf in the electrical mesh is set equal to zero and a force is introduced into the mechanical mesh (see Loudspeakers, p. 13-11).

12. FORCE ON THE MICROPHONE

In practically all microphones the electrical output is proportional to the net force on the generating element; less common types are those directly sensitive to the particle velocity (hot-wire) and to the temperature (pyroelectric) of the sound wave.

PRESSURE MICROPHONES. In pressure-responsive microphones the active surface is moved by a force which is the integral of the pressure over it. The pressure will deviate from that in the free wave owing to the effects of diffraction, cavity resonance, and mechanical impedance of the active surface. The last effect is usually small, and the others may be minimized or in some instances utilized by careful attention to the size and shape of the microphone. The microphone response may be stated in terms of the undisturbed pressure in the wave, or in terms of the pressure at the active surface; these are respectively the field and the pressure response.

Diffraction effects are important when the maximum dimension of the microphone becomes much greater than a tenth wavelength. For frequencies well above this region the pressure will be doubled (6 db) over the undisturbed value unless the diaphragm impedance is very low. Since diffraction effects are also functions of angle, large pressure-sensitive microphones may be expected to be directional at the higher frequencies. Screens are sometimes used to modify the diffraction effects.

When the active surface is recessed, the shallow cavity will exhibit a broad resonance which may be used to improve the high-frequency response. Though "gains" of the order of 5 db may be attained, the sensitivity to angle again introduces directivity. If the force resulting from a wave of normal incidence is to vary less than 2 db from that at grazing incidence, then the active surface should be recessed no more than 0.1 its diameter. At the highest frequency to be reproduced the diameter should be less than a half wavelength. In Fig. 1 is shown a miniature condenser microphone which approximates these conditions up to over 3 kc.

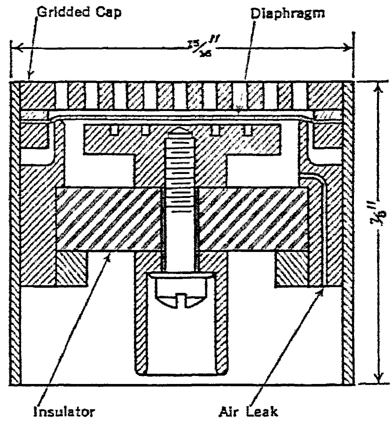

FIG. 1. Miniature Condenser Microphone

PRESSURE-DIFFERENCE MICROPHONES. When two points in space are separated by a small fraction of a wavelength the difference in pressure at these points approximates the product of the distance they are separated and the pressure gradient in the sound field. For this reason pressure-difference microphones are sometimes loosely called pressure-gradient microphones. (See also Ribbon Microphones, in article 13.)

When both sides of the active surface are exposed to a sound wave, the net force on it depends on the difference between the forces on the two sides. Let the acoustic path length from one side to the other be l_b. Then when a wave of undisturbed sound pressure amplitude, p, is incident on the microphone at an angle θ to the axis of symmetry, the magnitude of the net force, f, is, assuming no gradient along the active surface, and also assuming that the pressure difference may be replaced by the gradient,

$$f = 2S_d p \sin \frac{\omega l_b \cos \theta}{2c} \tag{1}$$

If ωl_b is sufficiently small,

$$f = \frac{S_d p \omega l_b \cos \theta}{c} \tag{2}$$

Thus, up to frequencies for which the path difference l_b is an appreciable fraction of a wavelength, the net force is proportional to that path difference and to the frequency. When the wave front is spherical, the pressure gradient exceeds its value for a plane wave by the factor $[1 + (c/\omega r)^2]^{1/2}$, which is small for ωr large. When the wave front is that due to a piston, the axial gradient contains terms dependent on the ratio of piston diameter to microphone distance. However, when this ratio is less than 0.5, the wave front is sufficiently spherical to permit the spherical wave correction factor to be used.

FLUID IMPEDANCE. Studies of reciprocity laws indicate that the force of the wave is applied through a "generator impedance" equal to that into which the active surface works when radiating the same wave fronts as those applied. See article 2 for results for some simple shapes. In general this added impedance is predominantly masslike up to the high-frequency region.

13. MOVING-CONDUCTOR MICROPHONES

In this class electrical energy is generated by the motion of single or multiple conductors in a magnetic field, as exemplified by ribbon and moving-coil types.

RIBBON MICROPHONES. The more important constructional details of a ribbon microphone are shown in Fig. 2. The moving ribbon element is both diaphragm and conductor; it may be 0.312 in. by 2 in. by 0.0002 in. and is corrugated to minimize spurious modes of vibration. As a low-frequency approximation, the effect of the fluid impedance is to add a mass of the order of magnitude of that of the ribbon; this added mass decreases at higher frequencies. The mechanical system is resonated at a frequency below the range to be reproduced, resulting in a mass-controlled device.

In pressure-difference responsive ribbon microphones, both sides of the ribbon are exposed to the wave. Thus the net force at low frequencies is roughly proportional to the pressure gradient and hence to the velocity in a plane wave. For this reason the term velocity is sometimes applied to microphones of this type. However, it appears desirable to reserve the term velocity to describe devices such as the Rayleigh disk in which the actuating force arises more directly from the particle velocity. Up to fairly high frequencies both the force and impedance (mass controlled) are proportional to frequency, leading to a constant ribbon velocity and hence constant generated emf. Control of the response beyond this point is achieved by adjusting the size and disposition of the pole pieces and other elements separating the two faces of the ribbon.

If one side of a ribbon microphone is shielded from the wave by a damped enclosure, the device becomes pressure-responsive. With a sound pressure independent of frequency the output is independent of frequency if the enclosure adds sufficient resistance to make the effective impedance of the diaphragm substantially resistive. Such a pressure-responsive ribbon microphone is used principally with a pressure-difference responsive type in a directional combination.

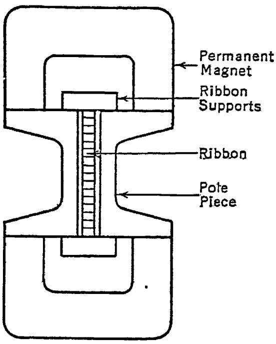

FIG. 2. Pressure-difference Ribbon Microphone.

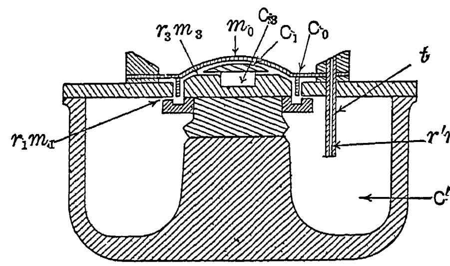

FIG. 3. Moving-coil Microphone

MOVING-COIL MICROPHONE. When the moving conductor is a moving coil, there results a form similar to that of a moving-coil loudspeaker, as in Fig. 3. With the net force in the mid and high frequency ranges largely due to that on the outside of the diaphragm, the device is pressure-responsive in these ranges. In order to obtain uniform coil velocity and hence response the moving system is designed to have substantially uniform impedance. The diaphragm and coil assembly is resonated in the low-middle frequency range.

Coupled circuits are used to maintain uniform response at the extreme frequencies. In Fig. 3 the circuit elements leading through the tube t to the rear of the diaphragm are so chosen as to achieve an increasing force at low frequencies to offset the increasing stiffness reactance of the diaphragm. At high frequencies the stiffness reactance of the air film under the dome and the impedance of the tuned cavity in the pole tip modify the impedance of the diaphragm and coil assembly so as to maintain approximately uniform velocity. Thus it is possible to attain a fairly uniform response from 40 to 10,000 cps.

It is possible to combine the output of adjacent pressure and pressure-difference microphones in such a manner that directional patterns are obtained which are members of the limaçon family of which the cardioid is a special case. Common types use moving-coil pressure and ribbon pressure-difference microphones connected through suitable phase and amplitude controlling networks.

14. CONDENSER MICROPHONES

Most variable-capacitance microphones are made pressure-responsive, with a mechanical system tuned above the desired range. A frequency-independent driving force acting upon this stiffness-controlled system results in a displacement independent of frequency. Since the output emf is closely proportional to the displacement, a flat pressure response is approached.

To the mass of the diaphragm is added the radiation mass, and to its stiffness, that of the air film between diaphragm and rear electrode. See Fig. 1. The diaphragm is of a high-tensile-strength aluminum or stainless-steel alloy of the order of 0.00075 in. thick, and is tuned by stretching, the smaller diaphragms being tunable to higher frequencies. The resistance of the thin interelectrode air film materially reduces the magnitude of the high-frequency resonant peak.

The small cavity and the high mechanical impedance of the condenser microphone make it particularly suitable for calibration by reciprocity methods. Two similar microphones whose comparative response is known are placed in a closed cylindrical volume of which each forms an end; the output of one is noted when the other is electrically driven.

As with all reciprocity methods, its success depends on the presence of a definite and calculable acoustic element, which here is the compliance of the common volume, corrected for microphone mechanical impedance. With careful control of acoustic and electrical parameters, excellent reproducibility of results is attained. The upper frequency limit may be extended to 15,000 or more cps by the use of hydrogen in which the wavelength is increased by a factor of nearly 4.

As reciprocity methods yield a pressure calibration, a correction for cavity resonance and diffraction is necessary. When the condenser microphone is used as a free field measurement standard, it is common practice to utilize these factors to extend the frequency range, with electrical equalizers added for smooth overall response.

15. MAGNETIC-ARMATURE MICROPHONES

A magnetic-armature microphone is a moving-iron (variable-reluctance) device which finds greatest application where ruggedness and high output are the main desiderata. An important use is in sound-power telephones (using no auxiliary source of power, such as batteries), which place a premium on maximum transmission of intelligence. This is achieved by resonating the moving system at two or more frequencies in the 1–3 kc band in which maximum articulation is obtained for a given amount of energy. (For force factor and force equations see article 7, Magnetic-armature Speakers.)

16. CRYSTAL MICROPHONES

In this type use is made of the piezoelectric properties of Rochelle salt, ammonium dihydrogen phosphate, or more rarely tourmaline and quartz. The sensitivity may be expressed in terms of the charge released for a given displacement of the driving point; this depends but slightly on temperature. However, the dielectric constant of Rochelle salt and hence the capacitance and emf generated changes considerably with temperature. The effect of this capacitance change is minimized by operating the crystal in a high-impedance circuit, or less frequently by shunting it with a fixed capacitance. The maximum operating temperature range is 40 to +130 deg fahr, and maximum output occurs at about 72 deg fahr.

The maximum operating temperature range of ammonium dihydrogen phosphate is −40 to +185 deg fahr. While the emf generated is greater than for Rochelle salt, the smaller dielectric constant results in such small capacitances that the full output is difficult to realize. The high resistances necessitated by the small capacitances also give rise to electrical noise problems.

Since the emf developed by crystals depends on the displacement, a stiffness-controlled system in which the displacement is substantially independent of frequency is used. When the microphone consists of a pair of composite plates arranged as in Fig. 4 to form a sound cell, the resonant frequency may range from 8 to over 40 kc.

When a single composite plate is clamped at three corners and the fourth is driven by a small diaphragm, the output voltage increases some 15 db over the sound cell construction, but the resonant frequency is then reduced to a few kilocycles. The main use of this type is for speech, in which case the output is allowed to rise substantially at the fundamental resonant frequency of 3 or 4 kc. Auxiliary acoustic meshes are used to obtain smooth response with reduced sensitivity in broad-band types used for music.

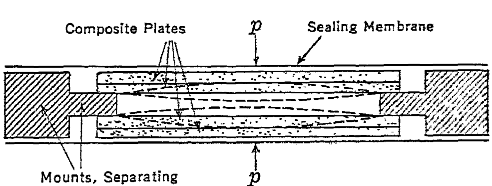

FIG. 4. Crystal Microphone ("Sound Cell" Type)

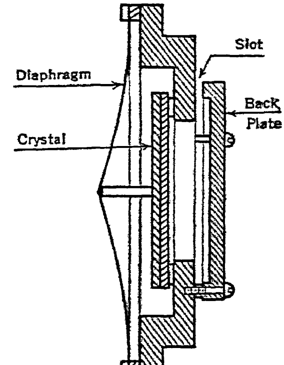

FIG. 5. Unidirectional Diaphragm-driven Crystal Microphone

A single transducer element crystal unidirectional microphone is shown in section in Fig. 5. When the slot is closed the microphone operates as a pressure type. (See Directional Characteristics, below.)

17. CARBON MICROPHONES

The carbon microphone, the most important irreversible microphone, is a variable-resistance type involving loose carbon contacts. The sound wave actuates a diaphragm which exerts a varying pressure on a large number of fine carbon granules, thus modulating a bias current obtained from a d-c source. Usually the resistance and output voltage are approximately proportional to the displacement, and so a stiffness-controlled system is employed. Because of the difficulty of obtaining uniform response, the present uses of carbon microphones are restricted to applications in which high output and "crisp" speech quality are paramount, as in military equipment. Another factor militating against its use for high-fidelity applications is the low signal-to-noise ratio, due to the random variation in contact resistance always present.

The small allowable size of the carbon button has been used to advantage in a close talking pressure-difference microphone with marked noise-reducing properties. Designed to be worn directly in front of the mouth, the microphone is immersed in the large pressure gradient field of the talker, while the ambient noise has a much smaller gradient. Thus the signal-to-ambient-noise ratio is improved, permitting intelligible communications from such noisy locations as planes, tanks, and engine rooms.

18. DIRECTIONAL CHARACTERISTICS

It is often important to collect sound arriving from a desired region to the exclusion of randomly incident sound, as in sound-reinforcing systems. The ability of the microphone to accomplish this is determined by the dependence on angle and frequency of the field response. There are many measures of directionality, such as the ratio of output for sound from the desired direction to the output for sound of random incidence of the same total power, the ratio of the output for sound of random incidence in the front hemisphere to that of random incidence in the rear hemisphere, or the ratio of the outputs at the angles of maximum and minimum response.

Most commonly used microphones may be classified as non-directional, bidirectional, and unidirectional. Since pressure is a scalar quantity, an ideal pressure microphone is non-directional. In practice complete freedom from directional effects is achieved only when the maximum transverse dimension is of the order of an eighth wavelength or less. Since most microphones are operated at frequencies up to 4000 or more cps, this requirement necessitates a microphone a centimeter or less in diameter. To provide adequate sensitivity microphones are made larger than the non-directional requirements dictate and commonly have a diameter of 2 to 5 cm. In pressure-actuated microphones this results in a non-directional microphone at low frequencies and a unidirectional one at high frequencies. Screens are sometimes mounted near the diaphragm to alter the sound field and make the microphone less directional.

The most common bidirectional microphone is the cosine pressure-difference or "gradient" type exemplified by the ribbon microphone discussed above.

Most unidirectional microphones have a directional characteristic, which, if taken in a plane through the principal axis, is given by $e_u = e_n + e_b \cos \theta$. If the microphone has separate non-directional (pressure) and bidirectional transducer elements, e_n and e_b are their respective voltages and e_u is their combined voltage. One type of unidirectional microphone is a pressure-difference type in which a single transducing element is used with a network to shift the phase of one of the pressures to alter the directional characteristic. In this type e_n corresponds to the voltage with no force contribution from the rear network and e_b to the voltage when the rear and front impedances are equal and the microphone is bidirectional. By adjusting the impedance of the rear network the relative values of e_n and e_b may be altered to give various directional characteristics. Single transducer microphones of this type are commonly made with crystal or moving-coil generators.

19. PERFORMANCE AND TESTS

The most important performance criteria are the field response (see Fig. 6), directivity, impedance, and inherent noise. Less important for general applications are the "dynamic" range (the range from minimum pressure, limited by electrical noise, to maximum pressure limited by non-linearity or by structural strength), the ratio of the responses for near and distance sources, termed the proximity index, and non-linear distortion.

OBJECTIVE TESTS. The field response of a microphone is a measure of the electrical output, for a specified frequency, when immersed in a plane progressive wave. When the effect of the impedance is considered, an expression of the form $20 \log E/p - 10 \log R$ results, in which E is the open-circuit emf, in volts, generated by the microphone; p is the undisturbed sound pressure, in dynes/cm^2; and R is the stated impedance of the microphone. This relation takes into account the effect of impedance in permitting the use of step-up transformers. For crystal and condenser microphones, R is sometimes assigned a value corresponding to the maximum stated value of transformer secondary impedance used with low-impedance microphones, usually from 30,000 to 100,000 ohms. This value permits a fairer comparison of all types in terms of the amount of amplification necessary, referred to an input grid.

The directivity is usually determined from field-response curves taken at various angles of incidence, or from the field response as a function of angle with the spectral composition of the test signal held constant. Single-frequency, narrow-band warbled or frequency-modulated and noise test signals are used. Unidirectional microphones should show greater than 10-db front-to-rear discrimination (15 db is a common value), while in the bidirectional (pressure-difference) type the front-to-side discrimination usually exceeds 20 db over a large frequency range.

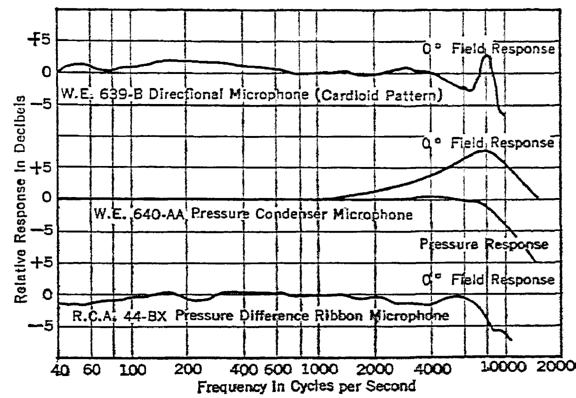

FIG. 6. Axial Response-frequency Curves of Three Microphones

To minimize frequency discrimination and reduce electrostatic and electromagnetic induction in long microphone lines, broadcast-type microphones have impedances ranging from 35 to 250 ohms, with a trend toward 150 ohms. These microphones are usually operated into impedances ten or more times that of the microphone's. This results in about a 3-db improvement in the signal-to-inherent-electrical-noise ratio over that obtained when the load resistance equals the modulus of the microphone impedance.

The present technique of primary calibration is by means of the reciprocity technique mentioned under Condenser Microphones, article 14. This yields a pressure calibration, from which the field response may be derived by calculation or measurement (with scaled models) of diffraction and cavity resonance effects. A microphone thus calibrated may be used as a standard from which the response of other microphones may be obtained by comparison, in absolute terms. The source may be a sufficiently distant loudspeaker with very smooth response; or for special purposes an artificial voice is used to obtain field shape and diffraction effects approximating those of a person speaking. Although it is possible to obtain free-field reciprocity calibrations, much work remains to be done before the precision and stability of the pressure reciprocity method can be attained.

SUBJECTIVE (AURAL) TESTS. As with loudspeakers, the final acceptability of a microphone depends on subjective tests. A live or artificial voice may be used as a source for two microphones being compared, the outputs being alternately connected to an audition system. Such qualities as naturalness, smoothness, presence, articulation, the objectionability of intermodulation distortion, loudness efficiency, and transient distortion may best be compared by aural tests with a trained jury.

MAGNETIC RECORDING AND REPRODUCING OF SOUND

By L. Vieth and H. A. Henning

The earliest record of magnetic recording is credited to Poulsen, who in 1900 described his "Telegraphone." Since that time, though much has been learned and vastly improved results have been obtained, extensive use of the method as a recording process of great potentialities was not achieved until the war years of 1941–1945.

The magnetic recording method possesses certain unique advantages. The mechanism may be simple to operate and rugged. The record can be played immediately after recording and can be replayed practically any number of times. The recording may be erased and the medium reused as often as desired.

Magnetic recording involves three fundamental operations or processes: (1) erasing; (2) recording; (3) reproduction or playback. Erasing is the process by which the magnetic recording medium is either neutralized or saturated to obliterate any signal previously recorded. In the early phases of development saturation by a strong d-c field was used. More recently neutralization of the medium by a high-frequency a-c field has been required in conjunction with modern methods of recording with an a-c bias. Recording is accomplished by applying, through the recording head, the signal to be recorded superimposed on a biasing current. The bias current may be either direct or high-frequency alternating current. Considerations governing the choice of biasing and erasing methods are discussed in article 21. The bias current is necessary to obtain a faithful recording of the impressed signals. The medium, as it passes under the influence of the recording head, is magnetized in proportion to the variations of the signal current, and this magnetization remains until erased. Reproduction or playback is accomplished by passing the recorded medium over a magnetically sensitive head, usually at the same velocity as in recording. The voltages induced in the head are then amplified and equalized to obtain the desired frequency characteristic. All these processes may be accomplished with the same head at some sacrifice in performance.

20. ERASING, RECORDING, AND REPRODUCING ARRANGEMENTS

Physical arrangements by which the magnetic forces are applied to a magnetic medium (usually in the form of a tape or wire) have taken several forms. They may be divided into three broad classifications: (1) perpendicular magnetization, in which the direction of magnetization is normal to the surface of the medium; (2) modifications of (1), which alter perpendicularity somewhat; and (3) longitudinal magnetization in which the direction of magnetization is parallel with the direction of motion of the medium. Transverse magnetization in which the direction of magnetization is parallel to the surface of the medium and normal to the direction of motion is a fourth possible classification which will not be considered here. Figure 1 illustrates schematically the three arrangements. Each consists essentially of cores of high-permeability material surrounded by one or more coils. Figure 1(*a*) shows the perpendicular application of magnetic force to a medium in the form of tape, moving between the poles, each consisting of one lamination in exact alignment. Each pole is surrounded by a coil. A concentration of recording flux is obtained by the small thickness of lamination in the direction of tape travel.

Figure 1(*b*) illustrates a more efficient and practical modification of (*a*). Much thicker cores are used, which are in contact with opposite surfaces of the tape. Flux concentration is accomplished by offsetting the poles in the direction of travel by an amount almost equal to their thickness. A coil surrounds the advance pole. The tape is therefore magnetized in a preponderantly perpendicular manner with a longitudinal component. Induction at short wavelengths is most pronounced on the side of the tape in contact with the coil-bearing pole. Omission of the coil on the receding or following pole avoids a secondary concentration of recording flux as the tape leaves the influence of the recording head, thus avoiding modulation of the already recorded signal. The schemes illustrated in 1(*a*) and 1(*b*) require that intimate contact must be maintained by pressure against both surfaces of the tape. Joints must therefore be carefully made, and the two surfaces must be uniformly parallel to insure good contact at all times. Furthermore, these two schemes are of limited use on wire and are even less useful on non-magnetic tapes coated on one side with magnetic materials. Figure 1(*c*) shows an arrangement which applies magnetizing force longitudinally. Contact is made on only one side, and the principle is therefore conveniently applicable to all forms of recording media. A ring of permeable material

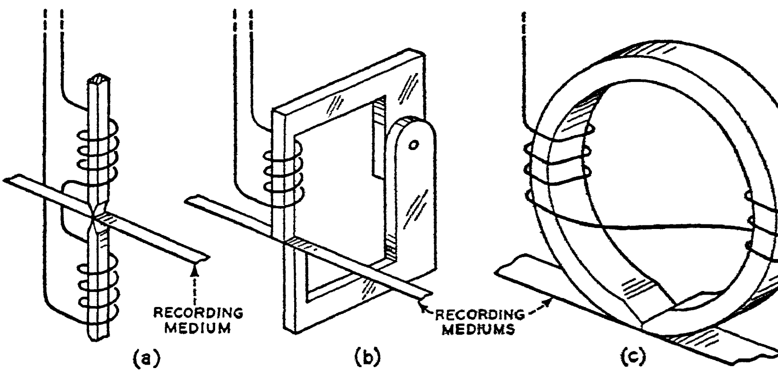

FIG. 1. Typical Magnetic Recording and Reproducing Arrangements

wound with a coil is provided with a small air gap at the point where it touches the recording medium. A portion of the flux in the air gap passes through the medium. The resulting magnetization is substantially longitudinal. The concentration of flux is accomplished by the use of very small gaps ranging from 0.003 in. to less than 0.0003 in., depending on the medium.

Although all the above arrangements may be used for erasing, recording, and reproducing, it is expedient to alter their characteristics in the interests of one process or another. Separate heads are frequently provided for each process. In each case it is important that the magnetic action of the head in recording and reproducing be concentrated along a line perpendicular to the direction of motion. The greatest concentration of active flux lines is obtained for a given pole-piece arrangement when the tip reluctance of the recording or reproducing pole piece is low. Poles or cores are usually laminated to reduce the frequency discriminating effects of eddy currents.

21. ERASING, RECORDING, AND REPRODUCING PROCESSES

RECORDING SPEED. The various systems used for driving the magnetic media will not be discussed here. There are, at present, no standardized recording speeds, and in most applications the medium is moved past the recording and reproducing heads at the slowest speed that will insure the desired high-frequency response. In practice these speeds range from a few inches to several feet per second. In order to obtain a frequency range of 10,000 cycles it is modern practice to employ recording speeds between 1 $^1/_2$ and 5 ft per sec, depending on the properties of the recording medium and the methods of recording.

ERASING. The process used to obliterate a previously recorded signal on a magnetic medium is called erasing. In most applications the erasing operation is performed during the recording process by a head located somewhat in advance of the recording head. There are, however, instances in which it is more convenient to perform the erasure as an independent operation.

A previous recording may be removed either by saturating the medium with a strong d-c field or by neutralizing the medium with an a-c field of diminishing intensity. In the first process every portion of the medium entering the erasing head is carried to saturation or a degree of magnetization exceeding the strongest recorded signal. The erasing head may consist of a permanent magnet or an electromagnet supplied by direct current. In certain designs the configuration of leakage flux lines around the head can cause a second and reversed field to act on the medium as it leaves the head. Under such conditions the initial saturation is followed by a partial demagnetizing operation, and the ultimate state of the medium may be considerably less than fully saturated. As the optimum d-c recording bias is determined by the magnetic state of the erased medium it is apparent that the design of the erasing head influences the constants of the recording process.

It is now common practice in high-quality magnetic recording to erase by a neutralizing or demagnetizing action. This is accomplished by subjecting each element of the medium to a cyclicly varying magnetic field whose maximum intensity between the poles of the head produces saturation. As the element moves away from the head it is subjected to a continuously diminishing cyclic magnetization which leaves the medium in a neutral state. A magnetizing force approximately three times the coercive force of the medium has been found to be satisfactory. A field intensity of 1500 oersteds may be required to demagnetize some of the modern high coercive force materials.

Some use has been made of an air-core coil for erasure of the lower-coercive-force materials. The medium is drawn through the center of the coil, and a comparatively low-frequency erasing current is required. If erasing is accomplished with the recording head a higher-frequency current is used to provide the necessary number of reversals in the short time the medium is within the influence of the head.

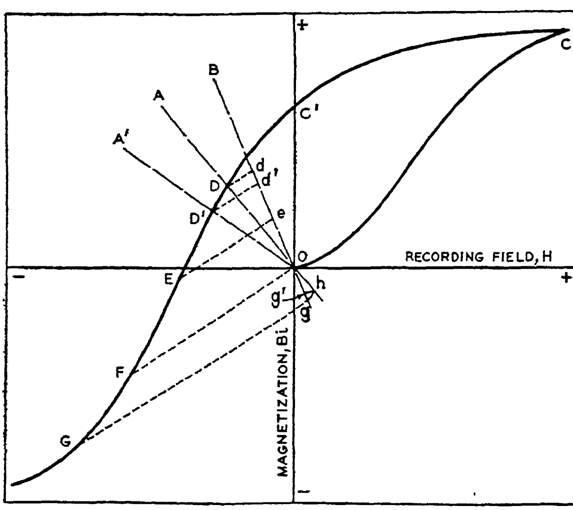

Fig. 2. Magnetic History of an Element of Recording Medium. Saturation erase, d-c Bias.

In certain instances a combination of d-c saturation followed by partial neutralization has been employed. In such circumstances the recorded signal is successfully erased but there remains a residual d-c component on the medium which is responsible for somewhat increased distortion.

RECORDING. The process of recording consists of impressing on the moving magnetic medium a varying induction which is directly proportional to the instantaneous value of the recording head current. The recording head is usually associated with an amplifier so designed that the recording currents are independent of the impedance characteristic of the head. In most applications recording currents are small and very little power is required. In certain applications electronic amplification is not used and the recording current is obtained directly from a carbon microphone.

The linear relationship between recording current and the resulting magnetization on the medium is obtained by the use of a superimposed biasing field, usually by superposing a biasing current on the recording current fed to the head. Without the bias the reproduced signals are weak and very distorted. The biasing field is adjusted to a magnitude that minimizes the distortion without introducing unnecessary background noise. The proper value is usually slightly less than that which will yield the strongest reproduced signal. Two biasing methods are available. It is now customary to use a high-frequency (supersonic) biasing current, and the greatest dynamic recording range may be obtained by this method. In earlier applications a d-c biasing current was used; it is advantageous where extreme compactness and simplicity of equipment are essential.

The magnetic processes involved during recording may be illustrated by hysteresis loops such as those of Figs. 2, 3, and 4. These curves represent *Bi* (or *B-H*) vs. *H*, or intrinsic induction vs. magnetizing force. They thus represent the fundamental characteristic of the recording medium. Each element of the medium, as it passes the recording point, is subjected to a magnetizing field which is proportional to the algebraic sum of the instantaneous recording current and the biasing current. The element is then withdrawn from the field. For long uniformly magnetized sections the resultant state of each element of the section would be represented by a point on the *Bi* axis. The magnetic state of an element of a short magnet (because of self-demagnetization) is represented by a point on an appropriate demagnetization coefficient line. The demagnetization coefficient line *OA* of Figs. 2, 3, and 4 may be called the open circuit line, and it defines the state of the element when removed from the head. Whenever the element under consideration is within the playback head, the self-demagnetizing field is partially removed and the magnetic state of an element moves along a reversible minor hysteresis curve which may be represented by a straight line such as *Dd* in Fig. 2 to a steeper demagnetization coefficient line *OB*. The slope of line *OB*, which may be called the closed circuit line, is determined primarily by the reluctance present at the contact point of medium and head and thus is substantially independent of the recorded wavelength. In longitudinal recording the slope of the open-circuit line *OA* is to some extent a function of the recorded wavelength, and thus the self-demagnetization is a function of frequency. The effect on the frequency response of this action may be at least partially offset[4] by the use of high-coercive-force materials.

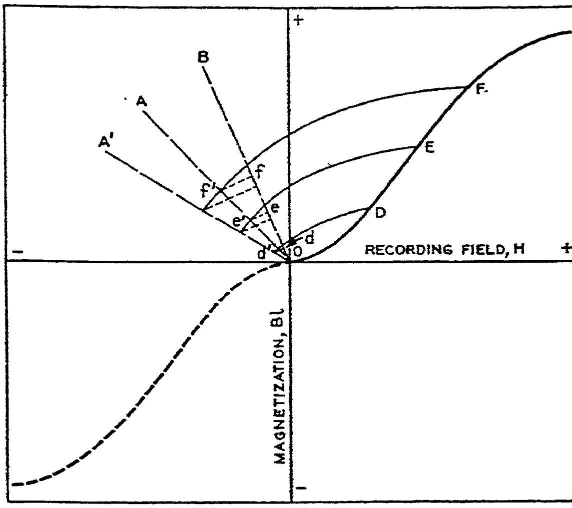

FIG. 3. Magnetic History of an Element of Recording Medium. Neutralization erase, d-c bias.

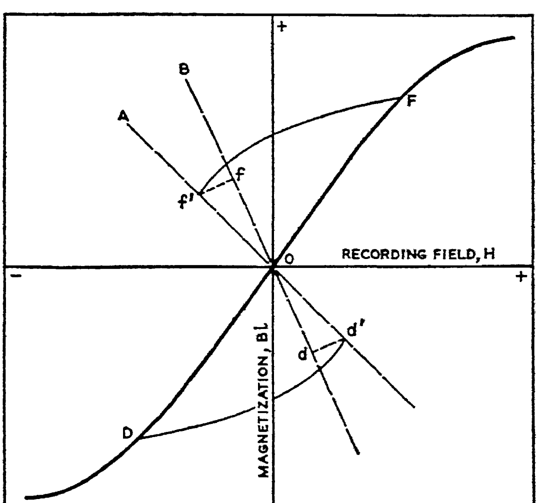

FIG. 4. Magnetic History of an Element of Recording Medium· Neutralization erase, a-c bias.

Figure 2 illustrates the magnetic process of recording with a d-c bias on a medium that has previously been saturation erased. During the erasing process the saturating field brings the magnetic state of each element of the medium to a point *C* on the hysteresis curve. Assuming that the element leaves the erasing field without being subjected to a reverse magnetization, the magnetic state of the element moves along the hysteresis curve *CC'D* to point *D* on the open-circuit line *OA*. Subsequently, when in the recording head, the state of the element is represented by point *d* on closed-circuit line *OB*, and as the minor hysteresis curve *Dd* traversed during this process is substantially reversible any applied recording field operating within this region leaves no change in impression on the medium. If after saturation a d-c bias is applied, the state of the element is brought to point E along the major loop, and this point is chosen to represent the midpoint of the available operating range. Variations in the recording field will then produce corresponding changes in magnetization. The combined action of the biasing field and the signal field then operates over a substantially straight section DEF of the hysteresis curve. When the element emerges from the recording head, its magnetic state returns along the minor loop to the open-circuit line OA and subsequently, when in the reproducing head, to the closed-circuit line OB along the same minor loop. Depending on the signal strength, the path of this action is along nearly straight, parallel, and reversible minor hysteresis curves lying between Dd and FO. Thus the flux induced during reproduction, for the state of magnetization corresponding to a point on the closed-circuit line OB lying between O and d, is practically linearly related to the applied recording field.

In Fig. 2, the point F represents one of the limits of the recording field which may be applied to the medium without serious distortion. This is because minor hysteresis curves have greater curvature after crossing the Bi axis and a minor hysteresis curve such as Gh leaves the magnetic state of the element at g' instead of the required point g.

The operating range during recording at short wavelengths is also restricted wherever the slope of the open-circuit line OA is a function of the wavelength. This is illustrated in Fig. 2 by line OA', which might be the slope of the open-circuit line in a medium longitudinally recorded at a short wavelength. The magnetic state of a saturated element is then represented by the point D'. The recording field is thus restricted to operation over the region between D' and F.

Figure 3 illustrates the magnetic process involved when a d-c bias is used with a completely demagnetized medium. The recording bias alone serves to carry the magnetic state of the element along the normal magnetization curve $ODEF$ to point E. The recording signal operates about E, which is chosen as the midpoint of the linear part of the magnetization curve. Upon leaving the recording head the magnetization of the element drops to line OA along one of substantially parallel hysteresis curves similar to and lying between Dd' and Ff'. The process is thereafter similar to that described for saturation erase. If, at shorter wavelengths, the slope of the open-circuit demagnetization coefficient line OA is reduced to OA', points d and f on the closed-circuit demagnetization coefficient line OB are proportionately reduced. This results in an attenuation of the recorded signal. It may be observed in Figs. 2 and 3 that the degree of magnetization of an element which has been biased but is otherwise unrecorded is substantially the same in either process, and also that the undistorted operating range is nearly identical. Because of these conditions the background noise and dynamic range in either process are substantially the same, and thus when operating with a d-c bias there is little advantage in providing extra equipment to demagnetize the medium.

It is now customary to erase by demagnetization and employ a high-frequency (supersonic) biasing current during recording. The action of the high-frequency bias has been variously explained. It is sufficient to say here that it serves the purpose of straightening out the bend in the normal magnetization curve around the origin. The resulting action is as shown in Fig. 4. The recording signal may then operate about the origin O and along the entire straight portion of the curve between D and F. The remainder of the process may be considered to be similar to that described for recording with a d-c bias on a demagnetized medium except that the recording range is doubled. This represents a doubling of the reproduced signal without an equivalent increase in background noise.

There is an even greater increase in signal-to-noise ratio inasmuch as the elimination of the d-c biasing component of magnetization serves to reduce the observable background noise. The biasing frequency employed in this method of recording is customarily quite high and usually leaves no permanent impression on the magnetic medium. Wherever a biasing frequency is recorded, it is beyond the range of the playback equipment and is not reproduced.

In common with all methods of sound recording, magnetic recording introduces a certain amount of distortion although modern magnetic recording systems are considerably improved in this respect. Distortion is introduced during the recording process from several sources. The most common source of distortion arises from the non-linear properties of the recording medium. It is apparent from Figs. 2 and 3 that there is an optimum value of d-c bias which will minimize curvature distortion. When using an a-c recording bias there is a minimum value which is sufficient to eliminate the curvature of the normal magnetization curve around the origin. Higher values than the necessary minimum may be used, but there is no advantage to be obtained. Distortion resulting from intermodulation between the bias frequency and the signal frequencies and their harmonics may be kept outside the operating range by using a sufficiently high biasing frequency. When recording with an a-c bias, distortion is increased by the presence of a residual d-c magnetization which may be present either in the recording and reproducing heads or in the erased medium.

A distortion may also be introduced by the recording head if the magnetizing field at the head is not sufficiently concentrated. At higher frequencies it is then possible for the recording signal to change while an element is within the influence of the head, and the element will retain an impression of the strongest magnetizing force to which it is subjected. The use of narrow recording gaps and modern high-permeability pole pieces has greatly reduced this type of distortion.

REPRODUCTION. In the reproducing process the varying magnetization impressed on the medium during recording produces a corresponding flux in the reproducing head. A portion of this flux threads the coil, and its variation due to the motion of the medium induces the signal voltage. Signal voltages are normally quite low, and considerable amplification is required.

The process by which the reproducing head picks up the signal flux is essentially similar for any of the heads of Fig. 1. The return path for all the signal flux in a magnetized element approaching the reproducing head is through the air. The magnetic state of such an element is described in Figs. 2, 3, and 4 by a point on an open-circuit demagnetization coefficient line such as OA. As the element approaches the head some of the flux which leaves the medium passes to the head. In the case of the head of Fig. 1(a) a portion of this flux threads the coil. The percentage of flux which threads the coil increases very rapidly as the element comes directly under the thin lamination and decreases as rapidly thereafter. Thus the total flux threading the coil is contributed by the magnetized elements under the thin lamination and those immediately adjacent. In the case of the offset pole pieces of Fig. 1(b) the major contribution to the flux threading the coil is made by the elements in the immediate region of the overlap point. Elements in contact with one pole tip and remote from the overlap point are either insufficiently coupled or, at short recorded wavelengths, are short-circuited by the pole tip and therefore do not contribute to the flux threading the coil. The ring-shape head of Fig. 1(c) operates in a somewhat similar manner. The head serves as a return path for flux leaving the surface of the longitudinally recorded medium. With the exception of flux from elements of the medium in the immediate vicinity of the air gap, the return path does not include the reproducing coil. Thus the flux which does thread the coil may be considered as being contributed by the elements in the immediate region of the air gap.

When the recorded element is in position at the reproducing point its magnetic state is described in Figs. 2, 3, and 4 by a point on the closed-circuit demagnetization coefficient line OB. The slope of this line is determined by the total reluctance of the return path for the element in question, and this reluctance is affected by the amount of contact between the medium and pole pieces. The flux threading the coil is then equal to the product of the Bi intercept of the point on OB, the normal cross-sectional area of the contributing elements, and an appropriate leakage factor. The contact reluctance of the narrow pole-tip structure of Fig. 1(a) is higher than that of the broad pole-tip structures of Figs. 1(b) and 1(c). Therefore the slope of the closed-circuit demagnetization line OB will be less in the former case and the flux threading the coil for a given magnetization of the medium will also be less.

The open-circuit signal voltage at the reproducing head is proportional to the rate of change of flux threading the coil. This factor in itself is responsible for a 6 db per octave rise in the signal characteristic. There are, however, several other factors that enter into the overall frequency response. (1) In both recording and reproduction the eddy-current characteristics of the head may introduce some attenuation at higher frequencies. (2) Following recording, the medium demagnetizes to a degree which is a function of the length of the recorded magnets. In longitudinal recording the resultant attenuation is an inverse function of the recorded wavelength. (3) In reproduction the response falls off when the dimension of the recorded wavelength becomes comparable to the active region of the reproducing head. Although the region in which a magnetized element of the medium may cause flux to thread the coil is not sharply defined, an effective dimension may usually be assigned, and this dimension has been called the "slit width" because of its similarity to the optical effect. In the ring-shape recording head experience has shown that the slit width is from 10 to 40 per cent greater than the air-gap length. (4) In certain reproducing heads, such as that of Fig. 1(b), the construction is such that the pole pieces are somewhat active over their entire dimension. Thus there is in effect a secondary slit width equivalent to the overall dimension of the poles which is responsible for irregularities in the response at longer wavelengths.

Lübeck has given, for ring-shape heads, a general expression for the open-circuit output voltage

$$E = CNI \frac{v}{s} e^{-\tau/\lambda} \sin \frac{\pi s}{\lambda} \tag{1}$$

where E and I are, respectively, the open-circuit output voltage and input current, C = a constant for the particular system, N = number of turns in reproducing coil, v = linear speed of medium, s = effective "slit width" of reproducing head, τ = a demagnetization constant for the medium, $\lambda = v/f$ = wavelength of recorded signal, f = frequency, and $\omega = 2\pi f$. The (electric to magnetic) frequency characteristics of the recording and reproducing head have been neglected in this expression.

Figure 5, curve (1), shows an illustrative frequency response characteristic. The factors determining the characteristic are independently plotted. It is seen that the function $\sin \pi s/\lambda$ which is the "slit width" characteristic plotted in curve (3) rises to a maximum

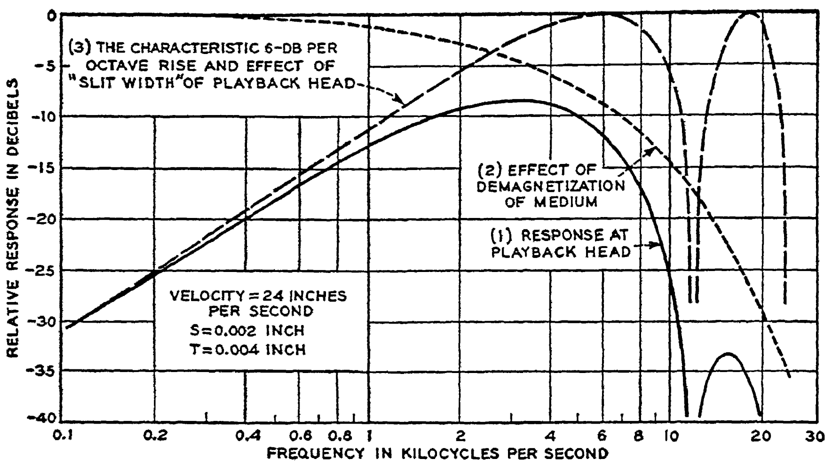

FIG. 5. Frequency Response of a Longitudinal Recording. Open-circuit playback voltage for constant recording current.

when the recorded wavelength is twice the effective slit width. Thereafter it goes through a series of dips and peaks. In a practical head design where the working gap is very small, the second and succeeding peaks are not reproduced because they lie in the region where the demagnetization, curve (2), of the medium causes a high loss and they usually fall outside the frequency range of associated electrical circuits.

At recording speeds in current use the slit width may be made sufficiently small so that $\sin \pi s/\lambda$ can be replaced by the angle itself within the working frequency range. Under these conditions

$$E = CNI \frac{v}{\lambda} e^{-\tau/\lambda} = CNI\omega e^{-\tau/\lambda} \tag{2}$$

and it is seen that, except for demagnetization, the output voltage rises 6 db per octave and is not influenced by the recording or reproducing speed or the width of the effective slit.

It is usually necessary to introduce an electrical equalization in the associated recording-reproducing circuits in order to obtain the desired overall frequency response. A major portion of the equalization is assigned to the reproducing circuits where it is limited only by the frequency spectrum of background noise.

When due consideration is given to the overload characteristic of the recording medium and the energy distribution of the recording signal, some of the equalization may be introduced in the recording circuits.

SOURCES OF NOISE. Background noise arises from a number of sources, many of which may be minimized in careful design. Among such sources may be listed amplifier hum, thermal noise, external noise pickup in the reproducing head, crosstalk transferred from a strong signal on adjacent turns of the medium when wound on the storage spool, mechanical irregularities on the surface of the recording medium which affect the degree of contact with the reproducing head, variations in the magnetic properties of the medium, and variations in the cross-sectional area of the medium. The remaining, and basic, noise source appears to be caused by a random distribution of small magnetic inhomogeneities. Some measurements at the reproducing head of noise from this source have indicated a fairly uniform frequency distribution of noise voltage per cycle. In most cases, after equalization, this background noise has a smooth character and so is not particularly disturbing. Basic noise is a function of the degree of magnetization of the medium. It is very low for a medium which has been thoroughly erased by a-c demagnetization, but it may be increased to a considerable extent by the presence of the a-c biasing flux. The noise level may be considerably increased by the use of a reproducing head in which there is some remanent magnetization, and the use of a d-c bias increases the noise markedly. Wherever the noise is decidedly affected by the presence of recording bias, there is detectable, back of the signal, a noise which rises and falls with the magnitude of the signal. A certain amount of such noise is not objectionable as it is partially masked by the signal.

22. RECORDING MEDIA

PHYSICAL FORMS. Most of the early magnetic recording equipment employed a solid homogeneous steel wire or tape as the recording medium. Recent refinements in the art of electroplating magnetic alloys and developments in the use of magnetic-powder-coated paper and plastic materials have removed many of the restrictions on the form of the recording medium. Although there are some technical differences between the media, the choice of physical form in general is determined by the desired application.

Magnetic wire is generally used wherever a very long playing time is required or a compact equipment is necessary. The wire diameter is limited only by the required breaking strength, and diameters between 0.004 in. and 0.006 in. are most common. Splicing is accomplished by tying a square knot which passes over a properly designed head without difficulty. A longitudinal recording head is usually employed, and the wire rides in a groove which is worn in the head. This method of recording is designed to distribute the recording signal about the circumference of the wire and serve as a protection against variation of the reproduced signal as the wire twists. There is, however, a considerable variation in the strength of the recorded signal around the circumference of the wire, particularly at short wavelengths, and it is fortunate that smooth round wire does not evidence a random twisting when properly used. The chief disadvantage of the use of wire is the tendency to uncoil, snarl, and kink whenever a free end becomes loose. For this reason it is advisable to mount the wire in a magazine containing the supply and take up reels and remove the magazine as a unit wherever record storage is required.

Magnetic tape, either solid or plated, is most useful for applications requiring a continuous record-reproduce-erase cycle. In such applications the tape is prepared in the form of an endless belt which is spliced, at the junction point, with a butt weld. Whenever a more extended playing time is required the tape is reeled like motion-picture film. Recording equipment has been commercially produced, using 0.002 in. by 0.050 in. tape and the offset recording and reproducing pole pieces of Fig. 1(*b*) in which an extended frequency response and dynamic range are realized at a comparatively low operating speed. The solid magnetic recording materials, both tape and wire, have the common disadvantage that accurate dimensional tolerances, smooth surface conditions, and uniformity of heat treatment must be maintained on large quantities of a material that is inherently very difficult to fabricate.

Coated paper and plastic recording media are applicable to all uses where requirements on playing time are not excessive and its low remanence can be tolerated. It has been used in the form of tape, sheets, and disks. The material is cheap to manufacture and may be cut and spliced by cementing. The material is usually 0.0015 to 0.0025 in. thick. In contrast to steel wire and tape, when a reel of the material is removed from a machine, there is little danger of freely uncoiling, a characteristic that is very desirable in the home recording field. When used with a properly designed ring-type recording-reproducing head a favorable frequency characteristic may be obtained with a comparatively low operating speed. Output levels are much lower than can be attained with solid wires and tapes, and care is required in shielding the reproducing head and in the design of reproducing amplifiers. Although the inherent dynamic range of the coated media is quite large, thermal and hum noise levels in reproducing equipment may limit the practical dynamic range.

Certain special applications of magnetic recording have employed magnetic media in the form of solid disks or cylinders. Most frequently the recording surface is electroplated on a non-ferrous backing material.

MAGNETIC MATERIALS. A carbon-steel recording medium was used in most of the early equipment because it is commercially available in the form of music wire. It has very little value in present-day recording applications. The coercive force is low, approximately 40 oersteds, and thus self-demagnetization is very pronounced. The residual induction is approximately 10,000 gausses. Because of demagnetization the short-wavelength (high-frequency) response from a longitudinal recording is very limited. The material magnetizes easily from the recording on adjacent turns of the storage spool, and crosstalk is therefore high. The basic background noise is rather high and is increased by surface corrosion of the material.

Thirteen per cent chrome steel has been used to a considerable extent in both magnetic wire and tape recorders because of its resistance to corrosion. This is a ferritic material depending mostly on the presence of carbon for its magnetic properties. The chromium is, however, instrumental in obtaining the desired hardness. When properly quenched, the material has a coercive force of 50–60 oersteds and a residual induction of 7000–10,000 gausses. A frequency response and dynamic range superior to carbon steel may be obtained from the material. High operating speeds are required, however, when an extended frequency range is desired. To prevent formation of chromium oxides, which are very abrasive, the material is heat treated in an atmosphere free of oxygen.

Nickel-chromium stainless steels such as 18 per cent chromium, 8 per cent nickel have been used in magnetic wire recorders. This is an austenitic steel which may be hardened by cold working. A somewhat more uniform product is obtained when the cold-worked material is then age hardened. After such treatment the coercive force is of the order of 150 to 350 oersteds with a possible maximum residual induction of 7000 gausses.

Several other magnetic alloys possess properties which make them exceptionally satisfactory as magnetic recording media. One such material is known as Vicalloy, a workable permanent-magnet alloy which is heat treated to obtain the desired magnetic properties. A typical Vicalloy composition is 38 per cent iron, 52 per cent cobalt, and 10 per cent vanadium. Vicalloy recording tape has been commercially produced with a coercive force of 225 oersteds and a residual induction of 6000 gausses.

One of the chief disadvantages of the solid magnetic recording media has been the difficulty of maintaining a uniform recording sensitivity and background-noise level throughout the entire length of the medium. Recently, an electroplated medium has been developed in order to correct this disadvantage and at the same time provide a cheaper recording material. The recording surface consists of a thin layer (approximately 0.0003 in.) of a nickel-cobalt alloy plated on hard brass wire or tape. The magnetic and physical properties are controlled in the plating process, and subsequent working or heat treatment is not required. The coercive force is approximately 200 oersteds with a residual induction of the order of 8000 gausses. A satisfactory frequency range may be obtained from this material at a comparatively low operating speed.

The use of powdered magnetic materials applied to paper or plastic carriers has recently received considerable attention in this country. Such a recording medium is comparatively cheap to manufacture and may be produced with very uniform and stable properties. Various magnetic materials in powder form are being investigated for properties advantageous to magnetic recording. One such material, black magnetic iron oxide, is commercially available in the required finely divided form. The powdered material is normally dispersed in a plasticized lacquer and applied to the carrier to a thickness of approximately 0.0005 in. When the powdered magnetic material is very finely divided and uniformly dispersed in the binder very excellent results have been obtained both in frequency response and background noise. Coercive forces ranging between 100 and 500 oersteds have been measured. The residual induction is very low, and of the order of a few hundred gausses. Demagnetization of signals of short wavelengths appears to be less pronounced in the powdered materials than in solid materials of equal coercive force. Output levels are very low, and, unless a very wide sound track is used, unusual precautions are required in the design of reproducing equipment which will take full advantage of the inherent dynamic range of the medium.

In Germany considerable work has been done on tape in which the magnetic medium is ferric and ferrous oxide in individual particles about 1 micron in size. This material is manufactured from precipitated finely divided black magnetic iron oxide by further oxidization in an agitated drier. The red ferric oxide has the crystal structure of the magnetic oxide and is also magnetic. Several types of recording tape have been manufactured in which the magnetic oxides are either cast on the surface of a plastic carrier such as cellulose acetate or polyvinyl chloride or are dispersed throughout a tape of polyvinyl chloride in a 50-50 mixture. It is reported that a frequency response uniform to within ±2 db from 50 to 10,000 cps is obtained at a tape speed of 30 in. per sec, the overall noise level is very low, and the useful life of the recorded tape exceptionally high.

MECHANICAL RECORDING AND REPRODUCING OF SOUND

By L. Vieth and H. A. Henning

The requirements for high-fidelity recording and reproduction of sound are (*a*) that the whole system, from the point where the sound reaches the pickup device to the point where it is actually reproduced as sound, shall have a linear relationship between its input and its output, (*b*) that the system have a uniform response versus frequency characteristic, since any complex wave may be resolved into the sum of simple sinusoidal terms, and (*c*) that the system have a linear relationship between its phase shift and the frequency impressed upon it and that the phase angle have a value of $\pm n\pi$ at zero frequency where $n = 0, 1, 2, 3$, etc. The requirements of individual components may vary from the requirements of uniform response versus frequency characteristic (*b*), but in general the requirements for the system apply to its components.

Most sound recording and reproducing systems and components represent a compromise between the requirements for high-quality reproduction and the commercial requirements of size, cost, and general adaptability for a specific use. These compromises have resulted in a wide range of overall performances. Space limitations prohibit discussion of more than a few of the typical instruments in commercial use in the mechanical recording and reproducing of sound.

23. RECORDING INSTRUMENTS

Mechanical recording is used almost exclusively in the present-day phonograph industry, in electrical transcriptions for broadcast purposes, and in stenographic applications (dictation machines) and general utility recorders. Most mechanical recording is done on disks varying in diameter from 6 in. for general utility equipment to 16 in. in broadcast transcriptions. There are, in addition, several commercial devices in which the recording medium takes the form of standard motion-picture film base. The materials of which these media are made are discussed elsewhere. They may be grouped, in general, into two classes: (*a*) materials for recording for instantaneous playback; (*b*) materials for recording for subsequent processing. However, the function of the recording instrument is the same in all: to transfer to the recording medium, in the form of embossed or engraved modulations, a counterpart of the voltage impressed on the recorder modified in frequency characteristic in conformance with some preconceived plan of equalization which affords the optimum use of the recording equipment.

A typical recording instrument used in this work is illustrated by Fig. 1, which shows a phantom view of a lateral-type recorder (one in which the stylus moves laterally parallel

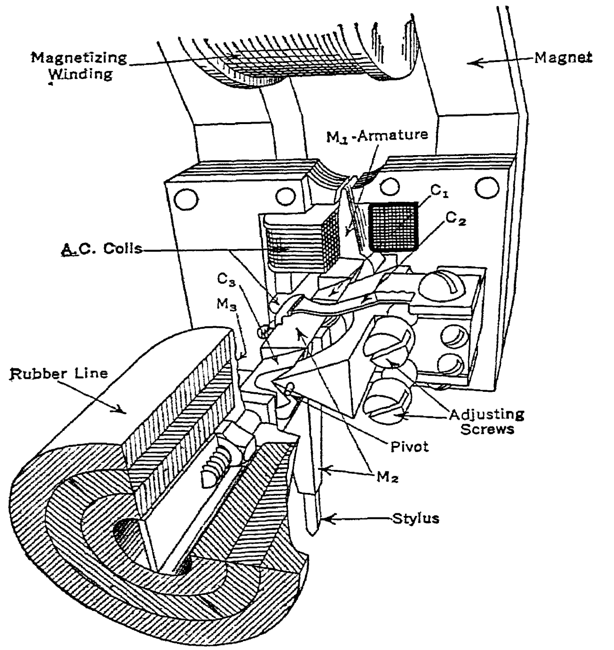

FIG. 1. Electromechanical Type Recorder

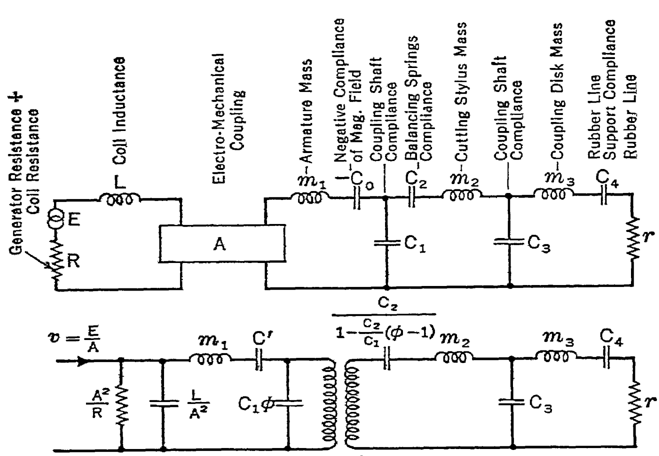

FIG. 2. Equivalent Circuits of Electromechanical Recorder Shown in Fig. 1

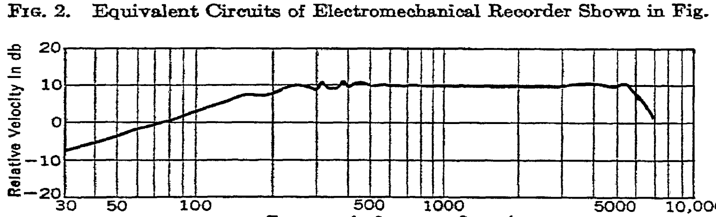

FIG. 3. Response vs. Frequency Characteristic of a Lateral Type Recorder

to the radius of the disk) designed by Bell Telephone Laboratories some years ago. The same general structure has been used in vertical-type recorders (one in which the stylus moves normal to the face of the disk). The structure is a mechanical filter whose electrical equivalent is shown in Fig. 2, in which the current in the second mesh is analogous to the

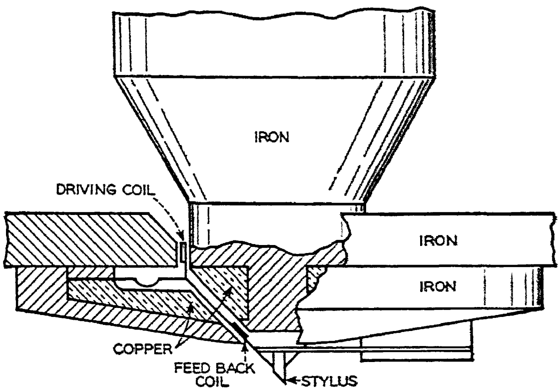

FIG. 4. Cross-sectional View of Vibrating System and Associated Magnetic Circuit of Western Electric Co. 1A Feedback Recorder

stylus velocity. Figure 3 shows a typical response versus frequency characteristic of such a recorder. The loss at the lower frequencies is part of a preconceived equalization plan which makes the best use of the recording medium by limiting amplitudes in the interest of record space economy.

The vibratory system of a more modern version of recording instrument is shown in Fig. 4. This device, also designed at Bell Telephone Laboratories, utilizes the principle of stabilized feedback to control the stylus velocity and involves an associated amplifier in which the recorder becomes an actual transmission element as well as a terminal transducer. Schematically, the device associated with an appropriate amplifier may be represented as shown in Fig. 5. The output voltage E_2 of the amplifier is supplied to the driving coil of the recorder, thereby driving the stylus with a velocity V. Motion of the stylus in turn generates in a suitable generating element, such as a small coil moving in a magnetic field, the voltage E_3. This voltage is returned to the amplifier input through a control circuit which may be either passive or active. The voltage available after modification in the control circuit is designated E_4.

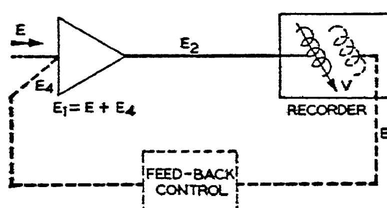

FIG. 5. Schematic Representation of an Electromechanical Feedback System

The voltages and velocities here referred to are to be considered as having both magnitude and phase and hence can be represented in complex number notation. Then

$$E_1 = E + E_4 \tag{1}$$

To obtain a simple expression for the relation of the stylus velocity V to the signal voltage E, let

$$A = \frac{V}{E_1} = \frac{E_2}{E_1}\frac{V}{E_2} \tag{2}$$

and

$$B = \frac{E_4}{V} = \frac{E_3}{V}\frac{E_4}{E_3} \tag{3}$$

and hence

$$AB = \frac{E_4}{E_1} \tag{4}$$

The product AB thus defines the transmission around the loop formed by the amplifier, recorder, and feedback control. The value of E_4 from this equation can now be substituted in the relation $E_1 = E + E_4$ to obtain

$$E_1 = E \frac{1}{1 - AB} \tag{5}$$

which, together with eq. (2), gives

$$V = E_1 A = E \frac{A}{1 - AB} \tag{6}$$

The right-hand side of eq. (6) is the familiar expression for feedback amplifiers in general, and the rules for stability, gain, distortion, etc., are equally applicable. In particular, when AB is very large compared to unity

$$V = \frac{1}{-B} E \qquad (|AB| \gg 1) \tag{7}$$

which indicates that over the frequency range considered the velocity of the stylus is independent of the amplifier gain or the efficiency of the recorder. Variations in B, however, directly affect the performance, and hence, if a flat frequency response is desired, B must remain constant. However, since B is the product of the mechanical-electrical conversion factor E_3/V and the control factor E_4/E_3, it will be seen that these factors may vary as long as their product remains constant. It is a simple matter to maintain the factor E_3/V constant, and hence a flat response characteristic depends only upon keeping the control factor constant.

If eq. (6) is rewritten to include noise and distortion products as well as signal, it becomes

$$V = E \frac{A}{1 - AB} + \frac{n}{1 - AB} + \frac{d}{1 - AB} \tag{8}$$

where n and d are the noise and distortion, respectively, introduced in the amplifier and recorder without feedback. Hence, when AB is large compared to unity, both the noise and the distortion components are reduced as compared with the corresponding effects in a non-feedback system.

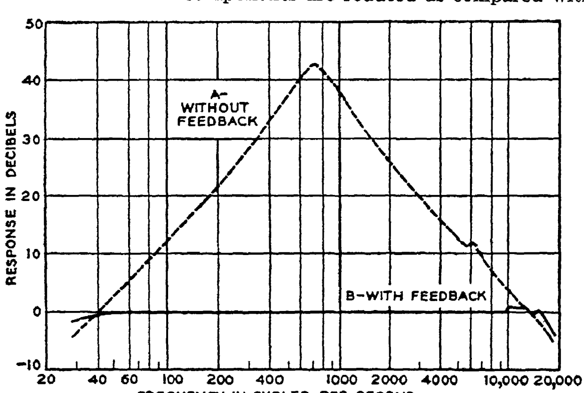

Fig. 6. Curves Showing the Stylus Velocity for a Constant Signal Input to the Recorder Amplifier System. (A) Without feedback; (B) with properly controlled feedback.

Variations in the impedance of the recording medium which act upon the stylus during cutting may be regarded as noise or distortion introduced in the recorder, and their effect upon the vibrational velocity is also reduced by the above factor. This is equivalent to a manifold increase in the driving-point impedance. A frequency response characteristic with and without feedback on a typical feedback-type recorder is shown in Fig. 6. The flat frequency response characteristic shown is, of course, of limited use in disk recording since the large amplitudes at low frequencies are prohibitive. However, since the overall characteristic of the device is flat, pre-equalization can be accomplished flexibly and simply by electrical networks.

24. RECORDING AND REPRODUCING MEDIA

Two broad classifications may be made of mechanical recording media: (a) the "wax" disk intended primarily for subsequent processing and duplication, and (b) the instantaneous media, disk or otherwise, intended mainly for reproduction directly from the embossed or engraved master. The latter are occasionally used for subsequent processing and duplication. "Wax" cylinders are used to some extent in dictating machines as direct playback media.

RECORDING DISKS FOR PROCESSING AND DUPLICATION. The shape of the recording stylus varies somewhat in commercial practice in the cutting of disks for subsequent processing and duplication. In general the cross-section and particularly the curvature of the unmodulated groove are kept within fairly narrow limits. The stylus used on Western Electric recorders has a tip radius of 0.0021 in. ±0.0001 in. Its contour is illustrated in Fig. 7. The disposition of grooves and land between grooves is a matter of compromise between playing time and signal-to-noise ratio and other factors. For lateral recording the groove pitch is usually between 0.007 and 0.010 in. as illustrated by Fig. 7. The maximum safe amplitude at any point on the groove will depend upon the amplitude and phase of the sound recorded on the adjacent grooves. For a groove situated between two unmodulated grooves, the maximum amplitude for the condition pictured in Fig. 7 will be nearly 0.004 in. The maximum amplitude for two adjacent grooves of equal amplitude and 180° out of phase with each other will be slightly less than 0.002 in. The space between grooves may be compressed, in vertically cut recordings, to increase the playing time of a record with less sacrifice in recording level than for lateral recording.

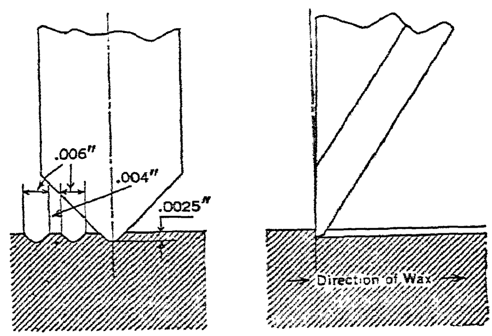

FIG. 7. Western Electric Co. Lateral Recording Stylus

In cutting, the "wax" (more correctly a metallic soap) must be leveled on the recording machine with reasonable care, and the stylus must be sharp and so ground that the cut will be very clean. As it is cut the wax shaving is removed by air suction. The operator is aided in maintaining the correct depth of cut by a so-called advance ball. Commonly an advance ball is a ball-shaped sapphire mounted in an adjustable holder which is in turn fastened to the recorder. The advance ball rides lightly over the wax close to the stylus and serves to maintain uniform depth of cut in spite of small inaccuracies of leveling of the "wax" or deviation from planeness. The advance ball is adjusted relative to the stylus by observing the cut with a calibrated microscope.

In commercial cutting, for processing, both solid and flowed waxes are popular. Solid disks are shaved with a sapphire knife to a highly polished surface on a sturdy high-speed turntable. After recording and processing the disk is reshaved and recut until it becomes too thin to be used with safety. The flowed disk is a thin layer of wax flowed onto a metal surface. The wax layer is cut once and discarded, the metal backing being reused indefinitely. Such a recording medium is extremely smooth, homogeneous, and free from mechanical strains incidental to shaving the "waxes" by the older method.

DUPLICATION OF DISK RECORDS. The surface of the wax, after being engraved, is rendered electrically conducting. This can be done in a number of ways, such as dusting with graphite and bronze or other electrically conducting powders, by the chemical precipitation of silver, or by sputtering a suitable material such as gold or silver in a cathode sputtering chamber.

The wax is then electroplated with copper, sometimes to a thickness of about $^1/_{32}$ in., or sometimes only to a thickness of a few thousandths of an inch and then backed up by a thicker metal plate of suitable material. This electrodeposited plate is then a negative of the wax and is called a "master." From this negative or master, positive copies may be made. In commercial practice the copies or records are usually pressed of some thermoplastic material. If the sound reproduction from a few records carefully pressed from a master is satisfactory, duplicate stampers are produced in order that the master may be preserved. These duplicate stampers are used for pressing or molding the commercial release records.

From the master one or more "mother" plates are made by electrodeposition. These mothers are positives and serve as the forms on which the final matrices or stampers are deposited. One of the important problems in this process is the treating of the metal surfaces of the masters and mothers so as to permit subsequent separation. The problem is to produce a surface which will still be conducting, but which is not "clean"; i.e., the deposited metal must not be in sufficiently intimate contact with the metal of the mold to cause permanent adherence. This may be done by either of two methods: (*a*) by the application of a thin "mechanical" layer of some substance such as grease, graphite, etc., or (*b*) by a chemical film usually produced by treating the previously cleaned metal surface with some chemical that will react with the metal and produce an insoluble compound. Typical substances for the purpose are soluble sulfides such as sodium sulfide (Na_2S) or the yellow "polysulfide" (Na_2S_x). These will react with the metal to form films of the corresponding sulfides. Frequently the phonograph industry has employed a film of silver iodide, formed by first treating the copper surface with a silver cyanide solution. The solution is either poured over the previously cleaned surface or mixed with an inert substance such as whiting or calcium carbonate ($CaCO_3$) to form a paste which is rubbed over the copper. A thin film is thus deposited by immersion. The film is then treated with a weak iodine solution. The iodine solution acts upon the silver to form a thin film of silver iodide upon which the copper can then be deposited and subsequently separated. Numerous other methods are employed in the industry.

Until recently the records themselves were molded of a thermoplastic mixture of shellac and earth fillers and were generally played with steel needles. The fillers were purposely made somewhat abrasive in order to grind the needle point to fit the groove since the needles were not usually accurately shaped to a suitable contour. The pressures at the needle point of a typical needle, before being ground to shape, are extremely high, and record wear under this condition is serious. In more recent years, reproducers of lower mechanical impedance have become available, which require much lower pressures. Accurately contoured permanent reproducing points provide further relief by reducing vibratory mass and maintaining a definite small radius of curvature. Any abrasive in the records adds to the background noise, hence homogeneous, non-abrasive records such as those made of cellulose acetate or vinylite are coming to be used. Such materials are, in fact, used almost universally in transcription recordings for broadcast purposes.

Records of the older shellac mixtures or of some of the more recently developed plastic materials are made in about the same manner, although the time, temperature, and pressure cycles may differ widely. The material to be molded is usually heated to a suitable softening temperature (of the order of 300 deg fahr) either on an auxiliary hot plate or in the record press itself in which the stampers are mounted. The stampers are commonly mounted in the press on platens which are heated and then cooled according to some predetermined cycle. The material may be further heated in the press at a suitable temperature before the pressure of the press is applied upon it. The pressure applied is of the order of 2000 lb per sq in. for many plastic materials. This pressure is maintained while the platens are cooled for a suitable time, after which the press is opened and the record removed.

INSTANTANEOUS PLAYBACK DISKS. This term covers a multitude of plastics and metals which lend themselves to easy engraving or embossing. A few will be discussed. In the higher-quality field of instantaneous recording media the 12 in. and 16 in. lacquer-coated disks of glass or metal are most common. A variety of materials may be compounded with cellulose nitrate to form a lacquer that is easily engraved. These coatings are approximately 0.010 in. thick and cut cleanly with a recording stylus similar to that used for cutting "wax," although it is general practice to somewhat dull the cutting edge to a radius of the order of 0.0003 in. The shaving may be directed toward the center and collected about the center pin of the disk or it may be removed by suction apparatus.

Disks of this kind are sometimes used as masters for subsequent processing and duplication in the same manner as described for wax disks. When the disks are used for instantaneous playback, the elastic properties of the recording material seriously affect the response characteristic. High-frequency losses, particularly at low linear velocities, are very severe and are not too satisfactorily relieved by predistortion in recording. Depending upon the type of reproducer used on these disks, they may be good for from one to fifty playings.

In the general utility field recording disks are most commonly made of vinylite or vinylchloride. Gelatin and soft metals such as aluminum are also used. These materials, in general, are not suitable for engraving, and in most applications an embossing stylus is used which rubs a shallow groove into the recording material, modulating the groove in accordance with the signal impressed on the recorder. The contour of such styli varies widely. Grooves so rubbed are about 0.001 in. deep and the maximum amplitude rarely exceeds 0.001 in. Signal-to-noise ratios are relatively low. These applications are definitely not high quality in their present state of development, emphasis being placed on obtaining good articulation. Useful playing life is uncertain. Extremely light reproducers and soft reproducing styli are required if more than a few playings are anticipated. Disks in general do not exceed 6 or 8 in. in diameter.

RECORDING MEDIA OTHER THAN DISK. Although the recording medium on most general-utility recording machines takes the form of a disc, two exceptions worthy of note are made. The first of these is film on which the recorded grooves are embossed in helical pattern on an endless loop of standard 35-mm safety motion-picture film base

(Amertype Recordgraph). The other exception is the well-known wax cylinder which approximates in its consistency the wax disk used in recordings for processing. Here a helix is cut in the cylinder to be erased for subsequent reuse after playing (Dictaphone and Ediphone).

A unique combination of mechanical recording and optical reproduction is found in the Philipps-Miller system, in which a wide-angle stylus cuts an extremely shallow groove through the darkened emulsion of a photographic film. The thin emulsion is therefore cut away in varying widths so that the transparent body of the film presents a pattern similar to that of variable area sound-on-film recording. Reproduction is accomplished optically in a similar manner to ordinary sound on film.

25. REPRODUCING INSTRUMENTS

The function of the reproducer in a mechanical recording system is to transform into electrical energy the modulations of the recorded disk or duplicate thereof. Since the inception of so-called "electrical recording" in contrast to the older method of acoustical recording, magnetic-type reproducers have played an important part. Such reproducers have taken a variety of forms, but in general an armature is rigidly attached to a stylus holder. The armature, moving in a magnetic field, generates a voltage in associated coils. Typical examples of such structures are illustrated in Figs. 8 and 9. Both these devices and others of the same vintage are lateral-type reproducers and are intended for use with a replaceable steel stylus or needle. To provide sufficient rigidity against flexing, such styli in themselves are quite heavy, and their mass plus that of associated driving elements produces a

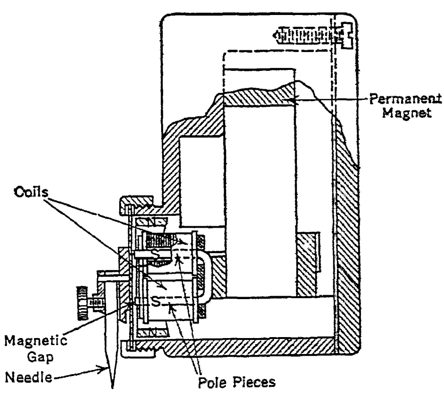

FIG. 8. Early Type Western Electric Co. Oil-damped Lateral Reproducer

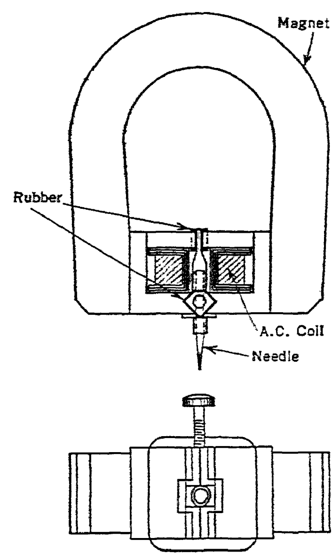

FIG. 9. Early Type RCA Victor Reproducer

high driving-point impedance with corresponding record wear and distortion. In general, the same applies also to the fitted jewel styli used in conventional-type lateral reproducers.

In reproducing vertical recordings the driving force is in direct line with the stylus axis and flexural rigidity is not so important a requirement. The mass of the stylus and associated vibratory system can therefore be kept comparatively small, thus reducing the driving-point impedance so that record wear is greatly reduced. Vertical reproducers in general have been built around the moving-coil principle and invariably are associated with a jeweled (diamond or sapphire) stylus that has been polished to fit the recorded groove accurately.

One of the more common of reproducers is the piezoelectric crystal type, in which a Rochelle salt crystal element is secured to a stylus holder at one end and anchored at the other. Stylus movement causes a flexing of the crystal element, which produces a voltage. In general that type of reproducer is of fairly high driving-point impedance, although some of the higher-quality devices provide a distinct improvement in this respect. Figure 10 shows a cross-section view of the "cartridge" of a typical crystal-type reproducer.

An interesting reproducer which serves to illustrate at once the moving-coil principle

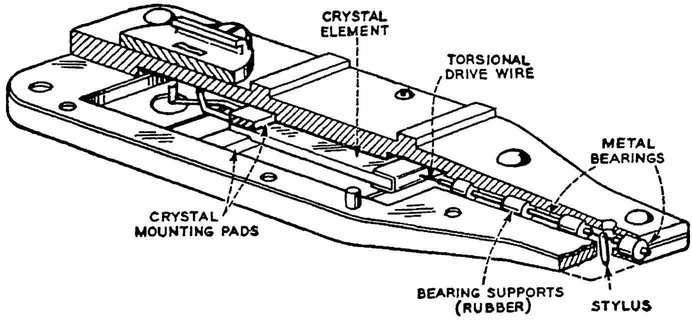

FIG. 10. Brush Development Co. PL-20 Crystal Reproducer

as applied to both vertical- and lateral-type reproducers is the Western Electric 9A reproducer, a phantom view of which is shown in Fig. 11. This is a universal reproducer, that is, one which will reproduce either vertical or lateral recordings by changing the electrical

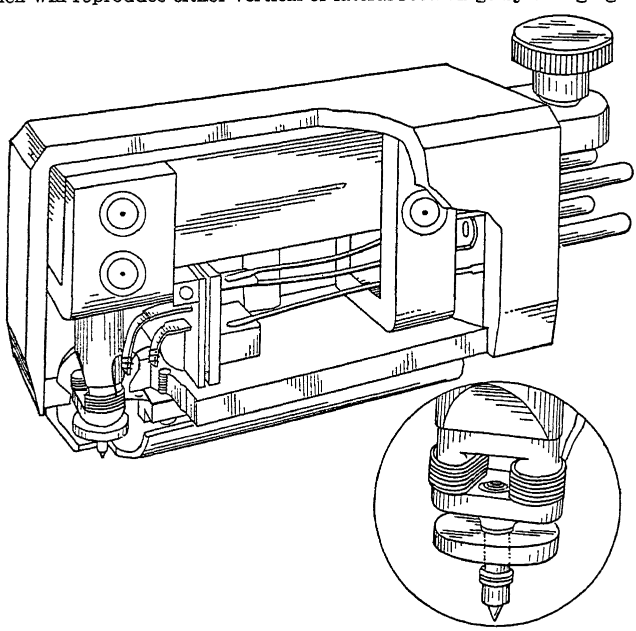

FIG. 11. Western Electric Co. 9A Universal Reproducer

relationship of the two voltage generating coils. Figure 12 shows the response characteristic of this device on both types of recordings.

Jeweled styli have become commonplace in many makes of reproducers. Their contours vary, but in general the radius of the spherical tip is held to between 0.002 and 0.003 in. The larger tip radii, though permissible and even desirable in certain types of lateral reproducers, in general induce serious distortion products.

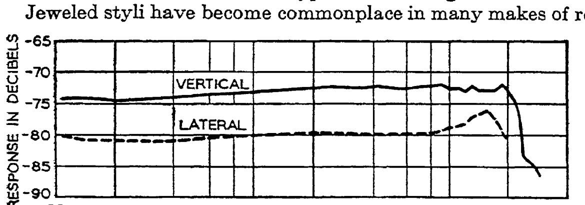

FIG. 12. Response vs. Frequency Characteristic of Typical 9A Reproducer

They do, of course, reduce wear on the record.

26. SOURCES OF DISTORTION

RECORDING. In all recording instruments sources of distortion common to most electromechanical transducers are present. Magnetic elements do not always behave linearly, and mechanical elements are frequently free to respond in modes other than the desired one. In general, however, distortion due to these effects can be minimized by good engineering and design. Recorders intended for use in a variety of recording media do not always meet the same impedance at the cutting point. Not only does this impedance vary from one medium to another; it may vary also with depth of cut in a given medium. It has been customary, therefore, to keep the driving-point impedance sufficiently high so that the recording medium has little or no effect on the recorder characteristics. The maximum force on the stylus in cutting is developed by the reaction of the record material to be cut away. This force is normal to the motion of the stylus, and yielding by the stylus arm in this direction occurs in the neighborhood of the stylus-arm resonance frequency. This motion is introduced on the time axis of the recording, and intermodulation with other frequencies results.

A less important source of distortion which intrudes also on the smoothness of cutting is the design of the stylus. The dimensions of the stylus, like so many other elements in recording systems, are a compromise between many factors, including linear velocity and recording amplitude. In order to provide adequate ruggedness at the tip, a short bevel at a rather blunt angle is provided, as is shown in Fig. 7. The slope of this bevel marks the maximum slope that can be tolerated in vertical recording without having the heel of the stylus abrade the modulated groove. The corresponding critical angle in lateral recording is approximately 45°, which means that the maximum recorded vibratory velocity must never be more than the linear velocity of the record.

PROCESSING AND DUPLICATION. Although electrodeposition is one of the most accurate methods known for duplicating a surface, several sources of distortion present themselves. Plating on the face of copper stampers of abrasion-resistant chromium or other metallic finish has a finite thickness sometimes comparable with the modulations of the grooves. When this process is repeated a number of times, as is common commercial practice, high frequencies are all but obliterated. Stampers are occasionally buffed before or after plating. This, of course, very rapidly erases, in a random manner, much of the higher frequencies.

REPRODUCING. The distortions introduced in recording and processing can be minimized by good design and careful handling. In the interest of commercial expediency these factors are sometimes overlooked. In reproducers, however, there are in the present state of the art several distortion-producing factors which might be characterized as inherent. The first of these, termed "tracing" distortion, is due to the fact that the reproducer stylus has finite size. The curve traced by the center of a spherical-tip stylus in tracing a sinusoidally modulated groove is not sinusoidal. This effect increases rapidly as the minimum radius of curvature of the recorded wave approaches the radius of the stylus tip. Practical considerations prevent relief by the simple expedient of making the stylus radius smaller.

The minimum radius of curvature of a sine-wave groove is given by

$$R = \frac{V^2}{100\pi^2 A f^2} \tag{9}$$

where R = minimum radius of curvature (inches), V = linear speed of groove (feet per minute), A = amplitude (inches), and f = frequency (cycles per second). The linear speed V of a 12-in. record at the standard turntable speed for phonographs, 78.26 rpm, varies between 1.3 and 3.8 ft per sec. At the standard broadcast transcription speed of 33.33 rpm the linear speed of a 16-in. record varies between 1.2 and 2.4 ft per sec. At high frequencies, therefore, for even extremely small amplitudes the radius of curvature of the modulated groove may be comparable with that of the stylus attempting to trace it. Fortunately, the distribution of energy in speech and music spectra is such as to alleviate this situation. However, in the interest of noise reduction and standardization of recording techniques it is an accepted procedure to accentuate high frequencies in recording with corresponding attenuations in reproduction.

In lateral reproduction the problem is further complicated by what has been described as "pinch" effect; i.e., since conventional lateral reproducers have no vertical compliance the stylus "pinches" between the walls of the grooves when the linear velocity drops below a certain point. This phenomenon results from the fact that the cutting surface of the recording stylus is always perpendicular to the unmodulated groove. A constriction therefore results in the width of those portions of a modulated groove which are at an angle to the direction of the unmodulated groove, i.e., at all portions of the modulated grooves except the maxima and minima and points of inflection. Some relief is afforded by providing appropriate vertical compliance in lateral reproducers, and in such reproducers it is advantageous to use an oversize reproducing stylus which never rides on the groove bottom but is always positively driven by the side walls. It has been shown that in this way even harmonics can be eliminated from "tracing" distortion.

Another source of distortion in reproduction is due to "tracking error." Tracking error may be defined as the angle between the vibration axis of the mechanical system and the tangent to the groove being reproduced. This angle results from the conventional device of pivoting the reproducer arm at a fixed point. The aforementioned vibration axis can therefore be truly tangent to the record groove at only one radius. In lateral reproduction when the tracking error is large a sinusoidal wave is not traced sinusoidally. This effect is minimized in lateral reproduction by the well-known device of an offset reproducer head or by making the pivoted reproducer arm very long. Mechanisms which keep the reproducer tangent at all times are employed in a few reproducing devices, eliminating this source of distortion entirely. In vertical reproduction, distortion due to tracking error is negligible.

The characteristics of the medium of which disks are made contribute to the distortion in reproduction. The modulated groove which drives a reproducer stylus has a finite impedance which at some frequencies may be comparable with or less than the stylus-point impedance. With modern high-quality reproducers the compliance of the record material resonates with the vibratory mass of the reproducer, frequently producing a peaked response at some high frequency, above which the response very rapidly declines. The most outstanding examples of the effect of record characteristics on response are found in the instantaneous types of playback disk. The materials of which these disks are made have a high compliance. The losses at high frequencies, particularly at low record velocities, are serious even with the best of commercial reproducers. Compensation for such losses is difficult because the magnitude of the loss varies widely, increasing as the linear velocity decreases.

PHOTOGRAPHIC SOUND RECORDING

By C. R. Keith

The photographic method of sound recording finds its greatest field in sound pictures, the sound record being usually on the same film as the picture or at times on a separate film operating synchronously with the picture film. Film records are particularly adapted to sound pictures since these films are usually made from numerous short "takes" which are edited and then spliced together. The sound and picture are usually photographed on separate films, except for newsreel recording where the sound and picture are commonly taken on the same film. Usually music and sound effects are recorded separately from the dialog; the various sound tracks are then rerecorded in synchronism with the finally cut picture film to make a sound negative which is used for making release prints.

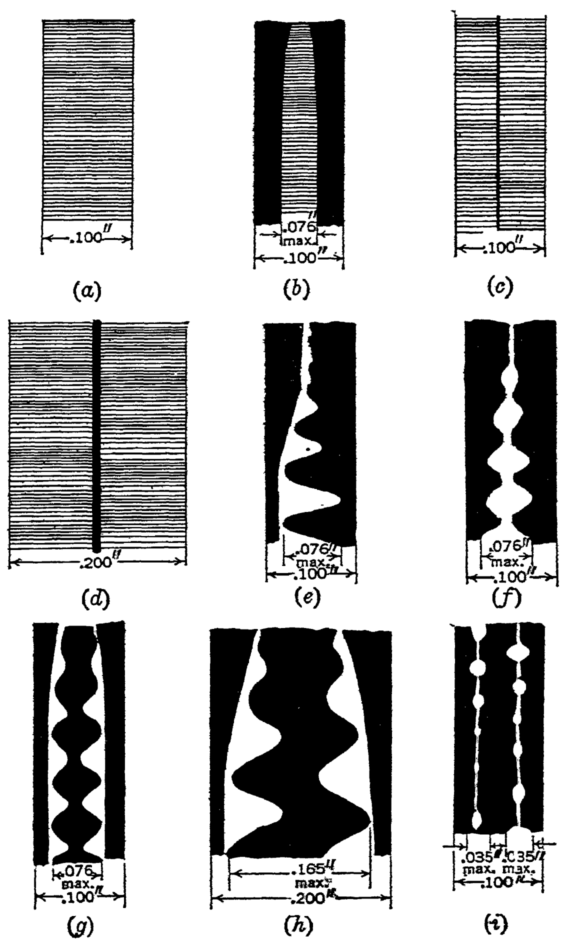

FIG. 1. Types of Sound Tracks

Two types of sound-on-film records are in common use today. One is the variable-density type—a series of striated bands as shown in Fig. 1 (*a*)–(*d*). The other is the variable-area type shown in Fig. 1 (*e*)–(*i*)—a serrated band with its toothlike projections. Both place the record on a narrow strip of the film at one side of the picture as in the sketch of a composite print with a variable-density sound track (Fig. 2). As the sound track must be played at uniform speed while the picture progresses with intermittent motion, it is displaced forward along the film 15 in. from the corresponding picture, so that the momentary difference in film velocity can be taken up by a free loop. Both types of sound track can be reproduced in the same machine without any change in the machine or in the electrical equipment.

The most commonly used sound tracks are illustrated in Fig. 1. Films exhibited in theaters ordinarily have single 100-mil tracks such as (*a*), (*b*), (*e*), (*f*), or (*g*). Original sound records are often made with 100-mil pushpull tracks such as (*c*) or (*i*) or more commonly, when the sound is recorded on a film separate from the picture film, with a 200-mil pushpull track such as (*d*) or (*h*).

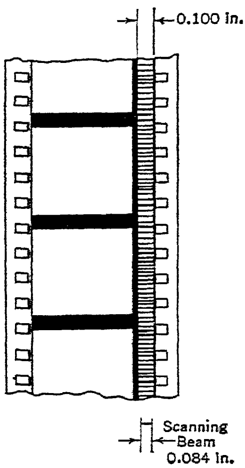

Fig. 2. Position of Sound Track on 35-mm Film

There are many methods of producing such film sound tracks: the light-valve method (Western Electric), the reflecting-galvanometer method (RCA), the flashing-lamp method (Fox-Case), the Kerr cell (Klangfilm), and many variations of these methods. The flashing lamp and the Kerr cell are used only for variable-density tracks, but the light valve and the reflecting galvanometer may be used for either variable-density or variable-area tracks.

27. LIGHT-VALVE RECORDING SYSTEM

In the light-valve system the light from an incandescent source is made to fall on a light valve, Fig. 3, formed of two strips of Duralumin 0.0005 in. thick by 0.006 in. wide spaced 0.001 in. apart. These are placed in a magnetic field and carry the speech currents. Since the two ribbons carry current in opposite directions they move together or apart as the current varies. In commercial practice the ribbons are tuned or resonated to about 9500 cps. The response in the frequency range near resonance depends on the damping, and in early types of light valves the response at resonance was 20 to 25 db higher than at low frequencies. This variation in response can be reduced to 1 or 2 db by using a feedback circuit in which signal voltage across the light-valve ribbons is amplified and applied to the valve input in opposite phase. However, the more recent light valves have sufficiently high flux density (30,000 gausses) so that the resonance peak is only about 6 db. Additional damping is obtained by passive networks in the valve input circuit, so that the resonance peak may be reduced to about 1 db. These measures also almost entirely eliminate extraneous vibrations of the light-valve ribbons when excited by steep transients.

In early types of light valves both ribbons were in the same plane so that it was possible for them to strike each other when caused to vibrate at large amplitudes, thereby increasing the normal overload distortion. This difficulty is avoided in later types by mounting the two ribbons in parallel planes separated by about the thickness of one ribbon. In addition to preventing distortion due to ribbons striking each other, this "biplanar" construction reduces the possibility of damage to ribbons through overmodulation.

When the light-valve ribbons are focused directly on the moving film the exposure at high frequencies does not correspond to the motion of the ribbons if the velocity of either edge of the image is comparable to that of the film. The exposure given to the film is

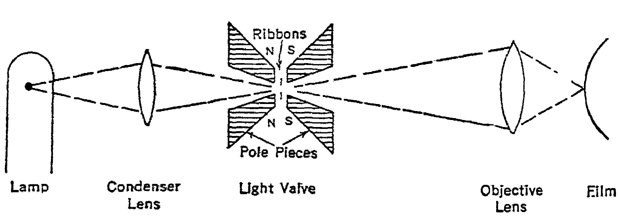

Fig. 3. Optical Schematic of Typical Light-valve Recording System

determined by the time required for any point on the film to pass through the image of the light-valve slit; in other words, the exposure (to a first approximation) is the product of time and intensity. If the frequency being recorded is low, so that the velocity of the ribbons is small compared with that of the film, the variations in film exposure will accurately correspond to the light-valve modulation. As the frequency becomes higher, however, the velocity of the ribbons increases, being substantially proportional to frequency for constant electrical power input to the light valve, until at the highest audio frequencies the ribbon-velocity effect may become important. For a sine-wave signal just sufficient to fully modulate a two-ribbon valve spaced to 0.001 in., the peak ribbon velocity becomes equal to the film velocity at about 6000 cycles. This results in a loss of high-frequency response which also varies with the average ribbon spacing. Consequently, when a high-frequency wave is superposed on a low-frequency wave, the high-frequency response varies during each cycle of the low frequency.

Distortion of this type is not indicated by harmonic measurements since it occurs mainly at frequencies whose harmonics would be greatly attenuated by other elements in the system, such as the width of the reproducing slit. Such distortion can, however, be detected by "intermodulation" tests in which two frequencies are recorded simultaneously (one high and one low) and the variation in high-frequency response measured. In usual practice the amplitude of the low frequency (60 cycles) is four times that of the high frequency (7000 cycles). The reproduced wave is passed through a high-pass filter, eliminating the 60-cycle component. When this wave is rectified a new set of low frequencies (60, 120, 180... cycles) is produced, owing to the presence of distortion frequencies in the high-frequency wave. The average amplitude of this new low-frequency wave is a convenient measure of the distortion. In a suitably designed light-valve modulator the intermodulation distortion may be reduced to 4 per cent or less, corresponding to approximately 1 per cent harmonic distortion as measured in a system in which distortion and transmission do not vary with frequency. This is accomplished by reducing the effective image width to 0.00025 in. or less, usually by means of a short-focus cylindrical lens placed close to the film surface.

NOISE-REDUCTION SYSTEM. A noise-reduction system is commonly used in film recording in order to lower the level of background noise when it is not masked by relatively loud sounds. This system is based on the fact that in a variable-density sound track the background noise output from a light print is greater than that from a dark print when reproduced with the same gain setting of the amplifier. However, when a print is made darker by merely increasing the exposure in the printer, both the ground noise and the wanted sound are reduced in approximately the same ratio so that no improvement in the signal-to-noise ratio results. The desired result is obtained by reducing the average exposure of the negative during periods of low modulation without reducing the amount of light modulated by the signal.

In the Western Electric system of noiseless recording the mean spacing of the light-valve ribbons is made to vary so that as modulation is impressed on the valve the mean spacing increases sufficiently to accommodate the increasing input. The spacing between light-valve strings is mechanically adjusted to 0.001 in., and a source of direct current is connected to the strings sufficient to reduce the spacing to 0.0003 in. (for 10-db noise reduction). In addition to this fixed bias a varying bias proportional to the envelope of the signal wave increases the ribbon spacing as the signal current increases. The lower average exposure of the negative during periods of low signal levels produces a positive with relatively high average density during such periods. The ground noise is thereby reduced when the signal is low, but, since the valve modulation due to the signal is unchanged, the effective signal-to-noise ratio is increased.

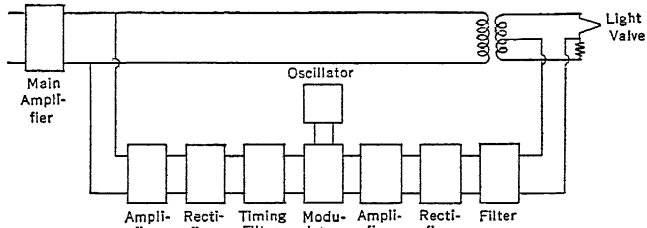

FIG. 4. Block Schematic of Noise-reduction System

A block schematic of a typical noise-reduction circuit is shown in Fig. 4. The timing filter not only serves to remove audible frequencies from the rectified signal but also shapes the bias wave so that, for rapidly fluctuating signals such as speech, the valve spacing increases at about the same rate as the signal increases, but the spacing decreases at a considerably slower rate. The oscillator, modulator, second amplifier, and rectifier merely form a convenient means of amplifying the fixed and variable bias currents.

28. REFLECTING-GALVANOMETER RECORDING SYSTEM

The reflecting-galvanometer method, commonly used for producing variable-area sound tracks, utilizes a recording device that operates on the principle of the mirror oscillograph. Light is reflected from the oscillating mirror of the recorder and is passed through a narrow slit onto the film. The resulting sound track has constant density but variable

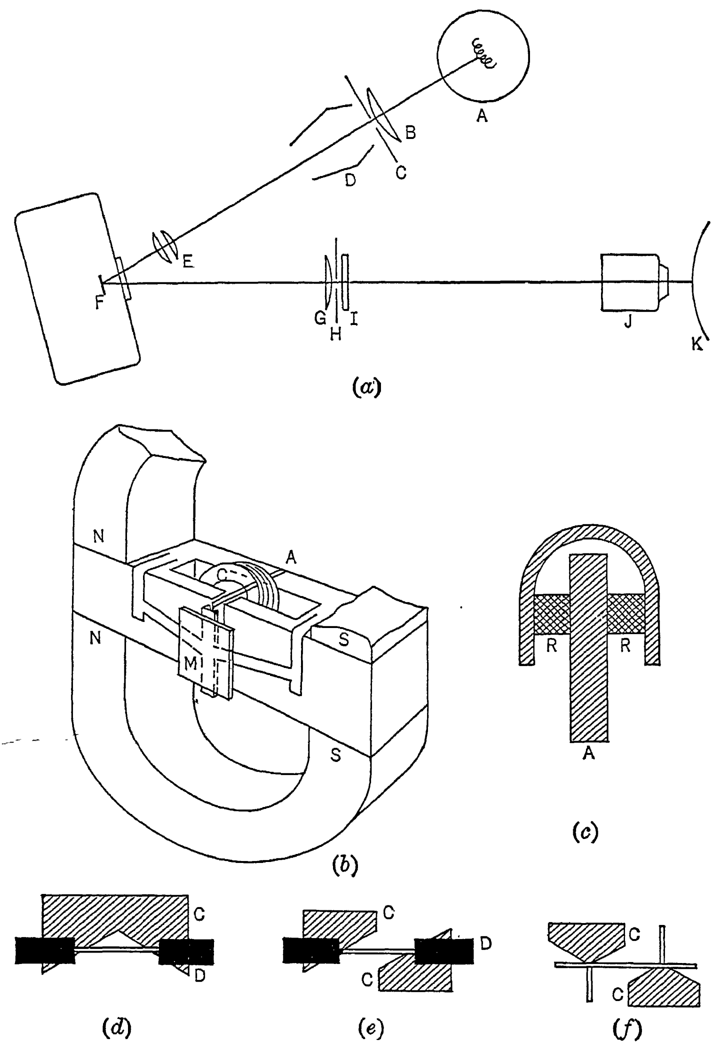

FIG. 5. (a) Optical Schematic of Typical Galvanometer Recording System. (b) Recording Galvanometer. (c) Armature Damping in Recording Galvanometer. (d) (e) (f) Typical Mask and Shutter Arrangements Used in Galvanometer Recording System.

width. A widely used type of light modulator accomplishes this by the use of a triangular beam of light which is caused to move at right angles to the axis of the slit by the recording galvanometer, so that, as it vibrates, the length of the illumined portion of the slit varies.

The RCA variable-width light modulator, Fig. 5(a), consists essentially of an incandescent lamp, a system of lenses to direct the light, an aperture and slit to limit the light, and a reflecting-mirror galvanometer to modulate the light. An image of filament *A* is formed at the galvanometer mirror *F* by the combination of lenses *B* and *E*. The aperture *C*, shown as the shaded area in Fig. 5(*d*), limits the light projected to the galvanometer mirror. Lens *E* forms an image of aperture *C* on slit *H*. Vibration of the galvanometer mirror moves this light beam back and forth across the slit so that the length of the illuminated portion of the slit is proportional to the angular deflection of the mirror. A reduced image of the slit is formed on the film *K* by objective lens *J*.

Ground noise is reduced in this modulator by cutting off the light from the ends of the slit during periods of low modulation. The two magnetically operated shutter vanes *D* are used for this purpose, producing the varying black margins shown, for example, in Fig. 1(*g*). Current for operating the noise-reduction shutters is derived from the signal and is proportional to the envelope of the signal wave. During periods of no modulation the clear area is reduced to a width of about 0.002 in.

Other common accessories in this modulator are a visual monitor system and an ultraviolet filter. The visual monitor is provided by forming an image of one edge of the aperture *C* on a monitor card. Vibration of the galvanometer mirror causes the image to lengthen in proportion to the mirror deflection. By means of suitably spaced lines on the card the operator is enabled to judge when the galvanometer deflection reaches the maximum allowable without exceeding the sound-track width (0.076 in.) that can be scanned by the slit in the reproducing machine. The ultraviolet filter *I* restricts the film exposure to a narrow band of wavelengths in the neighborhood of 3650 A, thereby reducing image spread due to scattering of light in the film emulsion. Recent fine-grain films have also contributed to improvement in image quality.

The recording galvanometer, Fig. 5(*b*), consists of a pair of permanent magnets, pole pieces, balanced armature *A*, signal and bias coils *C*, mirror support, and mirror *M*. A pair of phosphor-bronze springs hold a groove in the ribbon support against a knife edge on the end of the armature. Current through either the signal or biasing coils polarizes the armature, causing it to be attracted to the pole piece of opposite polarity and by its lateral motion rotating the mirror support and mirror.

One of the serious problems in electromechanical apparatus is the provision of suitable damping. Oil damping, although widely used in oscillograph galvanometers, has a number of objections, among which are the change of viscosity with temperature, relatively large mass required for the damping obtained, and difficulty of avoiding leakage. The damping in this galvanometer is obtained by utilizing the properties of tungsten-loaded rubber so mounted that damping is obtained in the frequency range near armature resonance, but without affecting the low-frequency response of the galvanometer. As shown in Fig. 5(*c*), two small pieces of tungsten-loaded rubber *R* are cemented to the sides of the armature *A*, and a bronze yoke presses against their outer faces. At low frequencies the yoke and pads move with the armature, but at high frequencies the inertia of the yoke causes it to tend to stand still while the armature vibrates inside it, compressing the rubber and damping the peak.

Other types of sound tracks can be made with the same modulator by means of masks of other shapes. For example a class *A* pushpull variable-width track may be made with the mask in Fig. 5(*e*). Class B pushpull variable-width tracks may be made with the mask shown in Fig. 5(*f*). Variable-density tracks can also be made by a modification of this modulator in which the uniformly illuminated triangles are replaced by a penumbra designed to give a linear gradation of light intensity. The galvanometer mirror causes this penumbra to move across the fixed slit, varying the light transmitted to the film in proportion to the mirror deflection.

29. FLASHING-LAMP AND KERR CELL RECORDING SYSTEMS

Although not widely used at the present time, the flashing-lamp method of recording has the advantage of extreme simplicity. The gaseous discharge is concentrated in a relatively small area and so designed that the current is proportional to the signal voltage. An early type of flashing lamp, called Aeolight, is a two-element tube containing an inert gas such as helium. One of the elements is of nickel; the other is coated with barium and strontium oxides. When sufficient voltage is applied to the electrodes, ionization takes place and a concentrated glow appears at the cathode. The intensity of the light so produced increases in proportion to the increase in applied voltage. In operation, sufficient polarizing voltage is applied to the tube to give the required average exposure of the negative, and sound voltages are superposed on this polarizing voltage. Since the light output is comparatively low, the lamp is usually arranged for direct illumination of the film rather than by means of the usual lens system. A fixed slit 0.0008 in. by 0.100 in., made by engraving the silvered surface of a small quartz block, is located within less than 0.001 in. of the film. The low light intensity obtained from flashing-lamp light modulators results in a very low value of negative exposure and is in the region known as the "toe" of the *H* and *D* curve. Prints made from these negatives must be printed on the "toe" of the positive *H* and *D* curve in order to minimize distortion. Consequently the permissible modulation ratio is reduced and the volume range is less than for the fully exposed type of record.

Another relatively low-intensity light modulator utilizes the Kerr electro-optical effect. A glass cell containing nitrobenzol is placed between two Nicol prisms, and an electrostatic field is applied to electrodes on either side of the cell. Light from an incandescent lamp is plane polarized by the first Nicol prism, and the second prism is so arranged that, when no polarizing voltage is applied to the cell electrodes, no light is transmitted. Since the plane of polarization of light transmitted through the cell is rotated as the polarizing voltage is increased, the transmitted light also is increased. However, the relation between transmitted light and applied voltage is not linear and introduces appreciable distortion at high modulation.

30. SOUND-ON-FILM REPRODUCING SYSTEMS

In the reproduction of either of the two normal types of single sound tracks, i.e., variable-density or variable-area, the light from an incandescent filament is made to fall on a fixed slit which is imaged on the film as a line of light 0.0012 by 0.084 in. Two common optical systems are shown in Fig. 6. In either, the light passing through the film falls directly on a photoelectric cell or is transmitted to it through a suitable combination of lenses and prisms. Usually the photocell optical system subtends a solid angle of less than 2π radians as measured from a point on the sound track. Light passing through the film emulsion is scattered through a variable solid angle depending on the density (Callier effect), so that at the higher densities a smaller proportion of the transmitted light reaches the photocell. This gives the effect of increased density gradation (gamma) and must be taken into account in processing variable-density sound tracks.

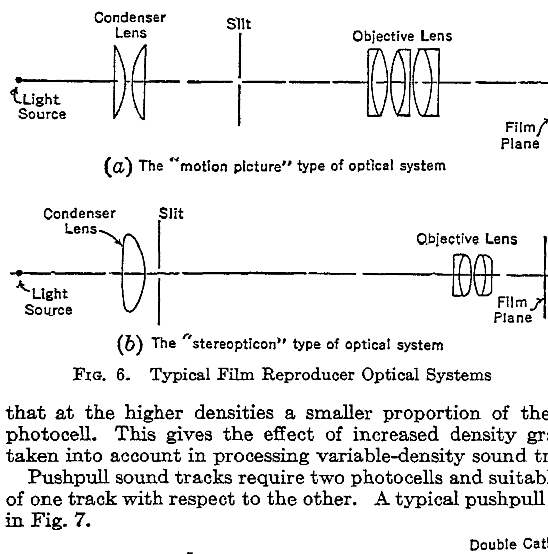

FIG. 6. Typical Film Reproducer Optical Systems

Pushpull sound tracks require two photocells and suitable means for reversing the phase of one track with respect to the other. A typical pushpull reproducer, simplified, is shown in Fig. 7.

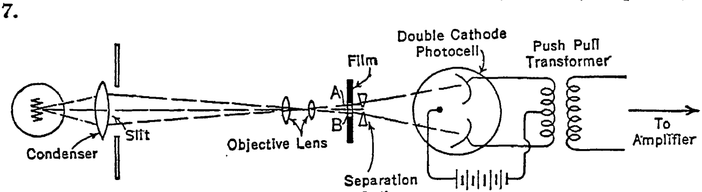

FIG. 7. Push-pull Reproducer Optical System

In the reproduction of photographic sound tracks there are unavoidable losses in output related to the speed with which the sound track is moved, and the dimensions and relative positions of recording and reproducing slits. Both the recording and the reproducing light beams should be exactly perpendicular to the direction of the film motion. Any deviation from this direction is called an error in azimuth and introduces a loss at high frequencies. Another important loss is due to the impossibility of producing on the sound track a line of light which is infinitely narrow. These conditions produce loss of efficiency at higher frequencies and in variable-area tracks may also introduce distortion. Figure 8 shows typical loss curves of these effects plotted from the following equations.

VARIABLE-DENSITY SOUND TRACKS. Effect of image width for zero azimuth:

$$\text{Scanning loss in decibels} = 20\log_{10}\left[\frac{\sin\left(\dfrac{2\pi f\beta}{V}\right)}{\dfrac{2\pi f\beta}{V}}\right] \tag{1}$$

where f = frequency in cycles per second, β = half image width, and V = film velocity.

Effect of azimuth for fixed image width:

$$\text{Scanning loss in decibels} = 20\log_{10}\left[\frac{\sin\left(\dfrac{2\pi f\beta\sec\alpha}{V}\right)}{\dfrac{2\pi f\beta\sec\alpha}{V}}\cdot\frac{\sin\left(\dfrac{2\pi fl\tan\alpha}{V}\right)}{\dfrac{2\pi fl\tan\alpha}{V}}\right] \tag{2}$$

where l = half width of sound track, and α = azimuth deviation angle.

If the azimuth is zero the last equation reduces to the equation preceding it. For very small angles (0° to 6°), which covers the cases of practical interest, $\beta\sec\alpha = l\tan\alpha$. Hence in the azimuth-loss equation the image-width factor becomes equal to the azimuth factor when the azimuth deviation is equal to the effective slit image width; i.e., the scanning loss for a particular azimuth deviation is equal to that of an image width of the same distance along the length of the film.

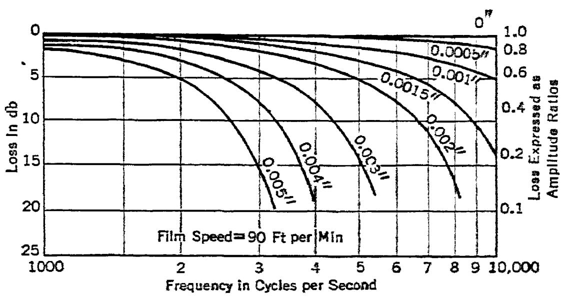

FIG. 8. Loss Due to Finite Slit Width

VARIABLE-AREA SOUND TRACKS. For variable-area sound tracks the calculation of the effect of the aperture on fundamental response and generation of harmonics becomes considerably more complicated and involves a number of assumptions that are not always realized in practice. However, the general effects may be obtained by assuming an ideal record in which the exposed portion has uniform density such as would be realized with an infinitely narrow recording slit and an ideal film emulsion. The effect of finite reproducing-slit width (with no azimuth error) is a reduction in response at high frequencies exactly the same as shown above for variable-density sound tracks. On the other hand, when the same ideal variable-area record is reproduced by means of a finite slit not perpendicular to the direction of motion, the loss in fundamental amplitude for a bilateral track is given by

$$L = \frac{1}{2am}k_1\frac{\sin\epsilon}{\epsilon} \tag{3}$$

and the ratio of second harmonic to fundamental by

$$R = \frac{k_2}{k_1}\cos\epsilon \tag{4}$$

where 2ϵ = width of reproducing image, a = width of unmodulated unbiased track, and m = per cent modulation, and

$$k_1 = 4pJ_1\left(\frac{am}{p}\right)\cdot\cos\left(\frac{a}{p}\right) \tag{4a}$$

$$k_2 = 2pJ_2\left(\frac{2am}{p}\right)\cdot\sin\left(\frac{2a}{p}\right) \tag{4b}$$

and p = cotangent of angle of azimuth deviation; also J_1 and J_2 are Bessel functions of the first and second order respectively.

Third and higher harmonics are also produced by an azimuth deviation of the reproducing slit. Distortion may also be caused by the finite width of the recording slit, but it may be compensated to some extent by choosing a suitable density for the print. The photographic image spread in the positive, then, to a first approximation, compensates for both the finite recording slit width and the negative image spread.

Distortion may also occur in the reproduction of variable-area sound records as the result of uneven illumination along the length of the reproducing slit. Although the amount of such distortion depends on the type of variable-area track and on the type and amount of unevenness of illumination, proper design of the reproducer optical system and a reasonable degree of adjustment should result in harmonics not more than 3 per cent of the fundamental (for full modulation) and in most cases considerably less.

In addition, variable-area records will obviously be distorted if the center line of the record in the reproducer is displaced from the center line of the slit image so that part of the record is not scanned. It is for this reason that 0.076 in. is considered the maximum track width for distortionless reproduction since with a standard 0.084-in. scanning image a tolerance of ±0.004 in. is then allowed for film weave.

PHOTOGRAPHIC REQUIREMENTS. The principal photographic requirement of sound recording is that the variation of light from the average amount transmitted by the film in the reproducer must be proportional to the corresponding variation from the average amount of light transmitted by the recording modulator. This general relation is true for both variable-density and variable-area tracks.

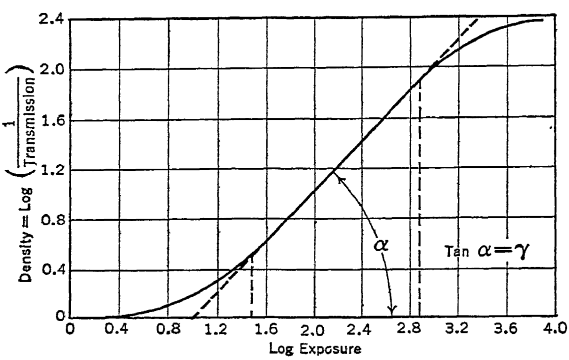

FIG. 9. *H* and *D* Curve

For a variable-density track, the exposure varies from point to point along the length of the track. Figure 9 shows the manner in which exposure and density are related in a typical film emulsion. The exact shape, and particularly the slope of the central portion of the *H* and *D* curve, depend on the development as well as the photographic properties of the film, but most *H* and *D* curves have a portion that is essentially straight when plotted as shown. The slope of the straight portion is called gamma, γ. If, when a negative is printed, a similar curve is drawn relating the exposure of the negative to the density of the positive, the slope of the straight portion of this curve is the overall gamma. It can be shown that for minimum distortion in variable-density recording the overall gamma should be unity. In this computation factors such as the Callier effect (projection factor) and the departure of actual gammas from the values measured by a sensitometer must be taken into account. Since the positive film carries both sound and picture, both images must be given the same development. The positive gamma is chosen to be suitable for the picture and is usually about 2.2. Consequently, the negative of a variable-density sound track is developed to a gamma of about 0.4 when measured on type 2B sensitometer.

Although optimum values of gamma and density for variable-density records can be obtained with a fair degree of accuracy from sensitometric measurements, the simplest and most reliable determination of these constants is made by means of intermodulation tests. Such tests measure the non-linear distortion in a print made from a negative on which two frequencies (usually 60 and 1000 cycles) are simultaneously recorded. Not only is this form of test more sensitive than a measurement of harmonics of a single frequency but also it corresponds more closely to audible distortion in commercial records.

In processing variable-area records the aim is to obtain minimum density in the clear area and maximum density in the exposed area. These are obtained by developing both negative and positive to relatively high gammas, although excessive development may result in fog in the clear area.

Variable-width records are also subject to non-linear distortion if they are not given proper exposure and development. This distortion is frequently due to spreading of the image and produces an effect similar to rectification. Optimum processing is determined by "cross-modulation" tests in which a modulated high frequency is recorded. Distortion is measured by the amount of low frequency produced by the photographic rectification of the modulated high frequency. Distortion may also be caused by non-linearity of the modulator and may be measured by harmonic or intermodulation tests.

PIEZOELECTRIC CRYSTALS

By W. P. Mason

31. DEFINITION OF EFFECTS

A piezoelectric crystal is a crystal which suffers a change in dimension or form proportional to an applied electrical potential, for small applied potentials, and conversely generates a surface charge when subject to stresses. These properties of piezoelectric crystals allow a coupling to be made between an electrical circuit driving a mechanical circuit or with the mechanical properties of the crystals themselves used to create an electric voltage as a result of mechanical motion. When a crystal is used to couple an electrical to a mechanical system it is said to be an electromechanical transducer. An example of such a device is a crystal used as the pickup unit in a phonograph, in which function it transforms the mechanical vibrations of the record into electrical vibrations which are amplified and produce sound vibrations through the loudspeaker. When the mechanical resonances of the crystal itself are used, the crystal is said to be a piezoelectric resonator or a piezoelectric oscillator.

The piezoelectric effect was discovered in 1880 by the brothers Jacques and Pierre Curie. They discovered first the "direct" effect, which is the production of charge on a crystal surface due to the effect of a mechanical force applied to the crystal surface. They also measured the "inverse" effect, which is the change in shape of the crystal due to an applied potential. Voigt (*Lehrbuch der Kristallphysik*, B. Teubner, 1910) later showed that all the linear properties of a crystal under applied stresses, potentials, and temperatures resulted in strains, electrical displacements, and increases in heat energy according to the equations

$$
\begin{aligned}
S_i &= \sum_{j=1}^{6} s_{ij}T_j + \sum_{k=1}^{3} d_{ik}E_k + \alpha_i\,\delta\Theta \quad (i, j = 1, \cdots, 6) \\
\frac{D_l}{4\pi} &= \sum_{l=1}^{3} d_{lj}T_j + \sum_{k=1}^{3} \frac{\epsilon_{kl}}{4\pi} E_k + p_l\,\delta\Theta \quad (k, l = 1, \cdots, 3) \\
\delta Q &= \sum_{j=1}^{6} \Theta\alpha_j T_j + \sum_{k=1}^{3} \Theta p_k E_k + \rho C_p\,\delta\Theta
\end{aligned}
\tag{1}
$$

where $S_i(i = 1 \text{ to } 6)$ are the six strains that can exist in a solid body, $T_j(j = 1 \text{ to } 6)$ are the six stresses in the body, $E_k(k = 1 \text{ to } 3)$ the three potential gradients (ratio of total potential divided by distance over which they are applied) that exist along the three axes, Θ is the absolute temperature in degrees Kelvin and $\delta\Theta$ the increase in temperature, $D_l(l = 1 \text{ to } 3)$ is the electric displacements along the three axes, and δQ is the increment in heat energy due to applied stresses, fields, and temperature increments. (These symbols have now been standardized by the Institute of Radio Engineers.)

The first equation says that any one of the strains, for example S_1, is in general proportional to the six stresses, the three electric fields along the three axes, and the temperature increment $\delta\Theta$. The constants s_{ij} which relate the strains to the applied stresses are the elastic moduli of compliance. Since it can be shown that $s_{ij} = s_{ji}$ there are 21 such constants for the most general crystal, a triclinic crystal. If any elements of symmetry exist in the crystal the number of independent constants is reduced. For example, ammonium dihydrogen phosphate (ADP) has six independent elastic compliances, quartz has seven, and Rochelle salt (sodium potassium tartrate) has nine. The d_{ik} constants are the piezoelectric constants which relate the strains to the applied fields. For the most general crystal there are 18 independent constants, but for more symmetrical crystals the number is reduced. ADP has two independent constants, quartz two, and Rochelle salt three. The α_i constants are the six temperature expansion coefficients which relate the six strains to the applied temperature increase $\delta\Theta$.

The second equation states that the electric displacement is proportional to the applied stresses (the constants of proportionality being again the piezoelectric constants), to the applied fields (the constants of proportionality being the dielectric constants ϵ_{kl}), and to the increase in temperature $\delta\Theta$ (the constant of proportionality being the pyroelectric constants p_l). (The equation as written is valid for the cgs system of units. For the mks system the 4π is removed from D_l and ϵ_k.) Since $1/(4\pi)$ times the normal component of the electric displacement at the surface of the crystal is equal to the surface charge σ, this equation shows the origin of the direct piezoelectric effect (while eq. [1] expresses the inverse effect).

The third equation states that the increment of heat δQ is proportional to the stresses, the fields, and the applied temperature increment. The first effect is called the stress-caloric effect, and the constant of proportionality is the absolute temperature Θ times the temperature expansion coefficients α_j. The second effect is called the electrocaloric effect, and the constant of proportionality is the absolute temperature Θ times the pyroelectric constant p_k. This last is the ratio of the electric displacement to the applied temperature $\delta\Theta$ measured at constant stress and constant field. The last term in the third equation expresses the increase in heat energy due to a temperature increase $\delta\Theta$, and the constant of proportionality is the density ρ times the specific heat at constant stress C_p. In all these equations the constants of proportionality for one variable are measured with the other two variables in the equation held constant. Thus s_{ij}, for example, could be written with two superscripts $s_{ij}^{E,\Theta}$, indicating that in determining the constants the fields E and the temperature Θ are held constant. They are therefore the constant field, isothermal elastic compliances. Similar superscripts can be written for the other terms.

For most piezoelectric applications the vibrations are so rapid that there is no time for an interchange of heat, and adiabatic conditions prevail. This can be taken account of in eq. (1) by setting $\delta Q = 0$. If we do this and eliminate $\delta\Theta$ from the remaining equations we have two equations given by

$$\begin{aligned} S_i &= \sum_{j=1}^{6} s_{ij}^E T_j + \sum_{k=1}^{3} d_{ik} E_k \\ \frac{D_l}{4\pi} &= \sum_{j=1}^{6} d_{lj} T_j + \sum_{k=1}^{3} \frac{\epsilon_{kl}^T}{4\pi} E_k \end{aligned} \tag{2}$$

All these constants are adiabatic, and they are related to the isothermal constants of eq. (1) by the relations

$$s_{ij}^E = s_{ij}^{E,\Theta} - \frac{\alpha_i^E \alpha_j^E}{\rho C_p^E}; \qquad d_{ik} = d_{ik}^\Theta - \frac{\alpha_i p_k^T \Theta}{\rho C_p^E}; \qquad \epsilon_{kl}^T = \epsilon_{kl}^{T,\Theta} - \frac{p_k^T p_l^T \Theta}{\rho C_p^E} \tag{3}$$

where the constants on the left side are understood to be adiabatic. Equations (2) represent all the linear adiabatic relations existing for a piezoelectric crystal, while eqs. (1) give all the isothermal linear relations existing for a piezoelectric crystal. Two second-order effects, the piezo-optical, and the electro-optical, are also of some interest, but they will not be discussed here. They result from a change in the dielectric constant as a function of applied stresses and applied fields respectively.

For ferroelectric crystals such as Rochelle salt the constants in the equations of the form (2) go through very wide variations over a temperature range. It has been found * that, if the electric displacement is used as the dependent variable instead of the field, the resulting constants are nearly independent of temperature. These relations can be obtained from eqs. (2) by solving in terms of D_l and T_j; they are

$$\begin{aligned} S_i &= \sum_{j=1}^{6} s_{ij}^D T_j + \sum_{l=1}^{3} g_{il} \frac{D_l}{4\pi} \\ E_k &= -\sum_{j=1}^{6} g_{kj} T_j + \sum_{l=1}^{3} \beta_{kl}^T D_l \end{aligned} \tag{4}$$

where

$$\beta_{kl}^T = \frac{(-1)^{k+l}\Delta^{k,l}}{\Delta}; \qquad g_{kj} = \beta_{k1} d_{1j} + \beta_{k2} d_{2j} + \beta_{k3} d_{3j}$$

$$s_{ij}^D = s_{ij}^E - [d_{i1}g_{j1} + d_{i2}g_{j2} + d_{i3}g_{j3} + d_{i4}g_{j4} + d_{i5}g_{j5} + d_{i6}g_{j6}]$$

and Δ is the determinant

$$\Delta = \begin{vmatrix} \epsilon_{11} & \epsilon_{12} & \epsilon_{13} \\ \epsilon_{12} & \epsilon_{22} & \epsilon_{23} \\ \epsilon_{13} & \epsilon_{23} & \epsilon_{33} \end{vmatrix}$$

and $\Delta^{k,l}$ is the determinant obtained by suppressing the kth row and lth column.

A ferroelectric crystal is one which shows a spontaneous polarization over a given temperature range. This is due to the movable electric dipoles exerting a mutual reaction and lining up for one direction of the crystal. The effect is similar to the ferromagnetic effect in magnetic substances and is accompanied by similar effects. The polarization vs. potential curves show hysteresis effects and very high dielectric constants. Large piezoelectric effects exist in the ferroelectric range, and Rochelle salt, for example, has a d_{14} piezoelectric constant which may be 1000 times as large as that for a quartz crystal. The limiting temperatures for the ferroelectric regions are called the Curie temperatures. For Rochelle salt these are -18 and $+24$ deg cent. Other ferroelectric crystals are also known, notably potassium dihydrogen phosphate and potassium dihydrogen arsenate (see Busch, "Neue Seignette Elektrica," *Helv. Phys. Acta*, II No. 3 [1938]), but their Curie temperatures are very low, namely, -151 and -182 deg cent. Rochelle salt was the first crystal discovered that had its ferroelectric region in the room-temperature range. This fact accounts for its wide use in acoustic devices in spite of its poor mechanical and

* See W. P. Mason, A Dynamic Measurement of the Elastic, Electric, and Piezoelectric Constants of Rochelle Salt, *Phys. Rev.*, Vol. 55, 775 (1939), and H. Mueller, Properties of Rochelle Salt, *Phys. Rev.*, 57, 829 (1940).

chemical properties. Another ferroelectric crystal, barium titanate, has recently been discovered which has a large electrostrictive effect. This crystal in ceramic form may be an important electromechanical transducing element (Mason, "Electrostrictive Effect in Barium Titanate Ceramics," *Phys. Rev.*, Vol. 74, No. 9, pp. 1134–1148, Nov. 1, 1948).

32. APPLICATION OF PIEZOELECTRIC CRYSTALS

The piezoelectric effect remained a scientific curiosity from the time of its discovery until the time of World War I, 1914–1918. During that time Professor Langevin in Paris devised an underwater sound-locating device using quartz crystals to convert alternating electrical energy into sound vibrations in water. The sound beam was sent out into the water and was reflected back from an object or the bottom of the ocean. This reflection impinged on the crystal transducer and generated an electrical voltage which could be detected by vacuum-tube devices. This use was a forerunner of the fathometers and underwater sound-locating devices that have been widely used by the Navy. Although quartz was originally used for this purpose it has been displaced by Rochelle salt and particularly a new crystal developed during World War II, the ammonium dihydrogen phosphate or ADP crystal. This crystal has so many mechanical, chemical, power-handling capacity, and temperature advantages over Rochelle salt that it appears likely to replace all other transducing elements for underwater sound applications.

In 1922 it was shown by Professor Cady of Wesleyan University that very stable oscillators could be obtained by using quartz crystals as the frequency-controlling element. These have been applied to controlling the frequency of broadcasting stations and radio transmitters in general. Quartz crystals using some one of the low-temperature-coefficient crystals described in article 33 produce the most stable oscillators and the best time-keeping systems that can be obtained. The use of crystals to stabilize oscillators was so prevalent during World War II that over 30,000,000 crystals were produced in a single year for this purpose.

Another application of piezoelectric crystals is in producing very selective filters. On account of the very high Q existing in crystals they can practically eliminate the effect of dissipation in filter structures. Such filters have been widely applied in the long-distance telephone lines and in single-sideband transatlantic radio telephone systems. Narrow-band crystal filters have been used in picking off single frequencies and narrow bands of frequencies for control and analyzing purposes. For this application quartz crystals have been mostly used. However, it appears that the requirements are lenient enough to allow some of the synthetic crystals to be employed.

Besides producing and detecting sound in liquids, crystals have been used to produce and detect vibrations in gases and solids. On account of their high mechanical and electrical impedances crystals are at somewhat of a disadvantage in coupling to low-mechanical-impedance air waves. By using bimorph types of units which employ bending or flexural vibrations the mechanical impedances of crystals can be lowered. For sound pickup devices the high electrical impedance is not a disadvantage, for they can be worked directly into the grid of a vacuum tube which inherently is a high impedance. Hence large numbers of crystals have found uses in microphones. For this purpose Rochelle salt is common, but the constants of ADP are favorable enough so that they may displace it.

Crystals have also been used in receivers, relays, oscillographs, and other devices for which displacements are required for a given applied voltage. For this purpose, crystals having large d piezoelectric constants are required, and Rochelle salt is universally used. On account of the large variation of d with temperature such devices are not very stable and reproducible and hence are unsuitable for high-quality equipment.

Crystals have also been employed in producing very high-frequency vibrations in gases, liquids, and solids. For this purpose quartz is the almost universal choice since it can be ground very thin and can be used to produce high frequencies. X-cut quartz is utilized to set up longitudinal vibrations and Y-cut quartz to produce shear vibrations. Such high-frequency sound waves are applicable for testing steel castings and other solid materials for flaws (Firestone, The Supersonic Reflectoscope, *J. A.S.A.*, Vol. 17, No. 3 [January 1946]). They have also been utilized to study the properties of liquids, gases, and solids and the way in which they vary with frequency.

33. PROPERTIES OF QUARTZ

There are at least 500 crystalline substances that have been tested and found to be piezoelectric, and it is to be presumed that among the many thousands of compounds that will form into crystals in the 20 out of the 32 crystallographic classes that may be piezoelectric most of them will show some piezoelectric activity. However, only three crystals have received wide application in practical devices: quartz, Rochelle salt, and ammonium dihydrogen phosphate (ADP). A fourth crystal, tourmaline, has received a limited application in sound-measuring devices because it is sensitive to hydrostatic pressures. It is to be expected, however, that, with several large laboratories actively engaged in investigating new piezoelectric materials, many more crystals will eventually find practical application.

It is the purpose of the following sections to discuss the properties and useful cuts of quartz, Rochelle salt, and ADP.

PHYSICAL PROPERTIES OF QUARTZ. Quartz is described by the chemist as silicon dioxide, SiO_2, and it crystallizes in the trigonal trapezohedral class. The Z or optic axis is an axis of threefold symmetry; i.e., if one measures any property of the crystal at a definite position in the crystal, this property will be repeated at angles of $\pm 120°$ rotation about the Z axis. The melting point of quartz is 1750 deg cent, the density 2.65, and the hardness is 7 on Mohs' scale. Under atmospheric pressure, α or low-temperature quartz transforms into β or high-temperature quartz at 573 deg cent. Under stress this transformation temperature is lowered. Alpha quartz is insoluble in ordinary acids but is decomposed in hydrofluoric acid and in hot alkalies. Quartz is soluble to some extent in water at high pressures and temperatures. In an enclosed system, crystalline quartz will dissolve in water to the extent of 3 grams per liter at 350 deg cent. Powdered fused quartz, which has a larger surface-to-volume ratio, will dissolve to a considerably larger extent.

Quartz is found principally in Brazil in several different types of deposits (see Stoiber, Tolman, and Butler, Geology of Quartz Crystal Deposits, *Am. Mineralogist*, Vol. 30, 245–268 [1945]). The preponderance of the crystals found is in the lower-weight class as shown by the table. Most of the clear quartz has recognizable natural faces, but some, particularly river quartz, has no natural faces.

Crystal Weight Groups weight in grams	Percentage of the Total Number of Crystals Which Were in Each Weight Group
200– 300	55.5
300– 500	29.5
500– 700	10.4
700– 1,000	2.1
1,000– 2,000	1.8
2,000– 3,000	0.5
3,000– 4,000	0.2
4,000– 5,000	<0.1
5,000– 7,000	<0.1
7,000–10,000	<0.1

Quartz occurs in optical right-hand and left-hand forms; i.e., the crystal will rotate the plane of polarization of polarized light passing along the Z or optic axis counterclockwise (left handed) or clockwise (right handed) from the point of view of the observer facing the source of light. Most crystals have sections with both handedness. In general, the middle section is likely to be all of one hand while the outside sections may have parts of each handedness. A conoscope may be used to locate the optic axis and will also show the handedness and position of any optical twinning. The principle of the conoscope is shown by Fig. 1. Light from the source is sent through a polarizer and through the converging lens L_1. This lens sends converging or conical beams through the crystal which are gathered by the second lens, focused, and sent through the analyzer. In practice the lenses and crystal are immersed in a liquid having the same index of refraction as the crystal along its optic axis. Such liquids may be mixtures of Decalin and Dowtherm or dimethyl phthalate and α monochlor naphthalene. The crystal breaks up all rays not parallel to the optic axes into two components which travel with different velocities. Hence the analyzer is not able to extinguish the light that has traversed the crystal except at angles for which the two rays are in opposite phase. Hence one sees a series of rings in the conoscope when the direction of the Z axis is along the line between the source and the eye. Owing to the rotation of the plane of polarization in the crystal one finds that the rings either expand or contract for a right- or left-handed crystal respectively for a clockwise rotation of the analyzer. This gives a method of determining the handedness of the crystal. Optical twinning also shows up in a viewing system of this type, for it deforms the ring pattern. If plane rays rather than conical rays are used, and a source of white light, color effects also show up the position of the optical twinning.

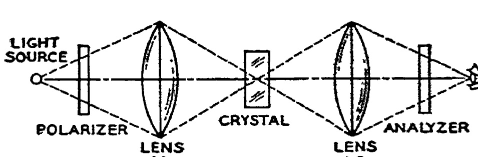

FIG. 1. Principle of Conoscope

The Dauphine or electrical type of twinning also exists in quartz. It results from a 180° change in the direction of the crystal atomic arrangements. As shown by Fig. 2, the silicon atoms normal to the Z axis are arranged in near hexagons all pointing in one direction. If the temperature is raised above 573 deg cent a change in the arrangement to the hexagonal pattern shown in the middle occurs. The result is high-temperature or β quartz. As the temperature is decreased below 573 deg, the crystal may return to the form at the bottom, or part of it may return to this form and part to the form in which the near hexagons point in the opposite direction. If both forms exist the crystal is said to have electrical twinning. The best method of detecting electrical twinning is by etching the surface with hydrofluoric acid, which eats away the crystal at rates depending on the orientation of the crystal surface. Since the two twinned areas will develop etch pits that point in opposite directions, grazing light will cause one part to reflect brightly while the other reflects diffusely, and hence one can see the parts that have different regions of electrical twinning. Since the piezoelectric effect is opposite for the two twinned areas, it is necessary that there be only one region in a useful crystal. Electrical twinning usually occurs in an untwinned plate if it is taken above the inversion point. It may also occur at lower temperatures if stress is applied. Such twinning has been observed when a hot soldering iron is pressed against a crystal, or it may even occur when the crystal is sawed. Wooster (*Nature*, Vol. 157, No. 3987 [March 30, 1946]) has found that the electrical twinning can be removed by exerting a twist around the Z or Z' axis and heating the crystal nearly to the inversion point.

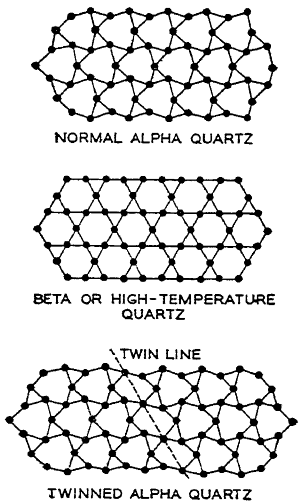

FIG. 2. Arrangement of Silicon Atoms in Quartz Normal to Z Axis

Other defects in quartz crystals are (1) "bubbles": bubble-like cavities which may be fine or large; (2) veils, heavy or fine, which are more or less continuous sheets of small bubble-like cavities; (3) clouds or haze: aggregates of fine bubble-like cavities; (4) ghosts or phantoms: outlines of earlier growths within the crystal, usually marking what were once edges of adjoining faces which become visible when a beam of light is reflected from the minute fractures or parting planes that outline them; (5) fractures. All these defects can be observed by shining a strong light through the crystal at right angles to the direction of observation. The crystal is usually immersed in an inspection tank which is filled with a liquid having the same index of refraction as the crystal. Opinions differ on how many inclusions or bubbles of a small size can be tolerated in the finished crystal.

All the inspection and orienting instruments as well as the methods of sawing and preparing the crystals are completely described in R. A. Heising, *Quartz Crystals for Electrical Circuits*, Van Nostrand, 1946, and in the May–June 1945 issue of the *American Mineralogist.*

USEFUL CRYSTAL ORIENTATIONS. The modes of motion and the properties of these modes depend markedly on how crystal plates are oriented with respect to the natural crystal faces. Figure 3 shows a natural quartz crystal, the three crystallographic axes, and some of the more important special cuts that have found use in the radio and telephone art. The Z or optic axis of the crystal is along the long direction of the crystal; the X axis lies through one of the apexes of the hexagon; and the Y axis is normal to the other two in a right-handed system. The piezoelectric, elastic, and dielectric equations of quartz take the form

$$
\begin{aligned}
S_1 &= s_{11}{}^E T_1 + s_{12}{}^E T_2 + s_{13} T_3 + s_{14}{}^E T_4 + d_{11} E_x \\
S_2 &= s_{12}{}^E T_1 + s_{11}{}^E T_2 + s_{13} T_3 + s_{14}{}^E T_4 + d_{11} E_x \\
S_3 &= s_{13} T_1 + s_{13} T_2 + s_{33} T_3 \\
S_4 &= s_{14}{}^E T_1 - s_{14}{}^E T_2 + s_{44}{}^E T_4 + d_{14} E_x \\
S_5 &= s_{44}{}^E T_5 + 2 s_{14}{}^E T_6 - d_{14} E_y \\
S_6 &= 2 s_{14}{}^E T_5 + 2(s_{11}{}^E - s_{12}{}^E) T_6 - 2 d_{11} E_y \\
\sigma_x &= \frac{D_x}{4\pi} = d_{11} T_1 - d_{11} T_2 + d_{14} T_4 + \frac{\epsilon_1{}^T}{4\pi} E_x \\
\sigma_y &= \frac{D_y}{4\pi} = -d_{14} T_5 - 2 d_{11} T_6 + \frac{\epsilon_1{}^T}{4\pi} E_y \\
\sigma_z &= \frac{D_z}{4\pi} = \frac{\epsilon_3}{4\pi} E_z
\end{aligned}
\qquad (5)
$$

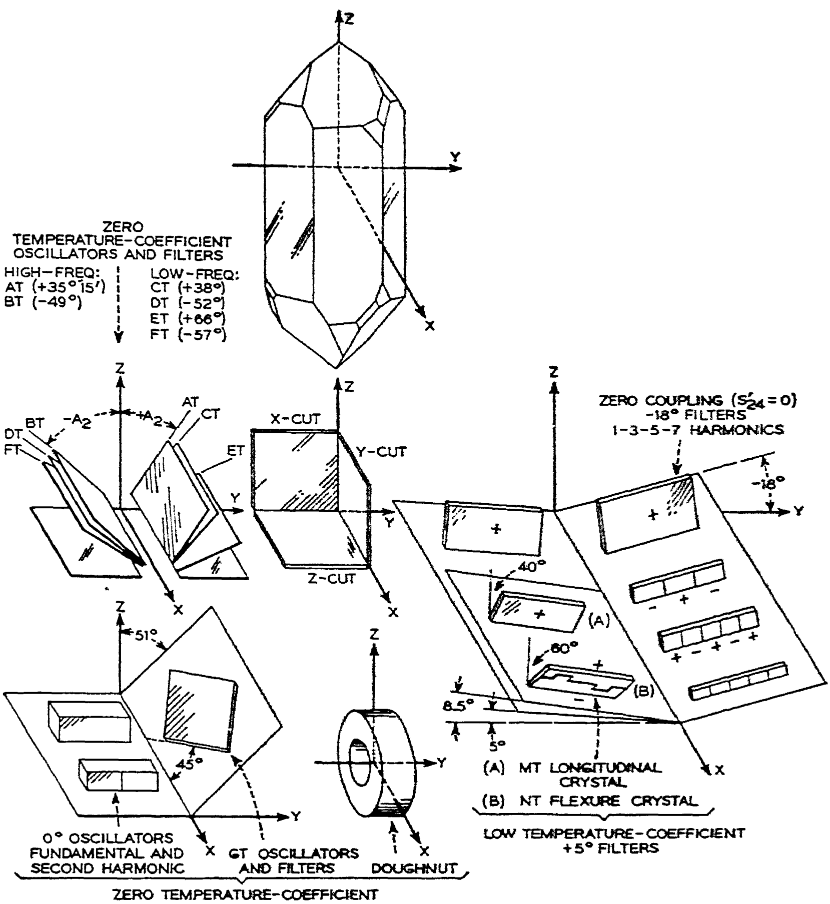

FIG. 3. Principal Cuts of Quartz

where S_1, S_2, S_3 are the three elongation strains along the X, Y, and Z axes respectively; S_4, S_5, and S_6, the three shearing strains; T_1, T_2, T_3, the three tensional stresses; T_4, T_5, and T_6, the three shearing stresses; E_x, E_y, E_z, the three fields; D_x, D_y, D_z, the three electrical displacements which at the outer surfaces are equal to the surface charge $4\pi\sigma_x$, $4\pi\sigma_y$, and $4\pi\sigma_z$. In cgs units the elastic, piezoelectric, and dielectric constants have the values (see Mason, "Quartz Crystal Applications," *B.S.T.J.*, Vol. XXII, No. 2 [July 1943]):

$$
\begin{aligned}
s_{11}^E &= 127.9 \times 10^{-14} \times \text{cm}^2/\text{dyne} \\
s_{12}^E &= -15.35 \\
s_{13}^E &= -11.0 \\
s_{14}^E &= -44.6 \\
s_{33} &= 95.6 \\
s_{44}^E &= 197.8 \\
s_{66}^E &= 2(s_{11}^E - s_{12}^E) = 286.5 \times 10^{-14}
\end{aligned}
\qquad (6)
$$

$$d_{11} = -6.76 \times 10^{-8}\,\text{statcoulomb/dyne} \qquad \epsilon_1^T = 4.58\,\frac{4\pi\ \text{statcoulomb}}{\text{statvolt}}$$

$$d_{14} = 2.56 \times 10^{-8} \qquad \epsilon_3 = 4.70$$

for the mks system the elastic compliances are multiplied by 10, the piezoelectric constants divided by 30,000, and the dielectric constants multiplied by the factor 8.85×10^{-12}.

X-CUT CRYSTALS. These equations are useful in predicting the type of motion that will be generated in a given type of cut and the magnitude of the electromechanical coupling. For example, the first equation of eq. (5) shows that a strain S_1, which is an elongation along the X axis, will be generated by a field applied along the X axis. The applied field will then generate a thickness longitudinal mode since the motion is in the same direction as the applied field. If the thickness is made small this type of crystal can produce a very high frequency, and it was originally used to control oscillators. Because of their poor temperature coefficient, such crystals have largely been replaced in the control of oscillators by *AT* and *BT* thickness shear mode crystals which have much better properties. *X*-cut crystals, however, will produce ultrasonic vibrations in solids, liquids, and gases, and such waves have been used in studying the properties of these materials and also in flaw detectors (see Firestone, *J. A.S.A.* [January 1946]) which determine whether any cracks or irregularities occur in metal castings. For this purpose it is desirable to transform as much input electrical energy as possible into mechanical energy. A measure of the efficiency of this conversion for statically or slowly varying applied fields is the electromechanical coupling factor k, which is defined by the equation

$$k = d_{11}\sqrt{\frac{4\pi c_{11}{}^E}{E_1}} = 0.095 \tag{7}$$

where $c_{11}{}^E$ is the effective elastic constant for a thickness mode. This is equal to

$$c_{11}{}^E = 8.60 \times 10^{11} \quad \text{dynes per cm}^2 \tag{8}$$

Inserting the values given in eq. (7), we find that the coupling is about 9.5 per cent. This means that, for a static field, the square of k or about 1 per cent of the input energy is stored in mechanical form. For alternating fields near the resonance of the crystal a considerably larger part, in fact, nearly all, can be converted into mechanical energy if the shunt capacity is tuned by a coil, but, nevertheless, the coupling is a measure of the width of the frequency range for which this conversion can be done efficiently. If f_B is the highest frequency and f_A the lowest frequency for which the loss is not more than 50 per cent it can be shown that

$$\frac{f_B}{f_A} = \sqrt{\frac{1+k}{1-k}} \tag{9}$$

Some synthetic crystals such as lithium sulfate and *L*-cut Rochelle salt have coupling factors of 0.35 to 0.4 and are to be preferred when it is desired to radiate a wide band of frequencies, but for high frequencies *X*-cut quartz is commonly used on account of its excellent mechanical properties.

The second equation of (5) shows that a strain S_2, which is an elongation along the Y axis, is excited when a field is applied along the X axis. Since the long direction of the crystal is taken along this direction this mode of motion is called a length longitudinal mode. It has been used to some extent to drive low-frequency oscillations in gases, liquids, and solids. Two modifications of this cut have received considerable use in the construction of quartz crystal filters. These cuts are the $-18°$ *X*-cut crystal and the $+5°$ *X*-cut crystal shown by Fig. 3. The $-18°$ cut is used because it produces a very pure frequency spectrum giving only a single resonance over a frequency range of 3 to 1 (see W. P. Mason, Electrical Wave Filters Employing Quartz Crystals as Elements, *B.S.T.J.*, Vol. XIII [July 1934]). The $+5°$ *X*-cut crystal is used because it is the best orientation of the X cuts for giving a low temperature coefficient of frequency. By putting a divided plating on the crystal as shown by Fig. 4 this crystal can be driven in a flexure mode at much lower frequencies than can be realized with a longitudinal mode. It has been used for picking off single-frequency pilot channels for controlling the gain of a carrier system.

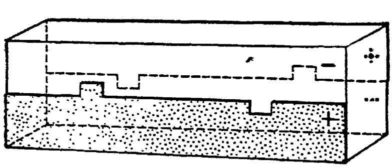

FIG. 4. Plating Arrangement for Driving a Longitudinal Crystal in Flexure

The temperature coefficient of the $+5°$ *X*-cut used for both longitudinal and flexure modes can be improved by rotating the thickness around the length of the crystal. This results in the *MT* and *NT* crystals shown by Fig. 3. These have temperature coefficients under one part in a million per degree centigrade but a smaller coupling than the equivalent $+5°$ *X*-cut crystals. (See Mason and Sykes, Low Frequency Quartz Crystal Cuts Having Low Temperature Coefficients, *Proc. I.R.E.*, Vol. 32, No. 4 [April 1944].)

Y-CUT CRYSTALS. When a field E_y is applied along the Y axis, eq. (5) shows that two types of strain are generated, S_5 and S_6. Both these strains are shearing strains which distort a square in the crystal into a rhombus as shown by Fig. 5. The S_5 strain, shown in Fig. 5, distorts the crystal in the XZ plane; the S_6 strain distorts the crystal in the XY plane. Since the field is applied along the thickness, which is the Y direction, the first strain S_5 is called a face shear strain and S_6 a thickness shear strain. The frequency of a face shear mode is controlled by the contour dimensions and hence will be relatively low. The frequency of the thickness shear mode is controlled by the thickness dimension which can be made very small and hence will result in a high frequency.

The Y-cut crystal was first used in the control of high-frequency oscillators but on account of its high temperature coefficient has largely been displaced by the AT and BT crystals which are modified Y-cut crystals. The Y-cut crystal is still used to generate shear vibrations in solids. For this purpose it has a higher coupling than the X cut, since the coupling for the shear thickness mode is

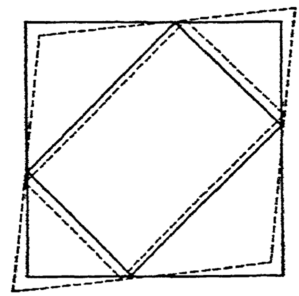

Fig. 5. Method for Obtaining a Longitudinal Vibration from a Shear Crystal

$$k = 2d_{11}\sqrt{\frac{4\pi c_{66}^E}{K_1^T}} = 0.142 \qquad (10)$$

Rotations of the thickness direction around the X axis have resulted in rotated Y cuts that have very favorable properties. Investigations made by Lack, Willard and Fair, Koga, Bechmann, and Straubel have shown how the properties of the thickness shear mode varied with angle of cut. As shown by Fig. 3 all the orientations resulting in useful crystals have their length along the X axis and their thickness makes an angle θ with the Y axis. Figure 6 shows the frequency constant (kilocycles for a crystal 1 mm thick) as a function of the angle of rotation. At an angle of rotation of $+31°$ and $-59°$ the frequency is minimum and maximum respectively. At these two angles, the mechanical coupling between the thickness shear mode, and the face shear mode and overtones, becomes zero and a crystal is obtained which is much freer from extraneous modes of motion than is the Y cut. Figure 7 shows a plot of temperature coefficient against the orientation angle, and at 35° 15′ and −49° crystals are obtained which have zero temperature coefficients. These cuts, known as the AT and BT crystals respectively, have been very widely used to control high-frequency oscillators. Frequencies as high as 10 megacycles are used for fundamental control, and by means of mechanical harmonics frequencies as high as 197 megacycles have been

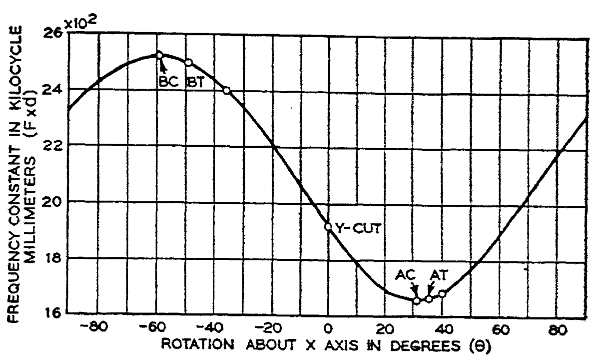

Fig. 6. Frequency Constants for Rotated Y-cut Quartz Crystals

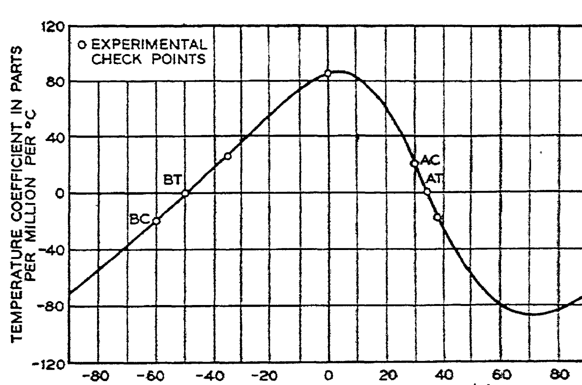

Fig. 7. Temperature Coefficients for Rotated Y-cut Quartz Crystals

obtained. (See Mason and Fair, A New Direct Crystal Controlled Oscillator, *Proc. I.R.E.*, Vol. 30, 464–472 [October 1942].)

Since the *AT* and *BT* are relatively near in angle to the *AC* and *BC* cuts they have a good frequency spectrum. Strong couplings still exist to flexure modes of motion. By measuring the modes of motion as a function of the length, width, and thickness, dimensional ratios can be obtained for which only the main mode exists for a large frequency range on either side of the main frequency. (See Sykes, Modes of Motion in Quartz Crystals, *B.S.T.J.*, Vol. XXIII, No. 1 [January 1944].) By maintaining this ratio fixed as the thickness is changed, a good crystal free from resonances over a wide temperature range is obtained. Crystals produced by the process of grinding to a set of predetermined dimensions are called predimensioned crystals and usually result in a higher-activity crystal and one having a smooth temperature frequency curve over a wide temperature range.

Another manufacturing process called the edge grinding process is sometimes employed. This consists in controlling the thickness dimension only and in removing troublesome couplings by grinding the edges of the crystal until the crystal has a high activity and is free from frequency hops over a temperature range. This process may be quicker for crystals that do not have to satisfy stringent activity and temperature requirements but is not likely to produce as satisfactory crystals as the predimensioning process. Thickness vibrating crystals may either be ground or etched to frequency. On account of an aging which appears to be due to loosely bound and misoriented layers of quartz on the surface caused by sawing and lapping processes, it has become customary to etch crystal surfaces to frequency, since this process removes the loosely bound material and leaves a surface that does not age appreciably. The aging appears to be caused by the attack of water vapor on the strained surface which results in either loosening or removing the strained material. The first process causes a lowering of the *Q* of the crystal (ratio of reactance to resistance) and a consequent lowering of the activity of the oscillator controlled by the crystal; the second process causes an increase in the frequency of the crystal. Aging can be prevented by etching the crystal surface to a depth of several microns or by hermetically sealing the crystal.

Two other methods of adjusting the frequency of crystals have been employed. One (see Sykes, High Frequency Plated Quartz Crystal Units for Control of Communications Equipment, *Proc. I.R.E.*, Vol. 34, No. 2 [February 1946]) etches the crystal frequency above the desired frequency by a predetermined number of kilocycles and then lowers the frequency by plating; by an evaporation process an amount of metal necessary to load the crystal down to its desired frequency is added to the crystal. By this method the frequency can be very accurately controlled in the final mounting. The other method utilizes the recently discovered fact that exposure to X-ray irradiation lowers the elastic constant of *BT* and *AT* crystals and hence lowers their frequency of oscillation (see Frondel, Effect of Radiation on the Elasticity of Quartz, *Am. Mineralogist*, Vol. 30 [May 1945]). The effect is produced by electrons being expelled from orbits around silicon atoms in the quartz and causing a lower energy of binding between molecules and hence a slightly lower elastic constant. This effect amounts to 0.1 per cent frequency change at the most and varies by considerable factors from crystal to crystal, presumably owing to the amount of their impurity content. Exposure to X-rays causes a darkening of the crystal, and the amount of darkening appears to be correlated with the amount of frequency change. On account of the variability of the effect, this process has not had a wide use.

Two other rotated *Y*-cut crystals that can be given zero temperature coefficients are the *CT* and *DT* face shear cuts (see Willard and Hight, *Proc. I.R.E.*, Vol. 25, 549–563 [1937]). These are nearly at right angles to the *AT* and *BT* cuts and use the same shearing moduli in the face shear mode that the *AT* and *BT* do in the thickness shear mode. The *CT* cut at $+38°$ orientation as shown by Fig. 3 has a frequency constant of 308 kc-cm for a square crystal and has been used in frequency-modulated oscillators in the frequency range from 300 to 1000 kc. The *DT* crystal is smaller for the same frequency and is used in the frequency range from 200 to 500 kc. Both these crystals had wide application in frequency-modulated oscillators for tank and artillery radio circuits during World War II.

The final rotated *Y*-cut crystal that has been used considerably for controlling very precise oscillators for time standards and in the Loran navigation system is the *GT* crystal (see Mason, A New Quartz Crystal Plate, Designated the GT, *Proc. I.R.E.*, Vol. 28, 20–223 [May 1940]). This crystal is produced, as shown by Fig. 3, by rotating the plane by $51° 7.5'$ from *Y* and by rotating the length 45° from the *X* axis. Whereas most other zero-temperature-coefficient crystals have a parabolic variation of frequency with temperature about the zero temperature coefficient as shown by Fig. 8, this parabolic variation is absent for the *GT* and a very constant frequency is produced over a wide temperature range. Hence a very moderate temperature control produces a very constant frequency. A crystal mounted by means of several wires soldered to its surface (see Greenidge, Mounting and Fabrication of Plated Quartz Crystal Units, *B.S.T.J.*, Vol. 23, 234 [July 1944])

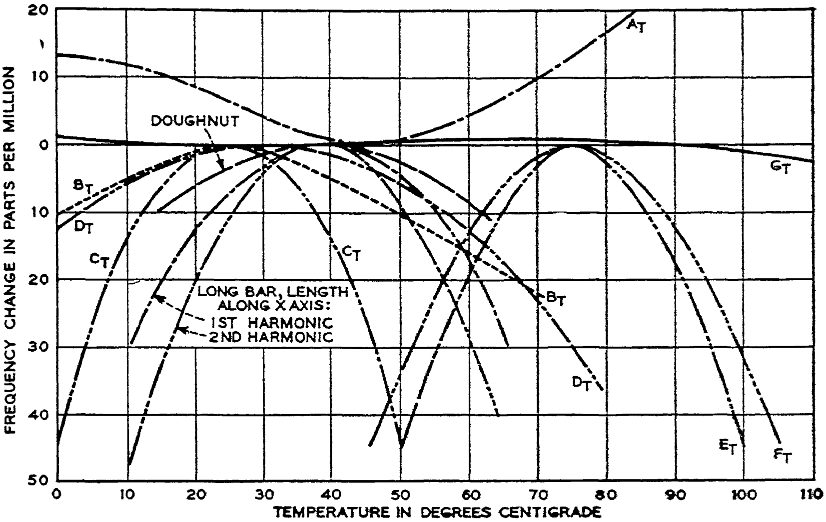

FIG. 8. Temperature Frequency Characteristics for Low-coefficient Quartz Crystals

is very stable, is little affected by shocks, and ages very little over a long period of time. It constitutes an oscillator that maintains its frequency to 1 part in 10^9 or better over long periods of time and has made possible the precise timing necessary in the Loran system and in very stable time standards (see Spencer Jones, *Endeavor*, Vol. 4, No. 16 [October 1945]).

34. PROPERTIES OF ROCHELLE SALT

Rochelle salt is sodium potassium tartrate with four molecules of water of crystallization ($NaKC_4H_4O_6 \cdot 4H_2O$) and forms in the orthorhombic bisphenoidal class. The usual form of the crystal is indicated by Fig. 9(*a*), which shows the directions of the *X*, *Y*, and *Z* axes. Since the crystal has water of crystallization it has a vapor pressure. As shown by Fig. 10, lower line, if the humidity of the surrounding atmosphere is below 35 per cent at 25 deg cent, the water-vapor pressure of the crystal is greater than the vapor pressure of water in the surrounding atmosphere and the crystal will lose water and dehydrate. This causes a white powder of dehydrated material to form on the outside of the crystal which will ruin the operation of the crystal if it becomes too large. The crystal is stable between 35 and 85 per cent relative humidity. Above 85 per cent humidity the crystal will absorb water from the atmosphere on its surface and will slowly dissolve if kept

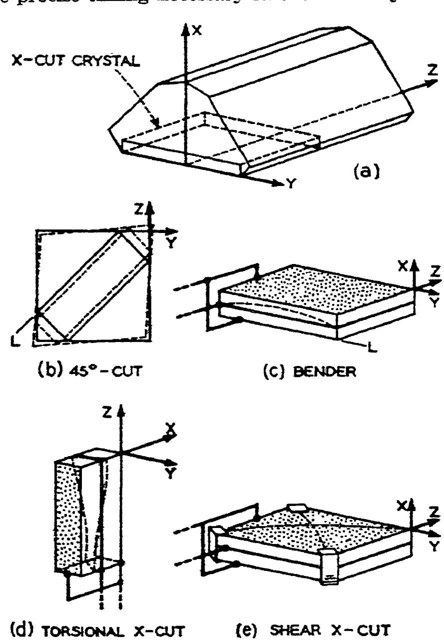

FIG. 9. Methods for Obtaining Longitudinal, Flexural, Torsional, and Plate Shear Vibrations from an X-cut Rochelle Salt Crystal

in such an atmosphere. To minimize these humidity effects the crystals are often coated with waxes, which, however, retard rather than prevent the dehydration of the crystal. If the crystal can be hermetically sealed in a container with powdered crystalline Rochelle salt and dehydrated Rochelle salt, it can be made to last indefinitely. The powdered salt will give up water if the temperature rises and the dehydrated salt will take up water if the temperature lowers, and the two will maintain a humidity that approximates the lower curve as a function of temperature. At a temperature of 55 deg cent (130 deg fahr) the crystal breaks up into sodium tartrate and potassium tartrate with the evolution of one mole of water which dissolves the two crystals in a liquid solution. If this solution is rapidly supercooled it remains quite fluid for a number of minutes before it crystallizes and hardens. This "melted" Rochelle salt forms a very stiff glue that has been used to glue together pieces of Rochelle salt.

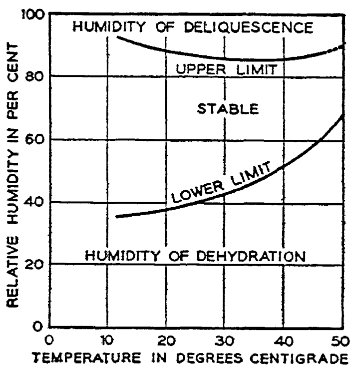

FIG. 10. Limits of Humidity Stability of a Rochelle Salt Crystal

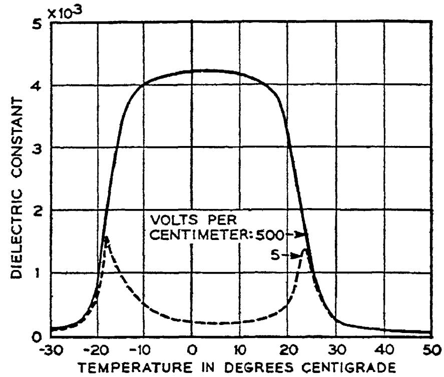

FIG. 11. Free Dielectric Constant of an X-cut Rochelle Salt Crystal as a Function of Temperature and Field Strength

Between the temperatures of -18 and $+24$ deg cent Rochelle salt has ferroelectric properties. By this is meant that it becomes spontaneously polarized in the $\pm x$ direction. A small applied field causes a large change in polarization and one which follows a hysteresis loop as does a ferromagnetic material. Since the piezoelectric strain is proportional to the polarization, a large distortion of the crystal occurs. Hence Rochelle salt is principally used when a large motion is required for a small applied voltage. The displacement, however, shows a hysteresis effect and varies considerably with temperature for a given applied voltage. The piezoelectric equations for Rochelle salt can be written in the form

$$\begin{aligned}
S_1 &= s_{11}T_1 + s_{12}T_2 + s_{13}T_3 & E_1 &= -g_{14}T_4 + \beta_{11}{}^T D_1\\
S_2 &= s_{12}T_1 + s_{22}T_2 + s_{23}T_3 & E_2 &= -g_{25}T_5 + \beta_{22}{}^T D_2\\
S_3 &= s_{13}T_1 + s_{23}T_2 + s_{33}T_3 & E_3 &= -g_{36}T_6 + \beta_{33}{}^T D_3\\
S_4 &= s_{44}{}^D T_4 + g_{14}\frac{D_x}{4\pi}\\
S_5 &= s_{55}{}^D T_5 + g_{25}\frac{D_y}{4\pi}\\
S_6 &= s_{66}{}^D T_6 + g_{36}\frac{D_z}{4\pi}
\end{aligned} \tag{11}$$

where in cgs units the constants have the values

$s_{11} = 5.18 \times 10^{-12}$ cm² per dyne
$s_{22} = 3.49 \times 10^{-12}$
$s_{33} = 3.34 \times 10^{-12}$
$s_{12} = -1.53 \times 10^{-12}$
$s_{13} = -2.11 \times 10^{-12}$
$s_{23} = -1.03 \times 10^{-12}$

$s_{44}{}^D = 7.98 \times 10^{-12}$
$s_{55}{}^D = 32.8 \times 10^{-12}$
$s_{66}{}^D = 10.08 \times 10^{-12}$
$g_{14} = 62 \times 10^{-8}$
$g_{25} = 170 \times 10^{-8}$

$g_{36} = 48 \times 10^{-8}$
$\epsilon_{22}{}^T = \dfrac{1}{\beta_{22}{}^T} = 10.0$
$\epsilon_{33}{}^T = \dfrac{1}{\beta_{33}{}^T} = 10.2$

For the mks system the elastic compliances are multiplied by 10, the piezoelectric constant g is multiplied by 3×10^5, and the dielectric constants are multiplied by 8.85×10^{-12}.

The only constant in the above equations that varies widely with temperature and field strength is the dielectric constant $\epsilon_{11}{}^T$ (the inverse of $\beta_{11}{}^T$). For low field strengths and frequencies above 1 kc, the dielectric constant as a function of temperature is shown by the dotted line of Fig. 11. It rises to very high values at the two Curie temperatures -18 and $+24$ deg cent. For high field strengths the dielectric constant, as shown by the solid line of Fig. 11, measured by the average slope of the hysteresis loop, becomes larger between the Curie points than it is at the Curie temperatures.

USEFUL CUTS IN ROCHELLE SALT. The cut most widely used is the X cut, which as shown by Fig. 9(*b*) is cut with its major face normal to the X axis. If a voltage is applied to this cut it shears so that the square changes into a rhombus. By cutting the crystal length 45° from the crystallographic Y and Z axis, a crystal is obtained which elongates along one direction and contracts along the width. This cut which is known as the 45° X cut is widely used in producing longitudinal vibrations. By combining two longitudinal crystals as shown by Fig. 9(*c*) a "bimorph" crystal is obtained which bends. This has a much lower frequency than a longitudinal crystal and is used in voice-frequency apparatus for picking up and reproducing sound. Figure 9(*d*) shows a combination of two X-cut crystals used to produce a twisting motion. The center faces of the two crystals form one set of electrodes and the two outside electrodes the other pair so that two opposing face shears are applied to the combination. This causes the whole crystal to twist and produces a torsional motion in the pair. Finally Fig. 9(*e*) shows two thin face shear X-cut crystals which, when they are clamped on three corners, produce a large motion at the fourth corner. All three of these bimorph type-crystals have been used in such devices as phonograph pickups, microphones, headphones, loudspeakers, surface-roughness analyzers, and light valves and have many other applications.

For a 45° X-cut crystal the equations applicable for the extension are

$$S_l = s_{22}'^D T_l + g_l \frac{D_x}{4\pi}$$
$$E_x = -g_l T_l + \beta_1{}^T D_x \tag{12}$$

where S_l is the strain along the length, T_l the stress applied along the length, g_l the effective piezoelectric constant for the 45° axis, and β^T the impermeability (inverse of the dielectric constant) which is measured when the crystal is free to move. In cgs units the above constants have the values

$$s_{22}'^D = 3.16 \times 10^{-12} \quad \text{cm}_2 \text{ per dyne}; \qquad g_l = 31 \times 10^{-8} = \frac{g_{14}}{2} \tag{13}$$

while the free dielectric constant, which is the inverse of β^T, has the value shown by Fig. 11 for low applied fields and for high fields (500 volts per centimeter). Equations (12) can be used to predict the action of the crystal under static conditions or at frequencies much lower than the resonant frequencies of the crystal. For example, if we wish to find the response of the crystal as a microphone, the second equation states that, for open-circuit conditions for which the charge on the surface, and hence the electrical displacement D_x, is zero, the potential generated for a given pressure (negative of the tension T_l) is

$$E_x = \frac{E}{l_t} = g_l T_l = 31 \times 10^{-8} \quad \text{(pressure in dynes per cm}^2\text{)} \tag{14}$$

Since the electrostatic unit of potential, the statvolt, is 300 volts, the volts generated per dyne per square centimeter pressure are

$$E_{\text{volts}} = 31 \times 10^{-8} \times 300 \times l_t \times p = 9.10 \times 10^{-5} \quad \text{volt per dyne per sq. cm. for a crystal 1 cm thick} \tag{15}$$

Since the voltage generated for a given pressure is directly proportional to the g_l constant, which is one-half the appropriate shear constant, eqs. (11) shows that a 45° Y-cut crystal, which will have a g_l piezoelectric constant equal to $\frac{1}{2} \times 170 \times 10^{-8} = 85 \times 10^{-8}$, will generate about 3 times the open-circuit voltage for the same pressure that a 45° X-cut crystal will. The 45° Y-cut has been used to some extent as a microphone and as a transducer in underwater sound equipment for transforming electrical into mechanical energy. When the crystal is used as a microphone working into a low impedance, the Y-cut will not deliver as much voltage as an X-cut crystal on account of the very low impedance (high capacity) of the X-cut crystal, but the voltage that it does deliver is not a function of the temperature as is the voltage of the 45° X-cut.

By eliminating D_x from eqs. (12), the strain S_l, which is the expansion per unit length, can be expressed in terms of the applied field as

$$S_l = \left[s_{22}{}^D + \frac{g_l{}^2 K_1{}^{LC}}{4\pi} \right] T_l + \frac{g_l \epsilon_1{}^T}{4\pi} E_x \tag{16}$$

In the absence of an external stress T_l the total free displacement of 1 volt applied is

$$d = S_l l = 1.03 \times 10^{-9} \frac{\epsilon_a^T}{4\pi} E \frac{l}{l_5} \tag{17}$$

This displacement as a function of the volts per inch applied is shown by Fig. 12 for several different temperatures. Outside the Curie region the displacement is much less since the dielectric constant ϵ_a^T is so much smaller, particularly for large fields.

When two crystals are glued together to form a bimorph unit it has been shown (see W. P. Mason, *Electromechanical Transducers and Wave Filters*, p. 214, Van Nostrand) that the displacement of the component longitudinal crystals is multiplied by the factor $3l/l_t$, where l is the length of the crystal and l_t the total thickness of the two elements. This is a method of enhancing the total displacement of the unit at the expense of a considerable lowering of the resonant frequency of the device. Since the dielectric constants of the two crystals glued together will be less than the free dielectric constant of Fig. 11 and will approach the dielectric constant of the clamped crystal shown by Fig. 13, the very

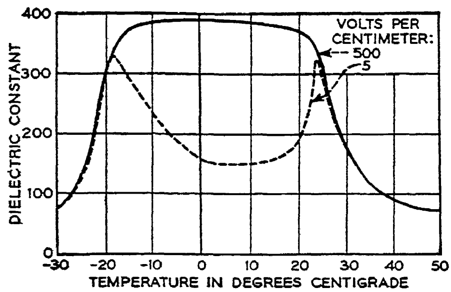

FIG. 12. Clamped Dielectric Constant of an X-cut Rochelle Salt Crystal as a Function of Temperature and Field Strength

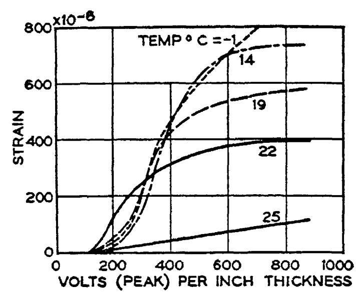

FIG. 13. Strain in Rochelle Salt as a Function of Temperature and Field Strength

large temperature and saturation effects noted for the free crystal will be considerably reduced for the bimorph type. However, the response may vary by a factor of 5 for a wide temperature range. A typical response in the ferroelectric range for a bender unit 1 1/2 in. long, 3/4 in. wide, and 0.040 in. thick is

33 volts	0.002 in.
77 volts	0.0045 in.
125 volts	0.006 in.
140 volts	0.0056 in.

The displacement for any other shape unit will vary in proportion to the factor $(l/l_t)^2$ and will be independent of the width.

When such units are used as voltage generators as in phonograph pickup devices, the mechanical impedance of the device is very considerably lowered over what would be obtained with a clamped longitudinal device. The response can be calculated by determining how much strain is generated by a given motion and calculating the voltage from eqs. (12). A typical unit 0.030 in. thick, 11/16 in. long, and 7/16 in. wide will give an output as high as 1 volt when played from a phonograph record. This response will be relatively independent of the temperature when the device is worked into the grid of a vacuum tube.

35. PROPERTIES OF AMMONIUM DIHYDROGEN PHOSPHATE (ADP)

Ammonium dihydrogen phosphate, which has been given the abbreviation ADP, is one member of four isomorphous salts whose dielectric properties were first investigated by Busch (Neue Seignette Elektrica, *Helv. Phys. Acta*, Vol. 11, No 3 [1938]). Two members of this group, namely, potassium dihydrogen phosphate and potassium dihydrogen arsenate, were found to have ferroelectric effects at 121 and 91 deg absolute temperature. Of these isomorphous crystals ADP was the crystal which had the largest piezoelectric coupling (about 30 per cent), and it was widely used during World War II as the transducing element for underwater sound projectors and hydrophones. It appears likely that, for devices that transform mechanical vibrations into electrical vibrations—phonograph pickups, microphones, etc.—ADP will give superior results to Rochelle salt and may eventually replace it for such applications. For devices that have to produce a large motion for a given voltage, however, Rochelle salt is still the only crystal that has a large enough d_{14} constant to be of interest.

ADP crystallizes in the tetragonal scalenohedral class with the habit shown by Fig. 14. The c or Z axis lies along the long direction of the crystal; this is an axis of fourfold alternating symmetry. The X and Y axes lie normal to the prism faces; they are axes of two-fold symmetry. Since the properties of crystals cut normal to these two surfaces are identical it is a matter of convention which is called X and which Y. The two diagonal axes, labeled P_1 and P_2, can be distinguished by piezoelectric tests, and P_1 has been taken as that axis along which a positive stress (tension) produces a positive charge at the positive (i.e., the upper) end of the Z axis. With the Z axis vertical and the P_1 axis toward the observer's right hand, the X axis has been taken as the axis that runs from front to back of the crystal and the Y axis the one that runs from left to right.

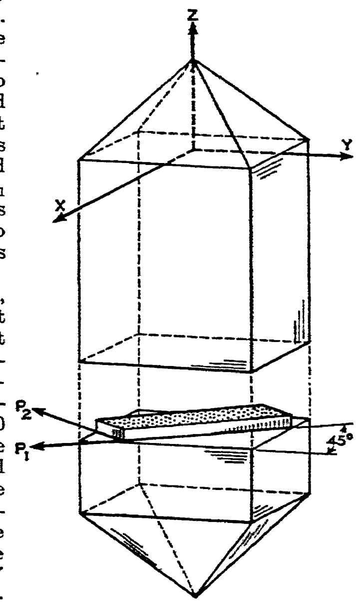

FIG. 14. 45° Z-cut ADP Crystal and Form of Natural Crystal

ADP, which has the chemical formula $NH_4H_2PO_4$, has no water of crystallization and hence will not dehydrate when the humidity becomes low. At about 93 per cent humidity, the crystal will deliquesce and will pick up water from the atmosphere. In practice it is necessary to keep the crystal in an atmosphere for which the humidity is 50 per cent or less since the water collected on the surface provides a leakage path across the crystal edges which becomes low enough to cause trouble for humidities above 50 per cent. Owing to the hydrogen bond system ADP also has a volume leakage which for a pure salt is shown by Fig. 15. For the Z-cut crystal having a dielectric constant of 15.7 this leakage will impair the response only for frequencies below 1 cycle per second. However, certain impurities introduced by the growing process can markedly decrease this resistivity, and for some applications it is necessary to specify a high resistivity. ADP can be taken up to 180 deg cent before it melts. However, ammonia is given off from the surface at temperatures above 100 deg cent, and since this impairs the adherence of the electrodes to the crystal surface it is desirable to keep the temperature of operation under 100 deg cent. The crystal, therefore, is useful under any likely ambient temperature conditions.

The piezoelectric equations for ADP take the form

$$\begin{aligned}
S_1 &= s_{11}T_1 + s_{12}T_2 + s_{13}T_3 & S_6 &= s_{66}{}^D T_6 + g_{36}\frac{D_z}{4\pi} \\
S_2 &= s_{12}T_1 + s_{11}T_2 + s_{13}T_3 & E_x &= \beta_1{}^T D_x - g_{14}T_4 \\
S_3 &= s_{13}T_1 + s_{13}T_2 + s_{33}T_3 & E_y &= \beta_1{}^T D_y - g_{14}T_5 \\
S_4 &= s_{44}{}^D T_4 + g_{14}\frac{D_x}{4\pi} & E_z &= \beta_3{}^T D_z - g_{36}T_6 \\
S_5 &= s_{44}{}^D T_5 + g_{14}\frac{D_y}{4\pi}
\end{aligned} \qquad (18)$$

where in cgs units the constants have the following values:

$$\begin{aligned}
s_{11} &= 1.74 \times 10^{-12} \text{ cm}^2 \text{ per dyne} & s_{44}{}^D &= 11.4 \times 10^{-12} \text{ cm}^2 \text{ per dyne} & \epsilon_1{}^T &= 59.0 \\
s_{12} &= 0.7 \times 10^{-12} & s_{66}{}^D &= 14.7 \times 10^{-12} & \epsilon_3{}^T &= 15.7 \\
s_{13} &= -1.1 \times 10^{-12} & g_{14} &= 1.06 \times 10^{-8} \\
s_{33} &= 4.35 \times 10^{-12} & g_{36} &= 118.5 \times 10^{-8}
\end{aligned} \qquad (19)$$

USEFUL CUTS FOR ADP CRYSTALS. Since the g_{36} constant is so much larger than the g_{14} constant in ADP it is obvious that most of the useful cuts will be those that are normal or nearly normal to the Z axis. A crystal cut normal to the Z axis will generate a face shear motion similar to that shown by Fig. 9(b) for Rochelle salt. Hence by cutting the length 45° from the X and Y crystallographic axes a longitudinal motion may be produced. The Z and the 45° Z cut are the principal ones used for ADP crystals. The Z cut has been used in generating face shearing modes and in the production of torsional crystals.

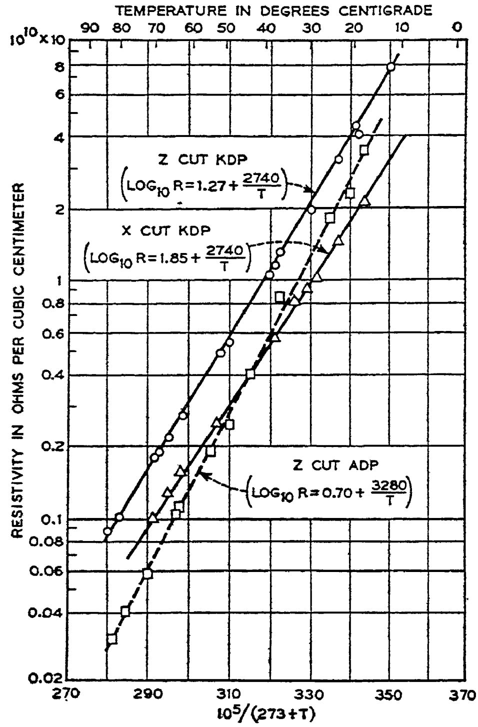

Fig. 15. Resistivity of ADP and KDP as a Function of Temperature

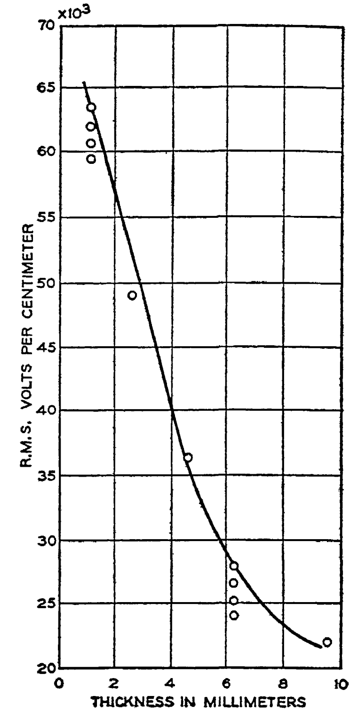

Fig. 16. Breakdown Voltage for an ADP Crystal as a Function of Thickness

The 45° Z-cut crystal has been used as the transducing element in underwater sound equipment and in microphones, in phonograph pickups, and in devices for transforming mechanical energy into electrical energy.

The equations of motion of a 45° Z cut take the form

$$S_l = s_{22}^{D\prime} T_l + g_l \frac{D_z}{4\pi} \qquad (20)$$

$$E_z = -g_l T_l + \beta_3^T D_z$$

where $g_l = g_{36}/2 = 59.2 \times 10^{-8}$; $s_{22}^D = 4.72 \times 10^{-12}$ cm² per dyne;

$$\epsilon_3^T = \frac{1}{\beta_3^T} = 15.7$$

When a crystal 1 cm thick is used as a voltage-generating device the number of volts generated on open circuit per dyne per square centimeter is

$$E_{\text{volts}} = 1.78 \times 10^{-4} \quad \text{volt} \qquad (21)$$

This is larger than for 45° X-cut Rochelle salt. On account of the lower dielectric constant this crystal has to be worked into a higher impedance than Rochelle salt to obtain the same output. Crystals of this sort are replacing Rochelle salt for applications such as microphones and phonograph pickups on account of their greater chemical stability and their ability to withstand wide temperature variations.

The electromechanical coupling factor of ADP is given by the formula

$$k = \frac{g_{36}}{2} \sqrt{\frac{\epsilon_3^T}{4\pi s_{22}'}} = 0.3 \qquad (22)$$

As can be seen from eq. (9) these crystals can convert electrical into mechanical energy, or vice versa, efficiently over a frequency range of

$$\frac{f_B}{f_A} = 1.36 \tag{23}$$

Considerable amounts of power can be transformed from electrical into high mechanical impedance systems. The crystal limitations are the breaking strain and the voltage gradient that the crystals will stand. Experiments with ADP crystals show that they will break if the strain exceeds from 4 to 10 × 10^{-4} cm per cm. The voltage gradient that they will stand before a voltage puncture occurs is a function of the thickness of the crystal. Figure 16 shows the voltage gradient that will produce a puncture on the average crystal. It can be shown that the particle velocity on the end of a quarter-wavelength or half-wavelength crystal is equal to

$$\dot{\xi} = vS_M \quad \text{or} \quad \dot{\xi} = 3.3 \times 10_4 S_M \tag{24}$$

where $\dot{\xi}$ is the particle velocity, v is the velocity of propagation, and S_M is the maximum strain that the crystal will suffer. This maximum strain occurs at the middle of a half-wavelength unit or at the glued joint of a quarter-wavelength unit. Since the crystal is stronger than most of the adhesives that can be used to attach it to high-mechanical-impedance solid materials, the half-wavelength crystal can be used to produce more power output than the quarter-wavelength unit. The two types of units are shown by Fig. 17.

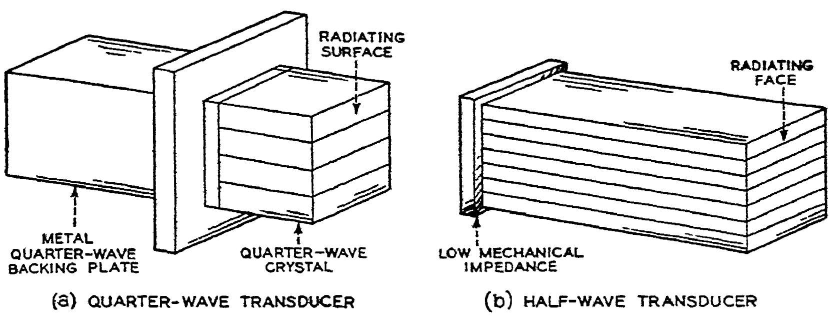

FIG. 17. Quarter- and Half-wave Transducers

The quarter-wavelength unit is glued to a heavy metal backing plate and radiates its energy from its free face. A half-wavelength unit, on the other hand, works into a low mechanical impedance on one end and radiates its energy from the other end. For a half-wavelength unit the maximum strain that the crystal can safely stand is 4 × 10^{-4}, so that the maximum particle velocity obtainable for an ADP crystal is about

$$\dot{\xi}_m = 132 \quad \text{cm per sec} \tag{25}$$

If the particle velocity is working into a high mechanical impedance such as the radiation impedance of water, which is R × 1.5 × 10^5 mechanical ohms per square centimeter, the energy radiated with this particle velocity is

$$E_{(\text{ergs/sec/sq/cm})} = \dot{\xi}_m{}^2 R = 2.6 \times 10^9 \quad \text{ergs per sec per sq cm} \tag{26}$$
$$= 260 \quad \text{watts per sq cm}$$

This power usually exceeds the power allowed by the voltage puncture limit (unless the crystals are made very thin) and this is the usual crystal limitation.

It can be shown that for a half-wavelength ADP crystal radiating into a mechanical load of R_M mechanical ohms per square centimeter (ratio of force in dynes per square centimeter to velocity in centimeters per second) the power radiated in watts per square centimeter is given in terms of the voltage gradient in volts per centimeter and the mechanical load R_M by the equation

$$\text{Power} = \frac{(E/l_t)^2}{24R_M} \quad \text{(half-wavelength radiator)} \tag{27}$$

For a quarter-wavelength unit, the power radiated is one-fourth of this for the same voltage gradient or

$$\text{Power} = \frac{(E/l_t)^2}{96R_M} \tag{28}$$

Hence if we know the limiting voltage gradients, the amount of power that the crystal will radiate before it punctures can be calculated. For example, if a half-wavelength radiator is working into the radiation impedance of water and is made up of crystals 0.25 cm thick, the crystals should withstand a voltage gradient of 50,000 rms volts per centimeter. From eq. (27) the power radiated should be 660 watts per square centimeter before dielectric breakdown occurs. Crystal fracture then becomes the limiting factor. In practice the limitation of power does not lie with the crystal but occurs in the medium if this is liquid or in the glued joint if a solid is used to transmit the power. A usual figure for continuous power is 5 watts per square centimeter. If the crystal is to radiate into a gas such as air, the limiting power is invariably determined by the limiting strain that the crystal can stand before it breaks. From eq. (28) the maximum amount of power that can be radiated into air by an ADP crystal is 0.075 watt per square centimeter since the radiation impedance of air is 43 ohms per square centimeter. A crystal is not an efficient means for exciting an air vibration.

Since the limiting particle velocity for an ADP crystal is about 130 cm per sec, a crystal cannot be used directly to produce very high strains in metals or terminal velocities approaching the speed of sound. If, however, a crystal mosaic is glued to a metal rod tapered exponentially like a horn, a very high strain and a very high terminal velocity can be produced at the small end. Figure 18 shows a construction proposed by the writer for

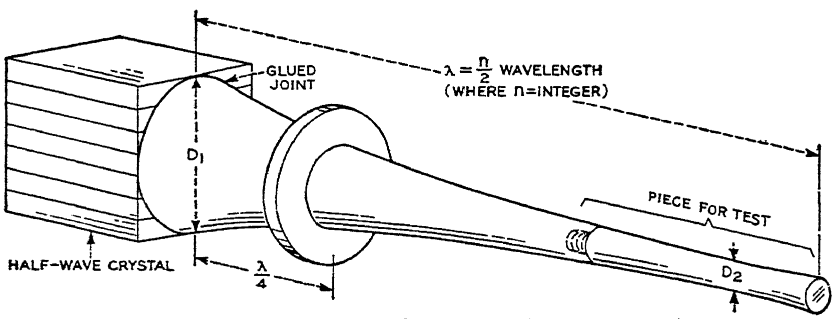

FIG. 18. Mechanical Horn for Producing a Large Strain in a Metal Sample

testing fatigue in metals. A crystal mosaic several inches in cross-section is glued to a steel rod which tapers from the crystal area down to a thickness of 0.05 in., after which it increases in diameter. The taper is an exponential function of the length and must satisfy the relation

$$T \leqq \frac{2\pi f}{v_s} \tag{29}$$

where the taper T is determined by the equation for the area

$$S = S_0 e^{-2Tl} \tag{30}$$

where f is the resonant frequency of the crystal, and v_s the velocity of sound in the steel. If the total length of the steel piece is made an integral number of half wavelengths of the frequency, the glued joint will come at a loop of the motion and will not be appreciably strained. The whole system will act as a resonant system and will produce a considerable motion for small applied voltages. The steel section adjacent to the crystal will have the same particle velocity as the crystal surface. Now it can be shown that the strain in the bar of uniform section at the nodal point (point of maximum strain) is equal to

$$S = \frac{\dot{\xi}}{v_s} \tag{31}$$

where v_s is the velocity of propagation of the wave in the steel and $\dot{\xi}$ the particle velocity at the surface. The effect of the tapered section is to increase the particle velocity in inverse proportion to the diameter. Hence if the diameter decreases from 2 in. to 0.05 in. the velocity is multiplied by a factor of 40 and the strain at the nodal point is equal to

$$S_s = 40 \times \frac{v_c}{v_s} S \tag{32}$$

where S_s is the strain in the steel, S_c the strain in the crystal, v_c the velocity of propagation in the crystal (3.3×10^5 cm per sec), and v_s the velocity of propagation in the steel (about

5.1×10^5 cm per sec). Hence, for a strain of 4×10^{-4} in the crystal, a strain of 0.01 can be generated in the steel. This is sufficient to cause plastic deformation in the steel, and by gradually increasing the drive on the crystal the fatigue properties of the steel can be investigated at a high rate of strain and of velocity.

This same system can be used to produce a high particle velocity on the small end of the steel bar. The only limitation is the strain that the metal will stand. Other uses appear to be delivering a large amount of power for a small area. By mounting a torsional crystal on the large end of the bar a torsional vibration can be given to the bar and the properties of the material under shearing strain can be tested. An ADP crystal can be made to vibrate in torsion by using the electrode system shown by Fig. 19. The inside

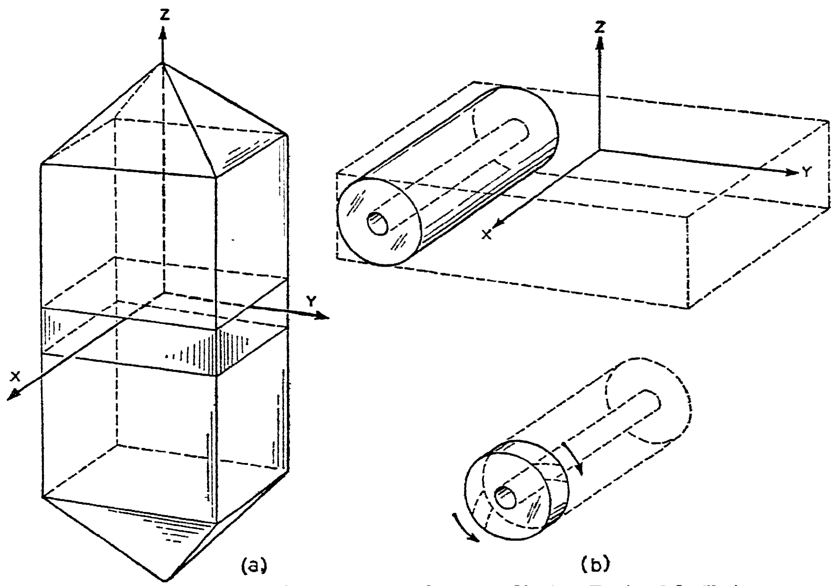

FIG. 19. Method for Cutting an ADP Crystal to Obtain a Torsional Oscillation

surface is covered by one electrode while the two outside electrodes, each of which covers a 90° segment, are connected together and form the other electrode. The centers of the two outside electrodes are normal to the Z axis, and the field is directed out from the center for both electrodes as shown by Fig. 19(b), thus producing a shearing motion for one segment and the opposite shear on the other segment so that the whole crystal is given a torsional motion.

OPTICS

GEOMETRICAL OPTICS

By D. W. Epstein

Geometrical optics is mainly concerned with the geometrical relations of the propagation of radiant energy.

Neglecting quantum effects, the propagation of radiant energy is governed by Maxwell's equations. Fermat's principle of least time, which is the fundamental law governing the propagation of "rays" in geometrical optics, follows from Maxwell's equations if the wavelength of the radiation is allowed to approach zero. Although geometrical optics applies strictly only to the propagation of radiation of zero wavelength, it provides a very good and extremely useful approximation to any case where the wavelength is negligibly small in comparison with the smallest linear dimension of the apparatus.

Fermat's principle of least time states that the path traversed by light in passing between two points is that which will take the least time. The general law expressed by Fermat's principle is also known as the law of extreme path. It is stated mathematically as

$$\delta \int_A^B N\,dS = 0, \tag{1}$$

$N = \dfrac{C}{V}$ = index of refraction.

C = velocity of radiation in vacuum.

V = velocity of radiation in medium.

dS = element of path length.

The product of index of refraction and path length, $N\,dS$, is known as the optical length of a "ray of light" or optical distance. Equation (1) states that a light ray going from point A to point B will always choose that path which will make the optical distance an extremum (generally a minimum but sometimes a maximum) with respect to all neighboring paths for rays of the same frequency. The laws of linear propagation, reflection, and refraction may be deduced from Fermat's principle.

Although the frequency is a constant for a given radiation, and its wavelength varies with the medium traversed, it has become customary to specify radiation, especially visible radiation, by its wavelength in vacuum. This is due to the fact that fundamental measurements yield wavelength rather than frequency. The units of wavelength commonly used in optics are:

$$\begin{aligned} \text{micron } (\mu) &= 10^{-6} \text{ meter} \\ \text{millimicron } (\text{m}\mu) &= 10^{-9} \text{ meter} \\ \text{angstrom unit (A)} &= 10^{-10} \text{ meter} \end{aligned}$$

The visible spectrum extends from about 0.39 to 0.75 μ; or 390 to 750 mμ; or 3900 to 7500 A; or from about 4.0×10^{14} to 7.7×10^{14} cycles per second.

1. REFLECTION AND REFRACTION

When a beam of radiant flux or luminous flux strikes a boundary separating two homogeneous isotropic media, it is in general partly reflected and partly refracted. If the boundary is smooth (relative to the wavelength of radiation), the following simple laws of refraction and reflection apply (see Fig. 1).

LAW OF REFRACTION OR SNELL'S LAW. The ratio of the sine of the angle of incidence to the sine of the angle of refraction is constant depending only on the indices of refraction of the two media; i.e.,

$$N_1 \sin I_1 = N_2 \sin I_2 \tag{2}$$

The incident ray, the refracted ray, and the normal to the surface at the point of incidence all lie in the same plane.

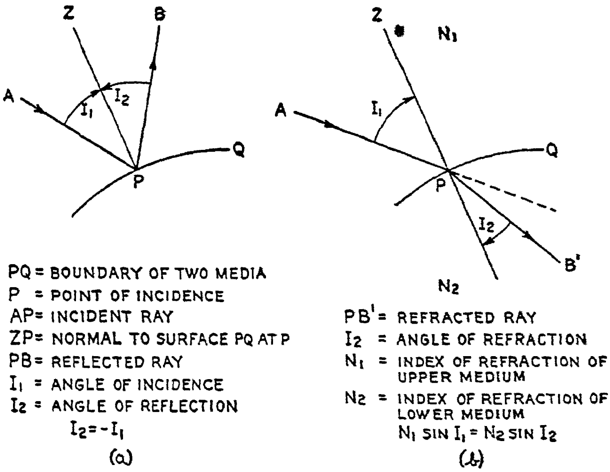

FIG. 1. Reflection and Refraction of Light Ray

LAW OF REFLECTION. The angle of reflection is equal to the angle of incidence; i.e.,

$$I_2 = -I_1 \tag{3}$$

The incident ray, the reflected ray, and the normal to the surface at the point of incidence all lie in the same plane.

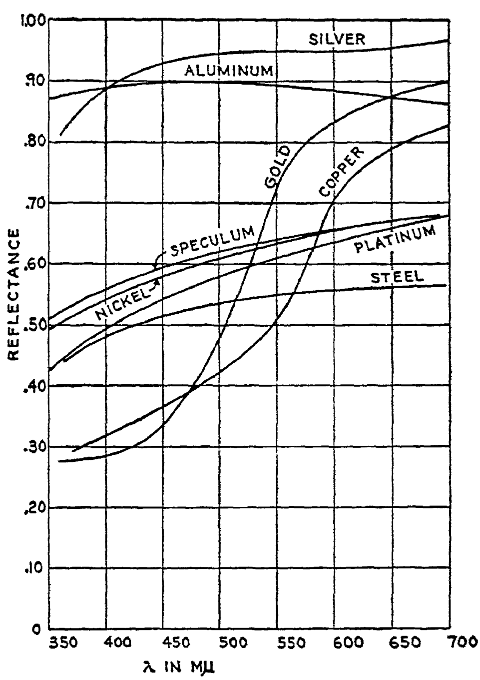

FIG. 2. Reflectance of Some Metals as a Function of Wavelength

Reflection from smooth surfaces is called *specular* or regular reflection. If the boundary is between a transparent dielectric (air, glass) and a metal, then, in general, most of the incident flux is reflected. Figure 2 gives the specular reflectance (ratio of reflected to incident flux) of various metals as a function of wavelength.

The specular reflectance r_f at the boundary of two transparent dielectrics is specified for normal incidence by Fresnel's equation:

$$r_f = \frac{(N_2 - N_1)^2}{(N_2 + N_1)^2} \tag{4}$$

where N_1 and N_2 are the indices of refraction of the two media.

Figure 3 shows the reflectance for unpolarized light as a function of angle of incidence for light traveling from a lower-index medium into a higher-index medium ($N_2 > N_1$). It is seen that, as the angle of incidence is increased, the reflectance rises gradually at first, and then rapidly, until it becomes unity at the angle of incidence of 90°. The remainder of the incident flux enters the medium of index N_2 at the angle of refraction I_2 given by Snell's law, eq. (2).

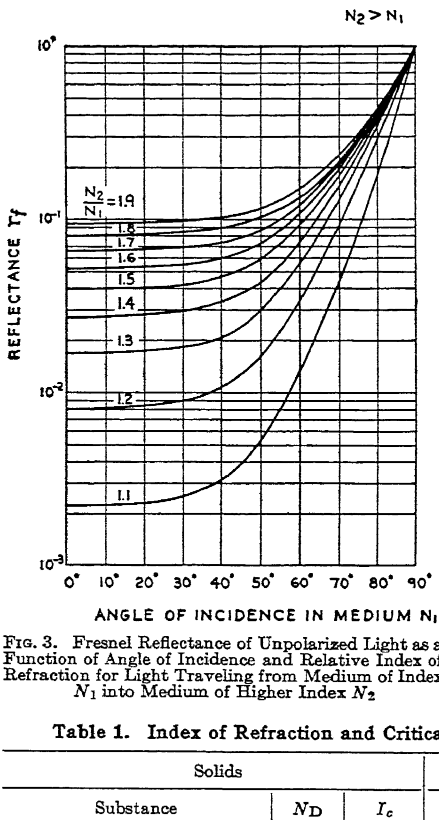

FIG. 3. Fresnel Reflectance of Unpolarized Light as a Function of Angle of Incidence and Relative Index of Refraction for Light Traveling from Medium of Index N_1 into Medium of Higher Index N_2

The Fresnel reflection can be greatly reduced by means of a transition layer between the two transparent dielectrics. For normal incidence and for a particular wavelength, the Fresnel reflection can be reduced to zero if, as in transmission lines, the index of refraction of the transition layer is $N = \sqrt{N_1 N_2}$ and the thickness of the layer is $\lambda/4$.

For light traveling from a higher-index medium into a lower-index medium ($N_2 < N_1$), a similar behavior is observed up to a certain critical angle of incidence, the critical angle being determined by the condition that

$$\sin I_1 = \sin I_C = \frac{N_2}{N_1} \tag{5}$$

since at this angle of incidence the angle of refraction is 90° ($\sin I_2 = 1$). For angles of incidence greater than the critical angle, the beam is totally reflected into the initial medium. Table 1 gives the index of refraction and critical angle of incidence relative to air for some solids and liquids.

Table 1. Index of Refraction and Critical Angle of Substances Relative to Air

Solids			Liquids, 15 deg cent		
Substance	N_D	I_c	Substance	N_D	I_c

Cadmium sulfide	2.52	23° 23′			

DIFFUSE REFLECTION. If the boundary between two media is rough, specular reflection can be considered to exist at a great number of small smooth areas oriented in various directions, and the reflected energy is distributed over a wide range of angles. In general, practical surfaces (boundaries) reflect partly specularly and partly diffusely.

Figure 4 illustrates this. Pure specular reflection is shown in (*a*); part specular and part diffuse, such as would occur at most matte surfaces, is shown in (*b*); pure or ideal diffuse reflection is shown in (*c*). In perfectly diffuse reflection, the flux reflected per unit solid angle is proportional to the cosine of the angle measured from the normal to the surface. This statement is known as *Lambert's law*.

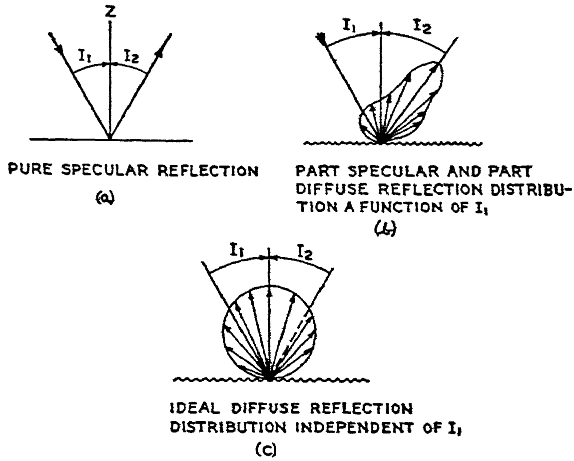

FIG. 4. Specular and Diffuse Reflection

DISPERSION. The variation of the refractive index of a substance with the wavelength (color) of the transmitted light is termed dispersion. The index of refraction of most glasses varies with wavelength in a manner which may be approximated by the dispersion formula of Cauchy:

$$N = a + \frac{b}{\lambda^2}$$

The refractive index of optical glass is generally measured with certain definite wavelengths or lines of the spectrum. It has become customary to use the spectral lines A′ (0.7665 μ); C (0.6563 μ); D (0.5893 μ); F (0.4861 μ); G′ (0.4341 μ). The differences in refractive index $N_D - N_C$, $N_F - N_D$, $N_{G'} - N_F$, $N_D - N_{A'}$, and $N_F - N_C$ are taken as a measure of the dispersion of the glass in the different parts of the spectrum. If a glass is specified by only one index of refraction N_D is generally meant. A quantity related to dispersion which is in very general use utilizes the F (blue), D (yellow), and C (red) portions of the spectrum and is designated by:

$$V = \frac{N_D - 1}{N_F - N_C} \tag{6}$$

The V values, $N_{A'}$, N_C, N_D, N_F, and $N_{G'}$, for some Bausch & Lomb Optical Company glasses are given in Table 2.

Table 2. Indices of Refraction and V-number of Some Optical Glasses Made by Bausch and Lomb Optical Co.

REFRACTION AND REFLECTION AT SPHERICAL SURFACES. Because of the relative ease of manufacture, most optical systems consist of a series of spherical surfaces, a plane being the limiting case of a spherical surface of infinite radius of curvature. By determining the plane containing the ray to be traced and the center of curvature, any problem of refraction or reflection at a spherical surface may be reduced to a problem in plane trigonometry.

SIGN CONVENTION. Referring to Fig. 5, let the paper represent the plane of incidence containing A_1Q, the ray to be traced through the refracting surface, and C the center of curvature of the spherical surface. The signs of quantities in optical calculations have not been standardized, but the sign convention indicated in Fig. 5 is very widely used.

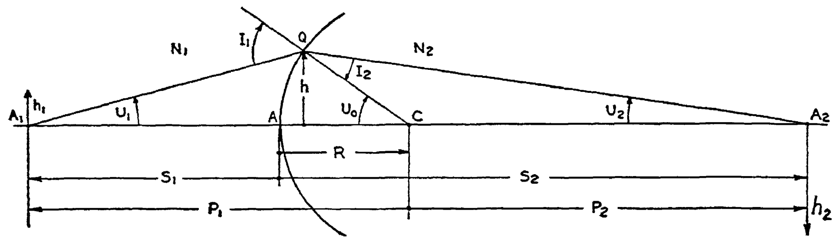

Fig. 5. Refraction at a Spherical Surface

Distances measured to the right of the pole A (or center of curvature C) are positive; those to the left of the pole A are negative. Distances above the axis are positive, and those below the axis are negative. Angles shown clockwise are positive; those shown counterclockwise are negative.

EXACT RAY TRACING EQUATIONS. Using the above sign convention, the standard ray tracing equations given below follow from the law of refraction and plane trigonometry. It is assumed that the quantities N_1, N_2, R, and S_1 (or P_1) are given and that U_1 is assigned an arbitrary value for each ray. The problem is to find I_1, I_2, U_2, and S_2 (or P_2).

$$\sin I_1 = \frac{S_1 - R}{R} \sin U_1 = \frac{P_1}{R} \sin U_1 \tag{7}$$

$$\sin I_2 = \frac{N_1}{N_2} \sin I_1 \tag{8}$$

$$U_2 = U_1 + I_1 - I_2 \tag{9}$$

$$S_2 - R = P_2 = R\,\frac{\sin I_2}{\sin U_2} \tag{10}$$

In dealing with a complete optical system with many surfaces the results of one surface are taken as the initial data for the next surface. The following equations which may also be derived with the aid of Fig. 5 have been found very useful in optical calculations:

$$P_2 N_2 \sin U_2 = P_1 N_1 \sin U_1 \tag{11}$$

$$U_0 = U_1 + I_1 = U_2 + I_2 \tag{12}$$

$$h = R \sin U_0 \tag{13}$$

$$\frac{N_1 \cos I_1}{P_2} - \frac{N_2 \cos I_2}{P_1} = \frac{N_2 \cos I_2 - N_1 \cos I_1}{R} \cos U_0 \tag{14}$$

Since at reflection $I_2 = -I_1$, $\sin I_2 = -\sin I_1$, the law of reflection may be treated mathematically as a particular case of the law of refraction, i.e., where $N_2 = -N_1$. Hence the refraction formulas given above apply to the case of reflection at a spherical surface by simply letting $N_2 = -N_1$. Thus for a spherical mirror, the above equations become (Fig. 6):

$$\sin I_1 = \frac{P_1}{R} \sin U_1 \tag{15}$$

$$\sin I_2 = -\sin I_1 \tag{16}$$

$$U_2 = U_1 - 2I_2 \tag{17}$$

$$P_2 = R\,\frac{\sin I_2}{\sin U_2} \tag{18}$$

$$P_2 \sin U_2 = -P_1 \sin U_1 \tag{19}$$

$$\frac{1}{P_2} + \frac{1}{P_1} = -\frac{2 \cos U_0}{R} \tag{20}$$

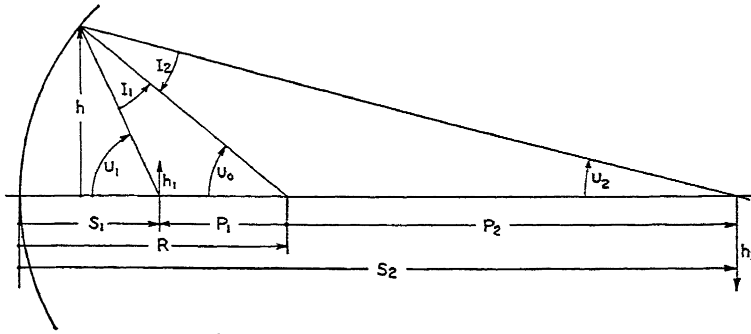

FIG. 6. Reflection at a Spherical Surface

PARAXIAL FORMULAS. The exact trigonometrical formulas just given are transcendental and are therefore extremely difficult to manipulate. Great simplification is obtained if the equations are restricted to paraxial rays, i.e., rays that make small angles with the optical axis and with the normals to the refracting and reflecting surfaces. The paraxial formulas given below are deduced from the exact formulas by replacing the sines of the angles by the angles and the cosines by unity. Paraxial quantities will be indicated by the corresponding lower-case letter:

$$i_1 = \frac{s_1 - R}{R} u_1 = \frac{p_1}{R} u_1 \tag{21}$$

$$i_2 = \frac{N_1}{N_2} i_1 \tag{22}$$

$$u_2 = u_1 + i_1 - i_2 \tag{23}$$

$$s_2 - R = p_2 = R \frac{i_2}{u_2} \tag{24}$$

$$p_2 N_2 u_2 = p_1 N_1 u_1 \tag{25}$$

$$\frac{N_1}{p_2} - \frac{N_2}{p_1} = \frac{N_2 - N_1}{R} \tag{26}$$

$$\frac{N_2}{s_2} - \frac{N_1}{s_1} = \frac{N_2 - N_1}{R} \tag{27}$$

The corresponding equations for a spherical mirror are:

$$i_1 = \frac{p_1}{R} u_1 \tag{28}$$

$$i_2 = -i_1 \tag{29}$$

$$u_2 = u_1 - 2i_2 \tag{30}$$

$$p_2 = R \frac{i_2}{u_2} \tag{31}$$

$$p_2 u_2 = -p_1 u_1 \tag{32}$$

$$\frac{1}{p_2} + \frac{1}{p_1} = -\frac{2}{R} \tag{33}$$

$$\frac{1}{s_2} + \frac{1}{s_1} = \frac{2}{R} \tag{34}$$

Paraxial relations are linear and therefore are easily manipulated algebraically. They are very useful for determining the approximate focusing action of an optical system.

If the object is at a very great distance, i.e., $1/s_1 = 0$, the image is located at the second focal point at the distance

$$f_2 = \frac{N_2}{N_2 - 1} R \tag{35}$$

to the right of the apex A. If the image is located at a very great distance, i.e., $1/s_2 = 0$, then the object is located at the first focal point at the distance

$$f_1 = -\frac{N_1}{N_2 - N_1} R \tag{36}$$

to the left of the apex A. For a spherical mirror

$$f_2 = f_1 = \frac{R}{2} \tag{37}$$

and both focal points coincide. It should be noted that in general

$$\frac{f_2}{f_1} = -\frac{N_2}{N_1} \tag{38}$$

This relation applies to any optical system where N_2 is the index of refraction of the image space and N_1 that of the object space.

MAGNIFICATION. The above relations suffice to locate an image of an object, but they do not explicitly give any information about the sizes of object and image. As is

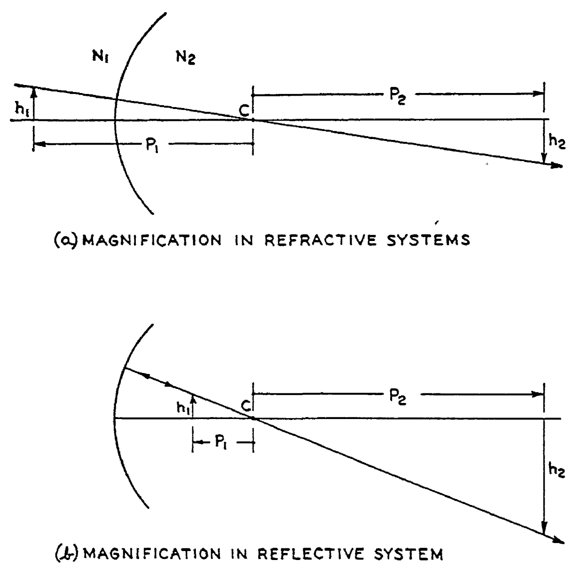

FIG. 7. Magnification in Optical Systems

seen from the geometry of Figs. 7(*a*) and 7(*b*), the *lateral magnification* which is defined as the ratio of image height h_2 to object height h_1 is

$$m = \frac{h_2}{h_1} = \frac{P_2}{P_1} \tag{39}$$

It is to be noted that m is negative for an inverted image (as in Fig. 7) and positive for an erect image. Inserting (39) into (11) there result the very important relations

$$h_2 N_2 \sin U_2 = h_1 N_1 \sin U_1 \tag{40}$$

$$m = \frac{N_1 \sin U_1}{N_2 \sin U_2} \tag{41}$$

Equation (40) or (41) is known as *Abbe's sine condition* and applies to any number of refracting and reflecting coaxial surfaces (N_1 index of object space, N_2 index of image space). The corresponding paraxial equations

$$h_2 N_2 u_2 = h_1 N_1 u_1 \tag{42}$$

$$m = \frac{N_1 u_1}{N_2 u_2} \tag{43}$$

are known as *Lagrange's theorem*.

The longitudinal magnification along the axis is

$$m_s = \frac{\Delta s_2}{\Delta s_1} = m^2 \tag{44}$$

The angular magnification is

$$m_u = \frac{u_2}{u_1} = \frac{1}{m} \tag{45}$$

The relation between these magnifications is

$$m = m_s m_u \tag{46}$$

2. LENSES

By applying the above paraxial relations to a lens in air, i.e., two refracting surfaces, as shown in Fig. 8, it may be shown that the two focal points (F_1, F_2) and the two principal points (H_1, H_2) completely determine the paraxial focusing characteristics of the lens.

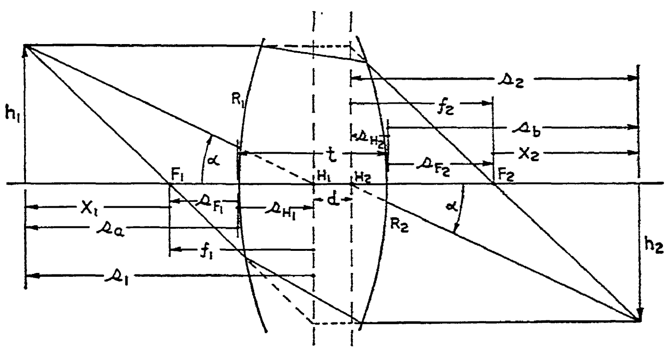

Fig. 8. Focusing Characteristics of Thick Lens in Air

The first focal point, F_1, may be considered as that object point which is focused at infinity in the image space so that all paraxial rays passing through the point F_1 are parallel to the axis in the image space. The second focal point, F_2, may be considered the image of an object at an infinite distance from the lens in the object space so that all paraxial rays which are parallel to the axis in the object space will pass through F_2 in the image space.

The distances indicated by f_1 and f_2 in Fig. 8 are known as the *principal* or *equivalent* focal lengths and are given by

$$f_2 = \frac{NR_1R_2}{(N-1)[N(R_2 - R_1) + (N-1)t]} = -f_1 \tag{47}$$

The positions of the focal points measured from the refracting surfaces are given by

$$s_{F_1} = -f_2\left(1 + \frac{N-1}{N}\frac{t}{R_2}\right) \tag{48}$$

$$s_{F_2} = f_2\left(1 - \frac{N-1}{N}\frac{t}{R_1}\right) \tag{49}$$

The focal distances s_{F_1} and s_{F_2} are known as the front focal length (F.F.L.) and back focal length (B.F.L.) respectively. These focal lengths are easily measured by imaging an object at a great distance from the lens and noting the distance between image and nearest surface of the lens and then turning the lens around and repeating the operation. The positions of the principal points H_1 and H_2 measured from the refracting surfaces are given by

$$s_{H_1} = -f_2\frac{N-1}{N}\frac{t}{R_2} \tag{50}$$

$$s_{H_2} = -f_2\frac{N-1}{N}\frac{t}{R_1} \tag{51}$$

The distance between the principal points is

$$d = \frac{N-1}{N} t \left[1 + \frac{N-1}{N} \frac{tf_2}{R_1R_2} \right] \tag{52}$$

From (50) and (51) it is seen that

$$\frac{s_{H_1}}{s_{H_2}} = \frac{R_1}{R_2} \tag{53}$$

In many practical cases the lens thickness, t, is numerically small in comparison with either R_1, R_2, or $(R_2 - R_1)$, and then

$$s_{H_1} = \frac{R_1 t}{N(R_2 - R_1)} \qquad s_{H_2} = \frac{R_2 t}{N(R_2 - R_1)} \tag{54}$$

$$d = \frac{N-1}{N} t \tag{55}$$

For a biconvex lens with $R_2 = -R_1(R_1$ positive)

$$f_2 = \frac{R_1}{2(N-1)} \qquad s_{H_1} = \frac{t}{2N} \qquad s_{H_2} = -\frac{t}{2N}$$

If $R_2 \neq R_1$, both principal planes move toward the surface with the higher curvature, and when $R_2 = \pm\infty$, i.e., for a plano-convex lens,

$$s_{H_1} = 0 \qquad s_{H_2} = -\frac{t}{N}$$

The positions of the focal and principal points of an optical system having been determined, its focusing action may be calculated with the aid of the following formulas (see Fig. 8).

$$X_1X_2 = f_1f_2 = -f_2^2 \tag{56}$$

$$\frac{1}{s_2} - \frac{1}{s_1} = \frac{1}{f_2} \tag{57}$$

$$m = \frac{h_2}{h_1} = -\frac{f_1}{X_1} = -\frac{X_2}{f_2} = \frac{s_2}{s_1} \tag{58}$$

$$s_2 = -f_2(m-1) \tag{59}$$

$$s_1 = -f_2 \frac{(m-1)}{m} \tag{60}$$

THIN LENSES. A lens of negligible thickness relative to its focal length is known as a thin lens. For a thin lens, $s_{H_1} = s_{H_2} = d = t = 0$, and great simplification in computation results. For a thin lens the distances s_1, s_2, f_1, and f_2 in eqs. (56) to (60) are measured from the (center of) lens, and the distance between object and image is

$$s_2 - s_1 = -f_2 \frac{(m-1)^2}{m} \tag{61}$$

COMPOUND LENSES. Because of the necessity for correcting aberrations most lenses are compound; i.e., they consist of several lenses having a common axis. Some of the surfaces of adjacent lenses may be in contact and others are separated by air spaces. The focal length of two thin lenses in contact of focal lengths f_{2a} and f_{2b} is

$$f_2 = \frac{f_{2a}f_{2b}}{f_{2a} + f_{2b}} \tag{62}$$

The power of a lens measured in diopters is defined as $P = 1/f$, where f is measured in meters. Thus the power of two thin lenses in contact is

$$P = \frac{1}{f_{2a}} + \frac{1}{f_{2b}} = P_a + P_b \tag{63}$$

If the two thin lenses are separated by an air space of thickness t, the resulting lens is effectively a thick lens and the focal length of the combination is

$$f_2 = \frac{f_{2a}f_{2b}}{f_{2a} + f_{2b} - t} = -f_1 \tag{64}$$

and the power is

$$P = P_a + P_b - tP_aP_b \tag{65}$$

The principal points and focal points are located at (see Fig. 9)

$$s_{H_1} = \frac{f_{2a}t}{f_{2a} + f_{2b} - t} \qquad s_{H_2} = -\frac{f_{2b}t}{f_{2a} + f_{2b} - t} \tag{66}$$

$$s_{F_1} = \frac{f_{2a}(f_{2b} - t)}{f_{2a} + f_{2b} - t} \qquad s_{F_2} = \frac{f_{2b}(f_{2a} - t)}{f_{2a} + f_{2b} - t} \tag{67}$$

The distance between the principal points is

$$d = -\frac{t^2}{f_{2a} + f_{2b} - t} \tag{68}$$

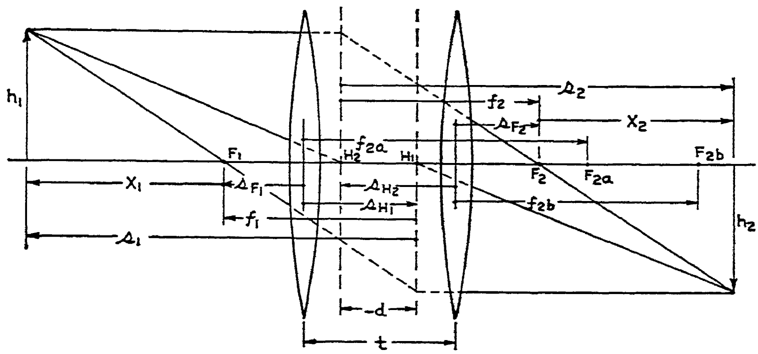

FIG. 9. Focusing Characteristics of Two Thin Lenses Separated by an Air Space

There are three ways of compounding two lenses.

1. Both lenses are converging; i.e., $f_{2a} > 0$ and $f_{2b} > 0$. In this case the focal length of the combination is a minimum and the power is a maximum when $t = 0$. The focal length increases as t is increased until when $t = f_{2a} + f_{2b}$ the focal length is infinite and the system is afocal or telescopic. Objectives, magnifiers, and eyepieces are generally compounded of two such lenses with $t < f_{2a} + f_{2b}$. The focal length of the combination is negative for $t > f_{2a} + f_{2b}$, and such a combination forms the compound microscope.

2. Both lenses are diverging; i.e., $f_{2a} < 0$ and $f_{2b} < 0$. The focal length of the combination is negative and decreases in absolute values as t is increased.

3. *One lens is converging* $f_{2a} > 0$ *and one diverging* $f_{2b} < 0$. If $|f_{2b}| < |f_{2a}|$ the focal length of the combination is negative for values of $t < |f_{2a} + f_{2b}|$, it is infinite for $t = |f_{2a} + f_{2b}|$; this is the optical system of the Galilean telescope which produces an erect image. The focal length is positive for $t > |f_{2a} + f_{2b}|$ and corresponds to the optical system of a telephoto lens. If $|f_{2b}| > |f_{2a}|$ the focal length is always positive.

ABERRATIONS. Actual imagery with practical lenses departs from the paraxial or first-order imagery discussed above. These departures are known as aberrations. There are seven independent third-order aberrations.

Spherical aberration or aperture defect is illustrated in Fig. 10. In the presence of spherical aberration the rays from a point object on the axis do not recombine to form a

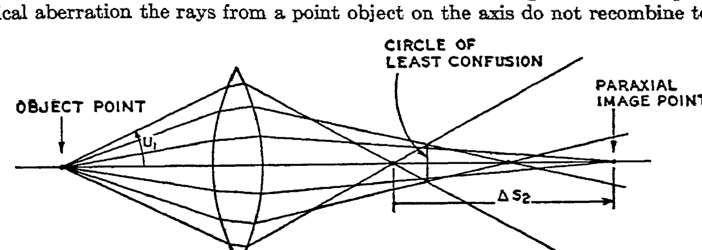

FIG. 10. Positive or Undercorrected Spherical Aberration

point image as required by paraxial theory. Spherical aberration is generally measured by the axial intersection distance, ΔS_2, which varies approximately as the cube of the convergence angle U_1. Any simple convex lens has positive spherical aberration and is corrected by compounding it with a concave lens which has negative spherical aberration.

In a single lens the spherical aberration is minimized if the deviation is equally divided between the two surfaces of the lens.

Coma is an extra-axial aberration; i.e., it affects image points not on the axis of the lens. It may be considered lateral spherical aberration for an extra-axial point. If coma is present a point object is imaged into a comet-shaped figure. It increases directly with the distance of the object point from the axis and as the square of the aperture of the lens. Coma, unlike spherical aberration, may be eliminated from a single thin lens for one object distance; however, a lens for zero coma is not the same as one for minimum spherical aberration. Coma may be eliminated by a stop of the proper aperture located at the proper distance from the lens. A lens corrected for spherical aberration and coma for a given object distance is called an *aplanatic lens*. If spherical aberration is absent the condition for freedom of coma is given by Abbe's sine condition, eq. (40) or (41).

Astigmatism, like coma, affects only extra-axial points. When astigmatism is present each object point has two images, one behind the other. These images are short lines at right angles to each other. One is called the sagittal or radial astigmatic line since it is in a plane containing the axis of the system. The other is called the tangential or transverse astigmatic line since it is at right angles to a line drawn from the lens axis. Midway the two line images the cross-section of the beam is a circle of least confusion. The astigmatism is positive if the sagittal focus is farther from the lens than the tangential focus. Otherwise it is negative. Astigmatism increases as the square of the distance of the object point from the axis and directly as the aperture.

Astigmatism and *curvature of the field* are generally present together, and the sagittal and tangential foci lie on curved surfaces as illustrated in Fig. 11. If only curvature of

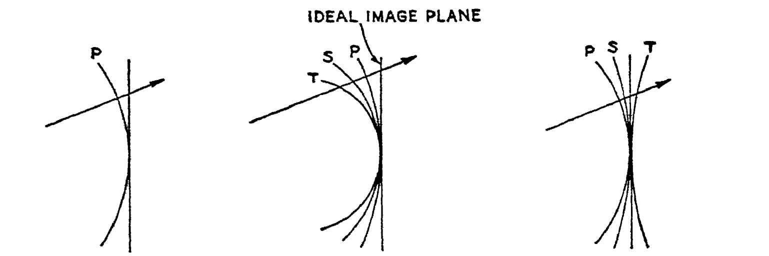

FIG. 11. Astigmatism and Curvature of Field

the field is present the image points lie on a spherical surface known as the Petsval surface, which is indicated in Fig. 11 by P.

Distortion is the variation of magnification with the distance of an object point from the axis. Positive, or "barrel" distortion, exists if the magnification decreases with increasing distance of an object point from the axis. Negative, or "pincushion," distortion exists if the magnification increases with increasing distance of an object point from the axis. Distortion increases as the cube of the distance of an object point from the axis.

Chromatic aberration is due to the fact that the focal length of a lens depends upon its index of refraction and thus upon the wavelength of the light used. As a consequence

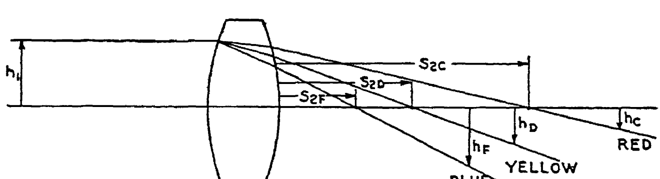

FIG. 12. Longitudinal and Lateral Chromatic Aberration

a single lens forms a series of colored images of different magnifications at different distances from the lens (Fig. 12). The variation of image distance with wavelength is known as *longitudinal chromatic aberration.* The difference $S_{2C} - S_{2F}$ is taken as a measure of the longitudinal aberration, and for a thin lens it is given by

$$s_{2C} - s_{2F} = \frac{1}{f_{2D}V\left(\dfrac{1}{f_{2D}} + \dfrac{1}{S_{1D}}\right)^2} = \frac{S_{2D}^2}{f_{2D}V} \qquad (69)$$

where V is given by eq. (6). The variation of image size with wavelength of refraction is known as *lateral chromatic aberration* and is measured by $h_C - h_F$.

STOPS. Any obstacle which limits the rays that can be transmitted through an optical system is a stop. Stops serve (1) to limit the aperture of any bundle of rays, and thus the amount of light, that reaches any image point, and (2) to limit the extent of the object which is imaged, or the field of view. The stop that limits the diameter of the bundle of rays that can enter the optical system is called the aperture stop or iris. The stop that limits the field of view is known as the field stop. In Fig. 13, NP is the image of AS formed

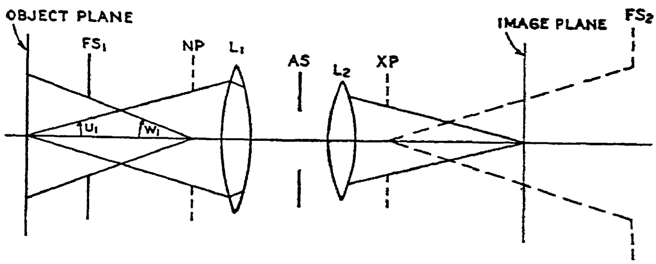

Fig. 13. Aperture Stop, AS, and Field Stop, FS_1, in an Optical System

by that part of the optical system (lens L_1) situated between AS and the object. Since NP limits the angular aperture U_1 of the beam, AS is the aperture stop. NP is known as the entrance pupil. If an actual stop were located at NP instead of AS, then the iris and entrance pupil would coincide. The image XP of AS formed by that part of the optical system (lens L_2) situated between AS and the image is known as the exit pupil. The angle subtended by the object at the center of the entrance pupil is known as the *angular field of view* of the object. In Fig. 13 the angular field of view of the object is limited to $2W_1$ by the aperture stop FS_1. If it is desirable to have a sharp boundary of the field of view it is necessary to have FS_1 in the plane of the object.

Stops play a very important role in eliminating those rays that would produce excessive aberrations.

DEPTH OF FOCUS. The maximum total distance, ΔS_2, that a viewing screen may be moved along the axis of an optical system to produce a circle of confusion of prescribed radius, r, is called the depth of focus (Fig. 14a). It is given by

$$\Delta S_2 = 2r\frac{S_2}{a_2} = 2r \cot U_2 \qquad (70)$$

where S_2 is the image distance, at best focus, measured from the exit pupil of radius a_2.

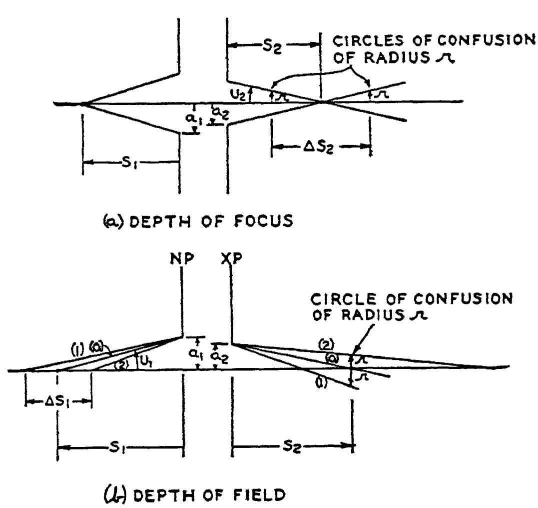

Fig. 14. Difference between Depth of Field and Depth of Focus

DEPTH OF FIELD. The maximum total distance, ΔS_1, that an object may be moved along the axis to produce, at a fixed image distance, a circle of confusion of prescribed radius, r, is called the depth of field (Fig. 14b). It is given by

$$\Delta S_1 = \frac{rS_1}{ma_1 - r} + \frac{rS_1}{ma_1 + r} \qquad (71)$$

where m is the magnification and S_1 is the object distance, at best focus, measured from the entrance pupil of radius a_1. If $r \ll ma_1$, then

$$\Delta S_1 = 2\frac{r}{m}\frac{S_1}{a_1} = 2\frac{r}{m}\cot U_1 \tag{72}$$

3. PHOTOMETRY

The problem in photometry is to obtain a quantitative evaluation of radiant flux with respect to its capacity to produce the *sensation of brightness*. The sensation of brightness evoked by a given amount of radiant energy is different for different individuals and is different for the same individual under different conditions of observation. Equal amounts of radiant energy per unit wavelength interval throughout the visible spectrum do not produce visual sensations of equal brightness. A luminosity curve shows as ordinates the relative effectiveness of various wavelengths to evoke, for a particular observer, visual sensations of equal brightness. Figure 15 shows two luminosity curves applying to

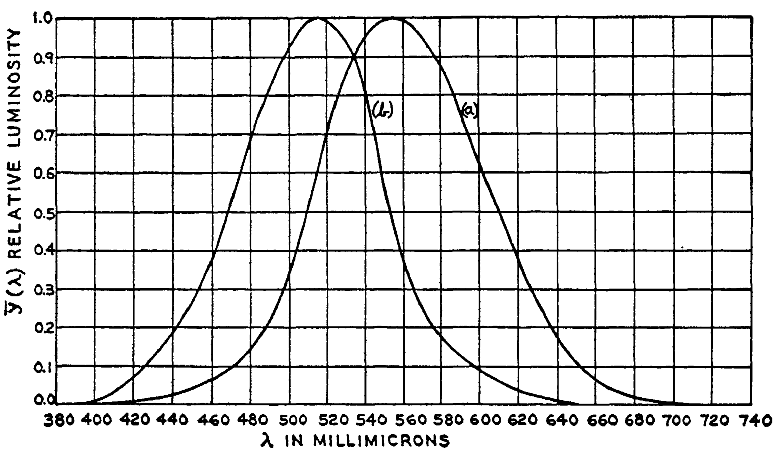

FIG. 15. Curve (*a*), Standard Luminosity Function, Applying to Normal Vision with Good Lighting Conditions; Curve (*b*), Luminosity Function Applying to Vision at Very Low Light Levels

photopic or normal vision (at high light levels) and to scotopic vision (at very low light levels). These are average luminosity curves obtained for a number of observers. The use of many luminosity curves would, obviously, lead to endless confusion and ambiguity in photometric measurements and specification. To avoid this, the International Commission on Illumination adopted Fig. 15*a* as the *standard luminosity curve*. It is important to realize that the standard luminosity curve is essentially an arbitrarily assumed standard for purposes of standardization and specification of photometric data and is not necessarily the retinal response of any individual. Table 3 gives the standard luminosity function, $\bar{y}(\lambda)$ of Fig. 15*a*, at 10-millimicron intervals.

Table 3. Standard Luminosity Function

λ in mμ	$\bar{y}(\lambda)$	λ in mμ	$\bar{y}(\lambda)$	λ in mμ	$\bar{y}(\lambda)$	λ in mμ	$\bar{y}(\lambda)$
380	0.0000	480	0.139	580	0.870	680	0.0170
390	.0001	490	.208	590	.757	690	.0082
400	.0004	500	.323	600	.631	700	.0041
410	.0012	510	.503	610	.503	710	.0021
420	.0040	520	.710	620	.381	720	.0010
430	.0116	530	.862	630	.265	730	.0005
440	.0230	540	.954	640	.175	740	.0003
450	.0380	550	.995	650	.107	750	.0001
460	.0600	560	.995	660	.061	760	.0001
470	.0910	570	.952	670	.032		

Table 4 gives the names, symbols, and basic mks units of radiometry and photometry as recommended by the committee on colorimetry of the Optical Society of America. The term "luminance" in Table 5 replaces the older term "brightness" which led to confusion between the objective concept of brightness as a measurable quantity and the subjective concept of brightness which refers to the sensation in the consciousness of the human observer. It is recommended that the term "brightness" be used only in the latter sense.

Table 4

Radiometry			Photometry		
Name	Symbol	Unit MKS	Name	Symbol	Unit MKS
Radiant energy......	U	Joule	Luminous energy.....	Q	Talbot
Radiant flux........	P	Watt	Luminous flux	F	Lumen
Radiant emittance...	W	Watt/m^2	Luminous emittance..	L	Lumen/m^2
Radiant intensity....	J	Watt/ω (steradian)	Luminous intensity...	I	Lumen/ω (candle)
Radiance...........	N	Watt/ωxm^2	Luminance..........	B	Lumen/ωxm^2 (candle/m^2)
Irradiance..........	H	Watt/m^2			
			Illuminance..........	E	Lumen/m^2 (lux)

The ratio of any photometric quantity to the corresponding radiometric quantity in Table 5 is equal to the absolute luminosity or *luminous efficiency* (generally expressed as lumens per watt) of the radiant energy. Thus 1 watt of monochromatic radiant flux of wavelength 555 mμ (corresponding to the peak of the standard luminosity curve) is equivalent to 685 lumens. This efficiency of 685 lumens per watt is based on the fact that the new proposed international photometric standard of a black body at the temperature (2043.8 deg K) of freezing platinum shall have a luminance of 6×10^5 candles per m^2 (60 candles per cm^2).

Table 5. Conversion Factors for Units of Illuminance

to Obtain ↓	Multiply Number of → by	Lux	Foot-candle	Phot	Milliphot
Lumen/m^2	Lux......................	1	10.76	10,000	10
Lumen/ft^2	Foot-candle..............	0.0929	1	929	0.929
Lumen/cm^2	Phot.....................	0.0001	0.001076	1	0.001
	Milliphot................	.1	1.076	1,000	1

If the radiant flux is monochromatic its luminous efficiency is simply $685\bar{y}(\lambda)$. If the radiant flux is not monochromatic but consists of a continuous spectrum, then if $P(\lambda)$ is the radiant flux per unit wavelength (watts per millimicron) the luminous efficiency is

$$K = 685 \frac{\int_0^\infty \bar{y}(\lambda) P(\lambda)\, d\lambda}{\int_0^\infty P(\lambda)\, d\lambda} \tag{73}$$

Luminous efficiency should not be confused with the efficiency of a practical light source, which is the ratio of the total luminous flux to the total power input. The efficiency of a source of light is less than K since generally a fraction of the total power input is not converted into radiant flux.

LUMINOUS INTENSITY OR CANDLEPOWER OF A SOURCE. By a source will be understood (*a*) any self-luminous object, such as an incandescent body, or (*b*) any illuminated object which so completely diffuses (either by reflection or transmission) the incident light that it acts as a source.

The intensity of a source is defined as

$$I = \frac{dF}{d\omega} \tag{74}$$

and is measured in lumens per steradian, or candles. In Fig. 16, let the small plane source of area A_0 emit P watts or $F = 685\int_0^\infty \bar{y}(\lambda)P(\lambda)\,d\lambda$ lumens. The two small receivers of areas A_1 and A_2 subtend the same solid angle $\Delta\omega$ at the (say, center of) source and are located at the same distance D from the source. The number of lumens ΔF_1 and ΔF_2 contained in the same solid angle $\Delta\omega$ will, in general be different. Thus the intensity normal to the source, $I_0 = \frac{\Delta F_1}{\Delta\omega}$, is not equal to the intensity, $I_\alpha = \frac{\Delta F_2}{\Delta\omega}$, measured along a direction at the angle α with the normal. In specifying the intensity or candlepower of a source, it is therefore necessary to state the direction in which the intensity was measured or give a candlepower distribution curve. The directional characteristic of many extended sources follow *Lambert's law*, which states that

$$I_\alpha = I_0 \cos\alpha \tag{75}$$

With a uniform point or spherical source, the intensity is independent of direction and is $F/4\pi$. Thus a uniform point or spherical source of an intensity of 1 candle emits 4π lumens.

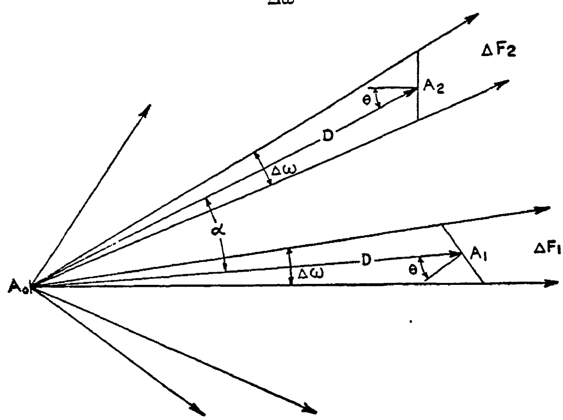

FIG. 16. Diagram Illustrating Some Photometric Concepts

ILLUMINANCE. A surface of area dA, placed in a field of flux, is illuminated with the illuminance

$$E = \frac{dF}{dA} \text{ (lumens per } m^2 \text{ in mks units)} \tag{76}$$

where dF is the flux incident on the surface. The illuminance of receiver A_1 (Fig. 16) is

$$E_1 = \frac{\Delta F_1}{A_1} = \frac{I_0 \Delta\omega}{A_1} = \frac{I_0}{A_1}\frac{(A_1 \cos\theta)}{D^2} = \frac{I_0}{D^2}\cos\theta \tag{77a}$$

The illuminance of receiver A_2 is

$$E_2 = \frac{I_\alpha}{D^2}\cos\theta = \frac{I_0}{D^2}\cos\alpha\cos\theta \tag{77b}$$

In normal incidence

$$E_1 = \frac{I_0}{D^2}, \qquad E_2 = \frac{I_\alpha}{D^2} \tag{78}$$

which is the well-known inverse-square law. The inverse-square law, which is the basis of most visual photometers, applies to large extended sources, if D is considerably larger than the extension of the source. Thus (78) holds to within about 1 per cent if D is at least 5 times the greatest linear dimension of the source.

LUMINANCE. The luminance, B, of the surface A_0 (Fig. 16) in any direction is the ratio of the intensity I_α in that direction to the area of the projection of A_0 on a plane perpendicular to the direction, i.e.,

$$B = \frac{I_\alpha}{A_0 \cos\alpha} \tag{79}$$

Luminance is measured in candles per square meter in mks units. If Lambert's law is followed, then

$$B = \frac{I_0 \cos\alpha}{A_0 \cos\alpha} = \frac{I_0}{A_0} = B_0 \tag{80}$$

and the luminance of a surface is independent of α. The *brightness sensation* when observing a surface, whether self-luminous (as the luminescent screen of a cathode-ray tube) or diffusely transmitting or reflecting (as a television or movie projection screen), depends upon the *luminance* of the surface. Hence if the surface obeys Lambert's law, its luminance is the same in all directions, and it will appear equally bright from whatever angle it is viewed.

LUMINOUS EMITTANCE. The luminous emittance, L, of a surface is the total luminous flux emitted per unit of area, or

$$L = \frac{F}{A} \tag{81}$$

Luminous emittance is measure in lumens per square meter in mks units.

The luminous emittance of a surface *obeying Lambert's law* is found to be

$$L = \pi B \tag{82}$$

Hence a perfectly diffusing (emitting, transmitting, or reflecting) surface, whose luminance is B candles per square meter has a luminous emittance of πB lumens per square meter. Or a perfectly diffusing surface of luminance B and area A emits

$$F = \pi BA \text{ lumens} \tag{83}$$

If the surface radiates on both sides with luminance B, then

$$F = 2\pi BA \tag{84}$$

PHOTOMETRIC UNITS. Equation (82) is the basis for another unit of luminance called meter-lambert. By definition 1 meter-lambert is the luminance of a perfectly diffusing surface emitting, reflecting, or transmitting, 1 lumen per m². Thus 1 meter-lambert equals $1/\pi$ candle /m². This unit (meter-lambert) is very convenient when dealing with non-self-luminous surfaces such as perfectly diffusing (transmitting or reflecting) surfaces. If these surfaces do not absorb any light, the number of lumens incident on them is equal to the number of lumens transmitted or reflected. Hence the illuminance in lumens per square meter, the luminous emittance in lumens per square meter, and the luminance in meter-lamberts are all numerically equal. If these surfaces do absorb some light, the luminance in meter-lamberts is equal to the illuminance in lumens per square meter multiplied by the fraction of the incident light that is transmitted or reflected. The luminous emittance in lumens per square meter is still equal to the luminance in meter-lamberts. If the surface does not obey Lambert's law its luminance depends upon the angle of observation and the advantage of this unit disappears. The luminance of such a surface in a particular direction in meter-lamberts may then be interpreted as the number of lumens per square meter that a perfectly diffusing surface of the same luminance would radiate.

Besides the mks units given above, there are many others in widespread use. They differ from the mks units only in being based on different units of area. Tables 5 and 6 give the names and the relative magnitudes of the more common units of illuminance and luminance.

Table 6. Conversion Factors for Units of Luminance

4. LIGHT MEASUREMENT

The methods of light measurement may be divided into two classes; visual photometry and physical photometry.

In visual photometry the human eye is the detector. Although the human eye is incapable of measuring, it is capable of fairly accurately judging the equality of luminances of adjacent areas. In a visual photometer, two adjacent areas of a screen are illuminated by a calibrated source and an unknown source. The observer adjusts the illuminance on the half-field produced by the calibrated source (by varying the distance between source and screen) until he judges the two half-fields to be equally "bright." The better visual photometers (such as the "Macbeth Illuminometer") use a Lummer Brodhun cube to split the field. Relatively accurate measurements may be made with visual photometers only if the spectral distribution of the calibrated and unknown sources are approximately the same. Although a series of filters may relieve this situation, measurements upon sources of different colors (heterchromatic photometry) are generally subject to great errors unless a flicker photometer is used.

In *physical photometry*, the detector is generally a photovoltaic or photoemissive cell. A cell will give true photometric values regardless of the color of the light if corrected with a suitable filter, so that its sensitivity throughout the spectrum is proportional to the luminosity curve of Fig. 15*a*. The most important error in physical photometry is generally due to the difference between the spectral response of the cell and the standard luminosity curve. Other errors arise from the directional and temperature characteristics of cells. Most commercial light measurements are now made using a photovoltaic cell with an "eye"-corrected filter.

5. PHOTOMETRIC RELATIONS IN NON-VISUAL OPTICAL SYSTEMS

One of the important performance characteristics of an optical system is its light-gathering power. In Fig. 17 the small object of area A_1 radiates in all directions, but the

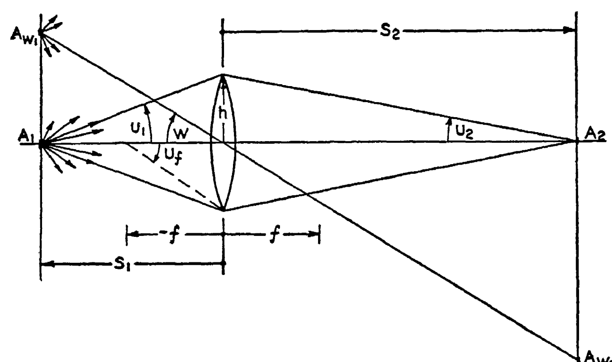

FIG. 17. Diagram Illustrating Some Photometric Relations in Optical Systems

lens accepts and focuses only a fraction of the flux on the image of Area A_2. If A_1 emits according to Lambert's law, then the fraction of the flux that the lens accepts is

$$e = \sin^2 U_1 \tag{85}$$

where U_1 is the angle subtended by the radius of the entrance pupil at A_1. The quantity e might be called the (geometric) efficiency of the optical system. If B_1 is the luminance of A_1, then the total flux, F, that A_1 emits is $\pi B_1 A_1$ and the flux accepted by the lens is

$$F_1 = \pi B_1 A_1 \sin^2 U_1 \tag{86}$$

If the lens has no losses, F_1 is the flux that will reach the image. If there are losses in the optical system, let k be the fraction of the incident light that it transmits, and

$$F_2 = kF_1 = \pi B_1 A_1 k \sin^2 U_1 \tag{87}$$

The quantity $k \sin^2 U_1$ might be called the effective efficiency of the optical system.

The illuminance of the image is

$$E_2 = \frac{F_2}{A_2} = \frac{\pi B_1 k \sin^2 U_1}{m^2} = \pi B_1 k \sin^2 U_2 \tag{88}$$

This equation is the basic relation giving the flux density on a small area (A_2 in Fig. 7) of the image, located on the axis of an aplanatic optical system, produced by an extended source emitting according to Lambert's law.

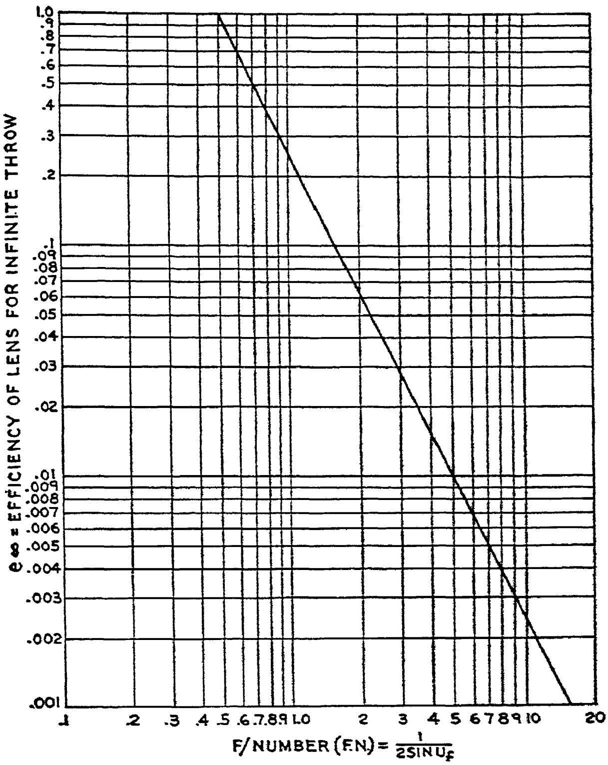

FIG. 18. Efficiency of a Lens Used for Projection at Infinite Throw as a Function of F/Number

Most lenses are rated (as to their light-gathering power) by

$$f/\text{number} = fn = \frac{f}{2h} = \frac{1}{2 \tan U_f} \tag{89}$$

and sometimes by

$$\text{Relative aperture} = RA = \frac{2h}{f} \tag{90}$$

Microscope objectives are rated by

$$\text{Numerical aperture} = NA = N_1 \sin U_1 \tag{91}$$

If the entrance and exit pupils coincide with the principal planes of the optical system, eq. (88) may be written

$$E_2 = \pi B_1 k \frac{h^2}{h^2 + S_1^2} \frac{S_1^2}{S_2^2} = \frac{\pi B_1}{4} k \frac{(RA)^2}{(m^2/4)(RA)^2 + (m-1)^2} \tag{92}$$

For camera and telescope objectives, the object distance, S_1, is usually very large and the image distance, S_2, is approximately equal to the focal length (or $m \cong 0$) so

$$E_2 = \frac{\pi B_1}{4} k(RA)^2 = \frac{\pi B_1}{4} \frac{k}{(fn)^2} \tag{93}$$

If the relative aperture is small or f/number large, then for any magnification

$$E_2 = \frac{\pi B_1}{4} k \frac{(RA)^2}{(m-1)^2} = \frac{\pi B_1}{4} \frac{1}{(fn)^2(m-1)^2} \tag{94}$$

For high-efficiency projection systems, it is preferable to define f/number as

$$FN = \frac{1}{2 \sin U_f} \tag{95}$$

instead of eq. (89). For values of U_f less than about 10°, $\sin U_f = \tan U_f$ and the two definitions agree, but they disagree for larger values of U_f. The efficiency of a projection lens for infinite throw is thus

$$e_\infty = \sin^2 U_f = \frac{0.25}{(FN)^2} \tag{96}$$

For a lens immersed in air, the smallest FN possible is 0.5, since then the efficiency is unity, and all the light emitted is accepted by the lens. For a lens immersed in a medium of index N_1 the efficiency is $e_\infty = N_1^2 \sin^2 U_f$ and the FN is $\frac{1}{2\,N_1 \sin U_f}$. Figure 18 shows the efficiency e_∞ of a lens as a function of f/number. It is seen that the efficiency of most lenses is very low.

The efficiency of a given optical system decreases when the magnification or throw decreases. The efficiency at a magnification m is

$$e_m = \frac{h^2}{h^2 + S_1^2} = \frac{e_\infty}{1 + (1 - e_\infty)\left(\frac{1 - 2m}{m^2}\right)} \tag{97}$$

Thus an ordinary lens with an FN of 2 has an e_∞ of 6.25 per cent and an e_m of about 4.6 per cent when used at a magnification of -6. Similarly a lens with an e_∞ of 25 per cent ($FN = 1$) will have an efficiency of 19.6 per cent at a magnification of -6.

The illuminance of an extra-axial area (Aw_2 Fig. 17) produced with a lens of small aperture is approximately given by

$$E_{2w} = \frac{\pi}{4} Bk \cos^4 W \frac{(\text{R.A.})^2}{4(m - 1)^2} \tag{98}$$

where w is the field angle (see Fig. 17).

6. REFLECTIVE OPTICAL SYSTEM FOR TELEVISION PROJECTION

Two important requirements of an optical system for television projection are: (1) that it be capable of focusing a large field (large tube face) and (2) that it have high efficiency. The need for a large field is that, owing to current saturation and heating of the luminescent screen, the light output from a cathode-ray tube increases with the size of the tube, for a given beam power input.

The most efficient optical systems capable of focusing considerable fields are, in general, of the reflective type. One of the simplest (and best) of these consists of a spherical mirror and an aspherical aberration-correcting lens located at the center of curvature of the mirror (Fig. 19).

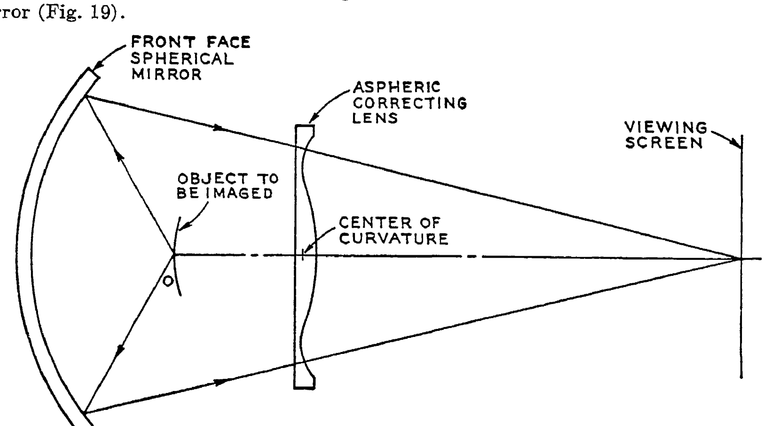

FIG. 19. Reflective Optical System for Television Projection

The aberrations of any optical system with a high geometrical efficiency can be sufficiently corrected for only one position of object and image. As a result a given system is good for only a small range of magnification, and different systems have to be designed for different magnifications or throws. A highly efficient system has, because of the large convergence angles, relatively shallow depth of focus and depth of field; see eqs. (70) and (71).

FOCUSING WITH MIRROR AND CORRECTING LENS. Because of the symmetry of the sphere, an optical system consisting of a spherical mirror and a small aperture located at the center of curvature of the sphere suffers from only two aberrations: spherical aberration which is uniform all over the field, and curvature of the field. With large apertures, extra-axial aberrations of higher order enter the field, but they are not too large (see Fig. 20).

The purpose of the correcting lens is to correct for the spherical aberration of the mirror without introducing any serious aberrations of itself. This is accomplished by making

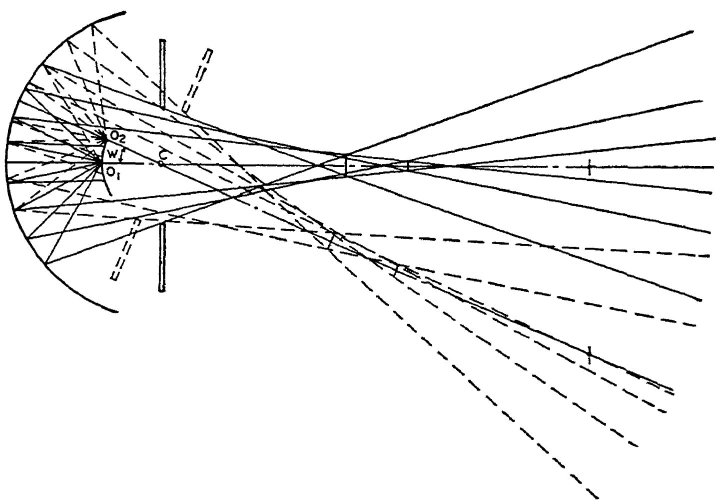

FIG. 20. Image Properties of System Consisting of Spherical Mirror and Aperture Located at Center of Curvature

the lens as weak as possible and locating it in the plane of the aperture at the center of curvature. In this way the symmetry property of the spherical mirror is least disturbed. The curvature of the field is not corrected as it is actually used to good advantage in cathode-ray-tube projection.

Equation (20) may be written

$$\frac{1}{P_1} + \frac{1}{P_2} = -\frac{2\cos U_0}{R} = \frac{1}{f_{U_0}} \tag{99}$$

where f_{U_0} is the focal length of a zone of the mirror of aperture sin U_0. The zonal focal length f_{U_0} thus increases with the aperture of the zone.

The spherical aberration of the mirror may be interpreted as focusing by means of zones, each zone having a different focal length. The correcting lens has to be such that each zone of the lens has a different focal length, compensating for the various focal lengths of the mirror and resulting in a focusing system with all zones of the same focal length.

The shape of the correcting lens will thus depend upon the zonal focal length of the mirror one chooses as the focal length of the optical system (mirror plus correcting lens). Since theoretically there are an infinite number of zones on the mirror, there are theoretically an infinite number of correcting lens shapes that will produce a system in which all zones have the same focal length.

Since the mirror with an aperture at the center of curvature has no extra-axial or chromatic aberrations, such aberrations are caused by the correcting lens itself, i.e., by the power or slopes on the correcting lens. From the standpoint of these aberrations, therefore, that shape should be chosen whose maximum slope is the least. Thus if the paraxial (central) focal length of the mirror is chosen as that of the system, then the central focal length of the correcting lens is infinite and the shape of the curve is concave. If a zonal focal length of the mirror is chosen as that of the system there will be a zonal focal length of the correcting lens which is infinite and the shape of the curve is convex at the center and concave past this zone. If a peripheral focal length is chosen, the required correcting lens is convex. The maximum slope is least for a convex-flat-concave curve.

The shape of the correcting lens must be such that all rays emanating from an object point O_1, and reflected by the mirror, shall meet at the image point O_2 located at a distance S from the correcting lens. Figure 21 shows three rays emanating from O_1 and

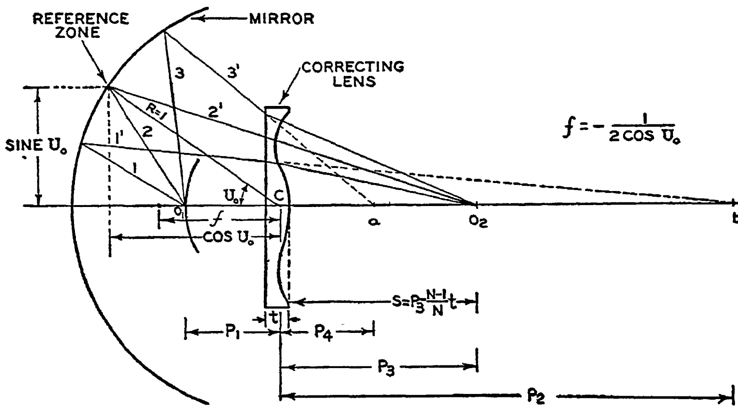

FIG. 21. Diagram Illustrating the Effect of the Correcting Lens

striking the mirror at different apertures. Without the presence of the correcting lens, rays 1, 2, 3 would intersect the axis at distances P_2, P_3, and P_4 from the center of curvature. The slopes on the correcting lens have to be such (approximately as shown on Fig. 21) that all three rays intersect at O_2; hence, the correcting lens has a flat zone at the point where ray 2′ passes, negative slope where ray 1′ passes, and positive slope where ray 3′ passes.

From the point of view of spherical aberration, if the zone where ray 2 strikes the mirror is taken as a reference, then the mirror has negative spherical aberration for smaller apertures and thus requires a positive lens for correction, and positive spherical aberration for larger apertures and thus requires a negative lens.

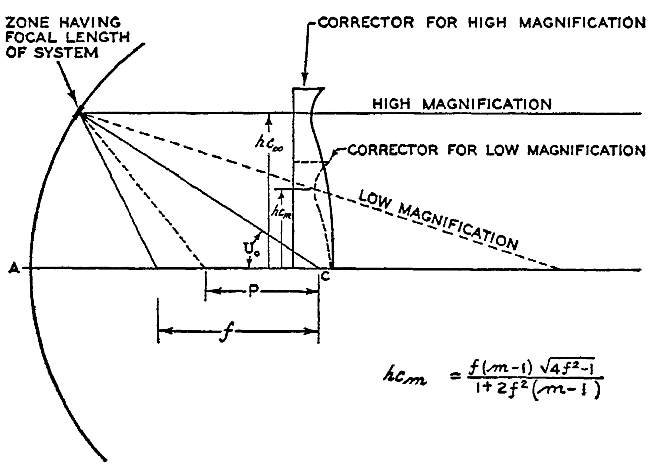

FIG. 22. Diagram Showing Why the Aperture of the Correcting Lens Depends upon Magnification

The shape and size of the correcting lens depend upon the throw or magnification for which the system is to be used. For a given focal length and relative aperture the correcting lens aperture decreases as the magnification decreases (see Fig. 22). That this must be so may be surmised from the fact that for unity magnification the lens aperture is zero, since object and image coincide at the center of curvature. Figure 23 shows the variation of correcting lens semiaperture and mirror semiaperture, with magnification, for a system of given focal length and efficiency. All distances in Fig. 23 are measured in terms of the radius of curvature of the mirror; i.e., the radius of curvature is taken as the unit of length.

The focal length of the complete optical system depends upon the shape of the correcting lens. In general, the higher the efficiency for which a system is designed the greater the focal length (in terms of R). Thus for an extremely inefficient system (requiring only a small aperture at the center of curvature and no correcting lens) the focal length would

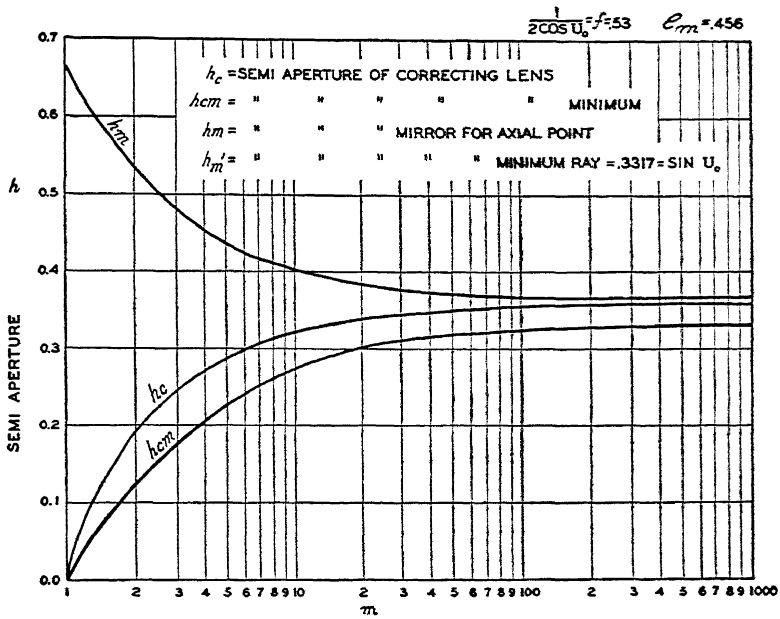

FIG. 23. Variation of Semi-aperture of Mirror and Correcting Lens with Magnification

be $0.5R$, whereas a reasonably good design of a system with an efficiency of about 50 per cent (requiring a correcting lens) will have a focal length of about $0.53R$.

Relations between the throw S, magnification m, object distance P_1, and the focal length f are:

$$S = mP_1 \tag{100}$$

$$P_1 = f\frac{(m+1)}{m} \tag{101}$$

$$S = -f(m+1) \tag{102}$$

Thus for a magnification of -6 (inverted image) and a focal length of $0.53R$ the throw is $2.65R$. In the reflective optical systems contemplated for home television projection receivers $R = 13.7$ in., and so for a magnification of -6 the throw would be 2.65×13.7 in. $= 36.3$ in.

TUBE FACE. Before striking the spherical mirror, the light emitted by the luminescent screen of the cathode-ray tube first passes through a thickness (generally about $1/8$ in.) of glass constituting the tube face. The tube face should preferably consist of two concentric surfaces, and thus it acts as a weak lens. The radius of curvature of the outer surface (for a thin tube face) is approximately equal to the focal length of the system. The lens action of the tube face changes the magnification of the system to

$$M = mm_t = \frac{S}{P_1}\frac{1}{1 - \dfrac{N-1}{N}\dfrac{t}{R_1}} \tag{103}$$

where N, t, and R_1 are the index of refraction, thickness, and radius of curvature of the outer surface of the tube face. However, the largest effect of the tube face is caused by images cannot be seen. The blind spot is roughly elliptical, the vertical dimension being longer. Its size varies greatly among individuals, with limits for horizontal dimensions of 3 to 8 degrees, averaging about 6 degrees. The nearest edge is located about 12 degrees on the nasal side of each retina.

Contrary to other sense organs, the entire nerve system leading to the cortical regions of the brain is found essentially in the retina itself. Here some of the functions may occur which usually take place in the cortex, for example the color-analyzing processes (Polyak).

THE REFRACTIVE MEDIA. The transparent intraocular fluids in all parts of the eye are derived from the blood and physiologically are essentially the same. The fluid in

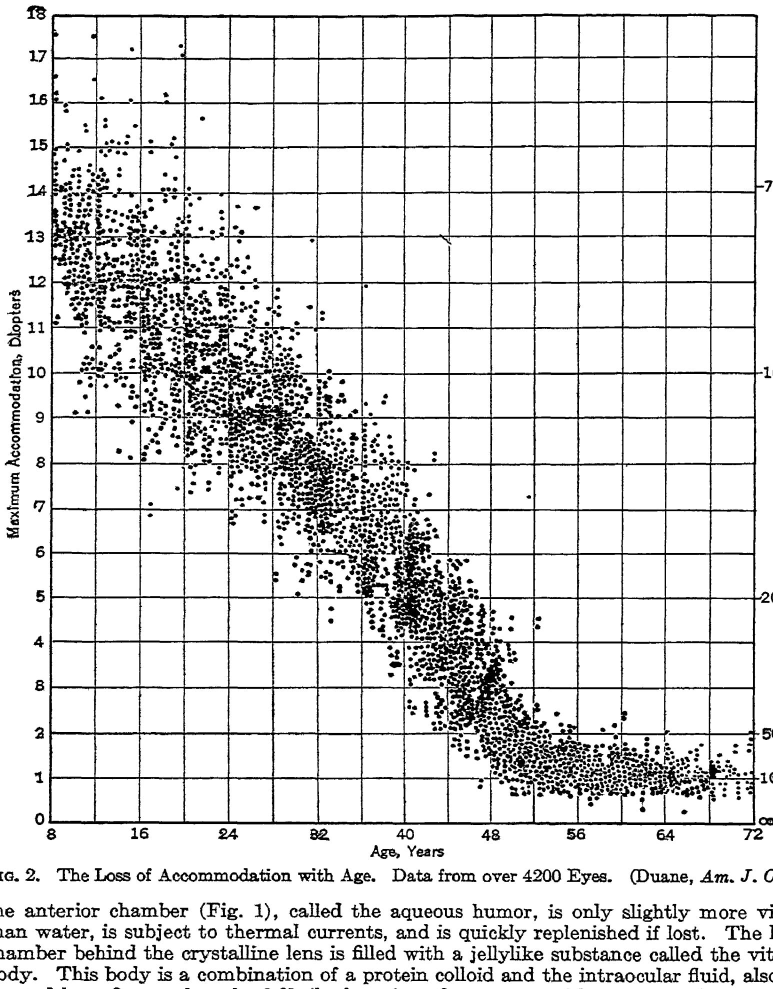

FIG. 2. The Loss of Accommodation with Age. Data from over 4200 Eyes. (Duane, *Am. J. Ophth.*)

the anterior chamber (Fig. 1), called the aqueous humor, is only slightly more viscous than water, is subject to thermal currents, and is quickly replenished if lost. The larger chamber behind the crystalline lens is filled with a jellylike substance called the vitreous body. This body is a combination of a protein colloid and the intraocular fluid, also permeated by a fine meshwork of fibrils that gives the mass a stable anatomical structure.

The crystalline lens is a transparent body having the shape of a biconvex lens, and it serves the same function as a lens. It consists of a non-homogeneous elastic substance made up of a number of layers or laminae, each with increasing density and increasing index of refraction toward the core at the center. By the action of the ciliary body, through a complex process, the lens may become more convex and in so doing serves the function of changing the position of the focal point of the light entering the eye. In this way, the eye can accommodate itself from distinct vision of distant objects to that of nearer objects, and vice versa. In this act of accommodation primarily the radius of the front surface decreases and the thickness of the lens increases.

With increasing age the average density of the lens increases; the lens becomes harder and less elastic and hence its accommodative function is less and less effective. The loss of accommodation with age is illustrated in Fig. 2 (Duane), where the nearest distance from the eye at which a test object remains clear is plotted against age. It is clear that, at about the age of 60 years, little or no accommodation remains, and the eye is then said to be completely *presbyopic*.

THE PUPIL. The pupil acts as the stop or aperture of the eye. It is in a constant state of activity and is subject to a number of reflexes. Although the pupil will contract when the iris is stimulated directly by light, normally it contracts through a light stimulation of the retina, the extent depending on the adaptation of the eye. The pupillary response to light falling on the central part of the retina is much greater than for that falling on the peripheral parts of the retina. The threshold for pupillary response of the central region of the retina, when dark adapted, corresponds quite well to the threshold of cone vision. Data showing the change in the diameter of the pupil in response to the luminosity of an extended surface are illustrated in Fig. 3 (Reeves). Theoretically the amount of light entering the eye would be approximately proportional to the area of the pupil (diameter squared), but it is evident from the figure that, whereas the illumination change is more than several million times, the amount of light entering the eye changes only about 15 fold. The contraction of the pupil cannot, therefore, even approximately compensate for increasing illumination. The rate of contraction of the pupil from darkness to light is much greater than the rate of dilation resulting from light to darkness. The response of the pupil to colored light is greater for yellow than for red or blue.

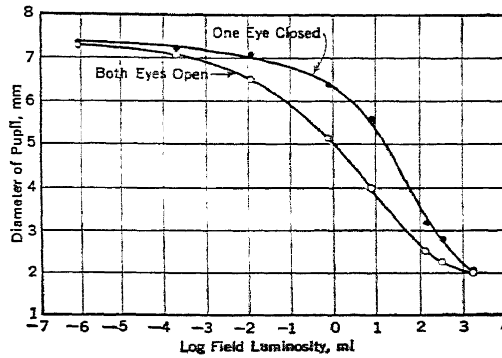

FIG. 3. The Relation between Pupillary Size and the Luminosity of the Visual Field. (Data of Reeves, *J. Optical Soc. Am.*)

In this connection, it has been shown (Stiles and Crawford) that the intensity of the light falling upon the retina is not directly proportional to the pupil area. Rays entering the pupil near the edge are much less effective in producing a sensation than those entering the center of the pupil. The relative effectiveness of the different pupillary zones is shown in Fig. 4.

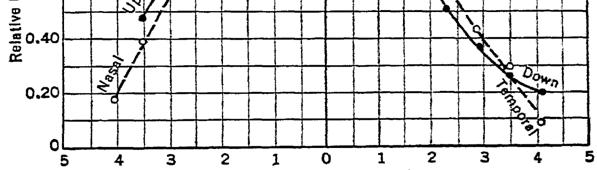

FIG. 4. Data Showing the Stiles-Crawford Effect. Light through peripheral zones of the pupil is less effective than that through the center. (From Moon, *Scientific Bases of Illuminating Engineering.*)

The pupil of the eye contracts when the eyes are converged and accommodated for near objects. This association is more closely related to convergence of the eyes than to accommodation. The reflex takes place in addition to changes in pupillary reaction due to changes in illumination. Automatic constriction of the pupil for near objects increases the depth of focus of the eye, where an increased depth is useful. Under normal conditions pupillary action takes place nearly equally in the two eyes, even if only one eye is subjected to illumination changes. The pupil is also influenced by psychic factors; a dilation is usually the rule, except when the individual is in a comatose state. There is some evidence that pupillary contraction can be conditioned.

SCHEMATIC EYE. Because of the non-homogeneity of the crystalline lens, and the general asymmetry of the optical elements, a schematic eye can be only an approximation to the living eye. Frequently, however, such a schematic eye is useful for reference and for optical problems. The data utilized by Gullstrand for the relaxed eye are given in Table 1. The greater part of the refractive power of the eye is due to the cornea (43 diopters), the lens contributing only $^1/_3$ of the total power. Since the distance of the second focal point from the second nodal point of the schematized eye is about 17 mm, an object subtending an angle of 1 minute of arc will subtend a linear distance on the retina of 5 μ (0.005 mm). In problems where the image on the retina must be considered blurred, it is convenient to know the approximate positions of the entrance and exit pupils. All optical imagery calculations can be referred to those positions if the magnification of the two stops are known. The center of the blurred image on the retina may, for practical purposes, be taken as the point of maximum light intensity.

Table 1. The Gullstrand Schematic Eye Relaxed for Distant Vision

Position of surfaces

Magnification of exit to entrance pupils	0.923	

EYE MOVEMENTS. The rotary movements of each eye are controlled by six (extrinsic) muscles; the opposing external and internal recti muscles which provide movements for looking to the right and left; the superior and inferior opposing recti-muscles which provide movements for looking upwards and downwards; and the two oblique muscles which provide torsional movements about the axes of fixation, as well as movements opposing the recti in certain eye positions. The innervations to the muscles for movements of the two eyes are said to be reciprocal in that a given movement will result from the contraction of one muscle and the relaxation of its antagonist. There is, therefore, a precise coordination of the muscles that leads to very delicate and accurate movements of the eyes. In general it can be said that the ocular movements are for the purpose of directing the eyes to the object of attention and preventing *diplopia* (double vision). The movements seem, essentially, to be reflex movements following the direction of attention and accordingly have been called psycho-optical reflexes. Because the actual movements of the eyes from one point in the visual field to another appear to be approximately correct, it has been assumed that the retinal elements have "motor values," differences in which lead to correct innervations for eye movements. The reaction time between the attention and the beginning of the eye movement, though varying with circumstances, averages between 0.17 and 0.20 sec.

Owing to the constant tonus of the muscles, the eyes are in a continuous state of activity. Thus, even with constant fixation, there are occasional large, jerky movements that average 4 minutes of arc and occur at intervals of 1 to 2 sec. In between these are smaller swinging movements, and superimposed on both are very small vibratory movements.

The voluntary movements are said to be *conjugate* if in the same direction, and *disjunctive* if in the opposite direction, as when the eyes converge for a near object. The limits within which the eyes can move without head movement determine the field of fixation. Obviously, this will vary with anatomical features of the head, but it is illustrated typically in Fig. 5. The disjunctive movements are primarily concerned with convergence movements within which binocular fusion can be maintained, and this is of importance in ophthalmology since abnormalties in this function often lead to ocular discomfort. The "far point" of convergence, which may be behind the head (a divergence of the eyes), can best be measured by ophthalmic prisms, while the "near point" can be measured by bringing a small object nearer and nearer to the nose until doubling occurs. Abnormalities in convergence are frequently associated with refractive errors but may have more deep-seated innervational origins. If one eye is covered while the other fixates a given point, the covered eye may deviate from the direction of the point. This deviation, when binocular vision is prevented, is called *heterophoria*. If the eye deviates outward, inward, upward, or twists about the fixation axis, the phorias are said to be exophoria, esophoria, hyperphoria, and cyclophoria respectively. Almost everyone exhibits at least a small phoria for certain visual distances, and in fact an exophoria of about 2 to 3 degrees for near objects would be considered normal. Phorias frequently are indications that sustained efforts are being made to maintain proper convergence of the eyes in binocular vision.

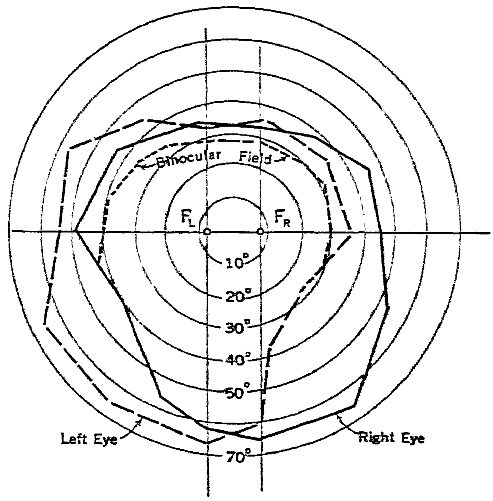

FIG. 5. An Illustration of Typical Monocular and Binocular Fields of Fixation (from Asher, *Arch. f. Ophthal.*)

In reading or similar visual tasks, the eyes make a series of short interrupted movements called saccadic movements. Even between two points, the movements do not occur exactly but may arrive by a series of small successive approximations, one eye usually leading. Eye movements are generally quicker in the horizontal than in the vertical directions, and lateral movements are faster than convergence movements. Convergence movements are more rapid than divergence movements. The speed of movement varies with the excursion, attention, and other conditions, but on the average is between 100 and 200 degrees per second.

8. THE OPTICAL CHARACTERISTICS OF THE EYE

ABERRATIONS. In addition to the usual aberrations, the image on the retina of the eye suffers also from irregular defects due to non-homogeneities in structure and the lack of symmetry in the optical media. The axis of the crystalline lens is tipped and decentered with respect to that of the cornea. The visual axis, which is determined by the fovea as well as the pupil, is usually decentered with respect to both the axes of the cornea and the lens. The spherical aberration is asymmetrical. From the central zone of the pupil to the outside zones the eye tends to be myopic, increasing at first rapidly, then reaching a maximum at 1 mm, beyond which the myopia decreases slowly. The problem of the spherical aberration of the eye is a complex one, and there are not yet enough data to understand it satisfactorily. The chromatic aberration of the eye from the C (656 mμ) to the F (487 mμ) lines of the hydrogen spectrum amounts to about 0.7 diopter. The red rays are focused to a point beyond the retina; blue rays, to a point anterior to the retina. The eye is said to be hyperopic to red, myopic to blue light. The change in chromatic foci for equal changes in wavelength is much less toward the red but increases markedly toward the blue. No entirely satisfactory explanation has been given as to why chromatic halos about images of point light sources are not seen by the eye. For emmetropes (individuals with no refractive error) the eye focuses approximately for the D (580 mμ) or yellow line of hydrogen.

Astigmatism at oblique incidence is a larger aberration. The primary (tangential) astigmatic field differs only slightly from the surface of the retina out to 20 degrees, while the secondary field rapidly increases in the myopic sense to nearly 1 $^1/_4$ diopters at a peripheral angle of 20 degrees. There is very little coma in the eye, and the curvature of the field approximates the curvature of the retina itself. The retinal image is believed to have a slight barrel distortion, though this is difficult to determine because of the subjective asymmetries of the retinas.

These aberrations in themselves, together with diffraction phenomena, would tend to reduce greatly the resolving power of the eye. However, as Gullstrand has pointed out, these aberrations together produce a complex caustic surface in the cone of light converging toward the retina, so that actually the area of maximum light concentration in the image may be small. This makes possible a resolving power whose limit is determined only by the diameter of the receptor nerve endings.

REFRACTIVE ERRORS. The eye can be defective as the result of anomalies in the refractive media or in the length of the eyeball, when it is said to be *ametropic*. The result is blurred retinal imagery, with the attendant loss in sharpness of vision. Regular ametropia is of two types—spherical and astigmatic. The first results from symmetrical abnormalities of the refractive media, or from an increased or decreased length of the eyeball. Astigmatic errors result only from non-sphericity of the surfaces of the cornea and/or of the crystalline lens. When the image focuses inside the position of the retina, the eye will be nearsighted (*myopic*), because only when the objects are brought to the eye will the images move back to the retina and appear sharply defined. In the reverse case, when the point of focus is behind the retina, the eye is said to be farsighted (*hyperopic*), because nearer objects are the more blurred. Nearsightedness can be corrected with a minus (diverging) ophthalmic lens of proper power before the eye; farsightedness with a positive (converging) lens. When astigmatism is present, the light, after entering the eye, focuses not as a point but as two lines separated in space and at right angles to each other. Images of lines in space which are parallel to that focal line nearest the retina will be seen more distinctly than those lines at right angles. For astigmatism, the corrective ophthalmic lens before the eye must have one toric surface. Astigmatism may (and usually does) occur in combination with spherical refractive errors.

Usually, when a refractive error is corrected by an ophthalmic lens, the magnification of the retinal image cannot be predicted. A spherical refractive error due to an elongation (or shortening) of the eyeball, when corrected by a lens, results in practically no magnification (or diminution) of the retinal images. If the refractive error is due to abnormalities in the refractive media, then a magnification (if the correcting lens is for farsightedness) or a diminution (if the correcting lens is for nearsightedness) will occur. The degree of magnification (or diminution) will be roughly 1 $^1/_2$ to 2 per cent per diopter power of the correcting lens. Differences in the magnification of the images of the two eyes may result in discomfort.

DEPTH OF FOCUS. As in any optical instrument, the image falling upon the retina of the eye can be slightly blurred, because of the eye's being out of focus, without an appreciable loss of perceived definition of the image. Thus, with the eye accommodated (focused) for a given distance, objects somewhat nearer and farther than this distance will appear clear. The distance between the two limits of visual distance within which the images on the retina appear not to suffer loss of definition is called the depth of focus. This fact arises, in part, because the maximum light concentration is in the center of the blur circle. Only when the intensity of this central portion is reduced as the blur circle is broadened will there be a loss in definition. The spherical and other aberrations of the eye are such that the depth of focus is greater than might be anticipated from ordinary theoretical expectations. Owing to the constriction of the pupil with accommodation and convergence, the depth of focus increases with the nearness of the fixation object. For distance vision the depth of focus, measured as the difference of the reciprocals of the nearer and farther limiting distances (in meters) for clear vision, is about 0.3 diopter, which increases to about 0.7 diopter for a visual distance of 20 cm. With the eyes relaxed for distant vision, and taking into account that the conjugate point to the retina is usually not at infinity, one could expect all objects beyond 12 ft to be clearly defined. With the eyes accommodated for the reading distance of 16 in. from the eyes, all objects from about 14 $^1/_2$ to 17 $^1/_2$ in. will appear clearly defined.

9. THE LIGHT SENSE

THRESHOLD OF LIGHT VISIBILITY. It must be clear that all determinations of visual thresholds involve problems in psychometrics (Guilford). A given weak stimulus may not always result in a definite response, and a still weaker stimulus will be responded to even less often. One determines, then, the percentage of responses for a number of exposures to the same stimulus strength. The stimulus strength is then varied in fixed steps. What percentage of responses corresponds to the threshold is a matter of definition and varies with the experimenter. It is well to know this in trying to understand and compare threshold data.

As a device for detecting radiant energy, the eye is exceedingly sensitive, though its response is confined to a narrow region of the spectrum, from about 360 $m\mu$ to 750 $m\mu$. The threshold of perception of light varies, of course, with the wavelength of the light, the size of the stimulus, and the length of exposure to the stimulus. It is also different for the cone and rod systems of the retina. Under optimum conditions, and taking the threshold as the 60 per cent response to exposures, Hecht found that with different observers the threshold varied between 2.2 and 5.7×10^{-10} erg measured at the cornea, which amounts to about 58 to 148 quanta of light energy. In this experiment a test light stimulus of wavelength 510 $m\mu$ was used, which subtended a visual angle of 10 minutes of arc, and which was exposed as a flash of 0.001-sec duration. The test light was arranged to stimulate rod vision 20 degrees temporally from the fovea, and the subject was, of course, completely dark adapted.

The relative thresholds of visibility for complete dark adaptation of the rods and cones of the fovea for different wavelengths are illustrated in Fig. 6 (Wald). Here the spectral sensitivities (reciprocal of the threshold stimulus strength) are plotted. The stimulus was a circular field subtending a visual angle of 1 degree, and this was exposed for $1/25$ sec. For the rod vision a point 8 degrees above the fovea was used. It is clear from the figure that the rods at an angle of 8 degrees into the periphery of the retina are 2.5 times more sensitive than the cones at the fovea. The maximum sensitivity (lowest threshold) for the cones occurs at 562 $m\mu$ whereas that for the rods occurs at about 505 $m\mu$. The displacement of the maxima toward the blue end of the spectrum from cone to rod vision is known as the *Purkinje* phenomenon. The fact that at the red end of the spectrum the rods and cones have essentially the same threshold sensitivities is also of special importance.

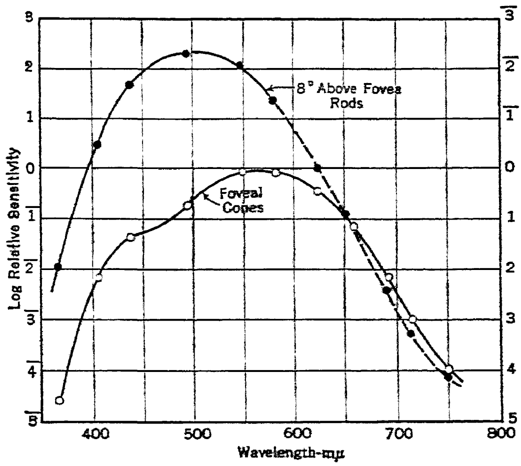

FIG. 6. Spectral Sensitivities of the Rods and Cones of the Eye, Expressed Relative to the Maximum Sensitivity of the Fovea (Wald, *Science*)

The exact relationship between the area of the light stimulus and its intensity just at the threshold of visibility is not entirely known. For the fovea, with areas less than 10 minutes of arc, and for the periphery, for areas between 2 and 7 degrees, the product of the area and intensity is approximately a constant. This fact is known as Ricco's law for the fovea and Piper's law for the periphery. These laws are wholly inadequate for wider ranges of area, and, in general, for larger areas the product of area and intensity appears to be a decreasing function of area.

In a somewhat similar manner, with a constant area, the relationship between intensity and the duration of the stimulus is not fully understood. For brief flashes of duration of less than 0.2 sec, and with small areas, the product of duration of the flash and the intensity is approximately constant (Bloch's law). However, for longer durations this constancy no longer holds, and finally the intensity alone becomes the determining criterion for threshold perception. It has also been found that the stimulation of one part of the retina by a small light source depresses the sensitivity of other parts of the retina for simultaneous but not for succeeding stimuli.

SPECTRAL LUMINOSITIES. The so-called visibility curves for daylight (*photopic*) vision and twilight (*scotopic*) vision are obtained in brightness-matching experiments. A small area illuminated by a narrow region of the daylight spectrum is presented adjacent to a standard field of constant brightness and one to which the eye is adapted. The subject adjusts the intensity of the colored light in the test area so that it is apparently equal to the brilliance of the standard field. The reciprocal of the intensity of the transmitted spectral colors for the match measures the relative brightness values of the visible spectrum. The data are obtained when the brightness of the standard field and the surroundings correspond to average daylight intensities and again to twilight visual conditions. Figure 15, p. 14-14, shows the curves which are usually found but in which the maxima are adjusted for the same height. With luminosities above about 0.01 lumen per sq ft, the photopic or cone visibility curve, which has a maximum at about 555 mμ, is found, while with luminosities below about 0.001 lumen per sq ft, the scotopic or rod visibility curve is found, with a maximum at about 507 mμ. For brightness levels between 0.01 and 0.001 lumen per sq ft there is a gradual shift of the position of the curve, this being a transition from cone to rod vision. The displacement of the maximum is again the Purkinje phenomenon. In very low illuminations the eye responds less and less to the red while still responding to the blue. No Purkinje displacement is found for foveal vision alone.

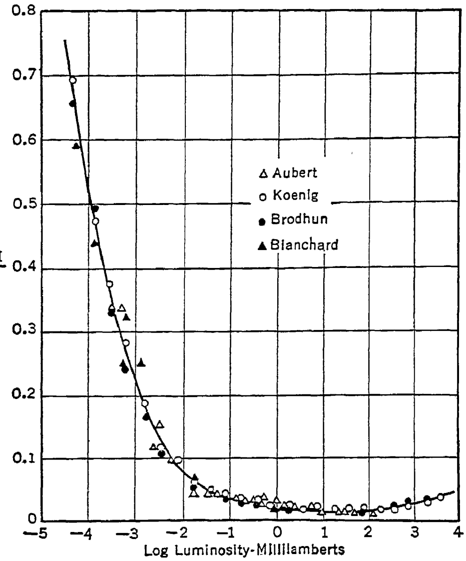

FIG. 7. Typical Data Showing the Differential Threshold of Brightness Discrimination (from Hecht, *J. Gen. Physiol.*)

DIFFERENTIAL SENSITIVITY. The smallest difference in brightness that can just be perceived (just-noticeable difference) between two areas is a measure of the differential threshold of visibility from which one arrives at a value of the differential sensitivity, or contrast sensitivity. The differential threshold varies greatly with the illumination, the wavelength, the size and separation of the test areas, and the luminosity of the surroundings. The differential threshold is expressed as the ratio $\Delta I/I$, where I is the luminosity of the standard area and the adapting field, and ΔI is the difference in luminosity of the test area and the standard area for the just-noticeable difference in brightness. The contrast sensitivity is the reciprocal of this quantity. Typical differential threshold results are shown in Fig. 7, showing data recomputed by Hecht. Because of the wide range in luminosities necessary, the abscissas are plotted on a logarithmic scale. In the photopic

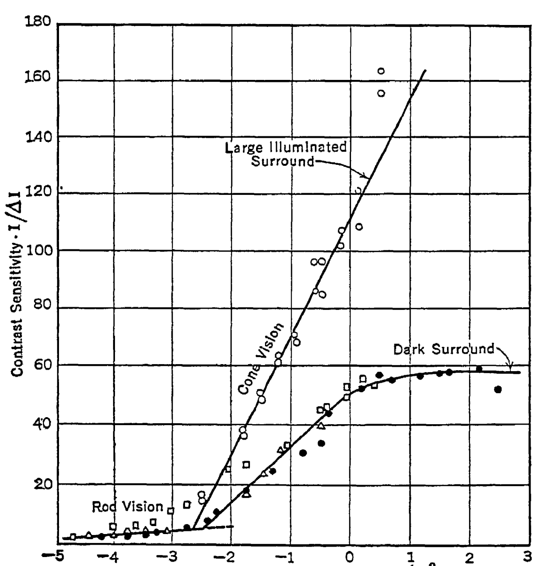

FIG. 8. The Contrast Sensitivity of the Eye, Showing Data of Koenig, Blanchard, Holliday, and Stiles and Crawford (after Moon, *Scientific Bases of Illuminating Engineering*)

part of the curve the fraction $\Delta I/I$ is nearly constant, and only in this region can the differential threshold of the eye be said to illustrate Weber's law. For very high luminosities a slightly decreased sensitivity may be found, but this can be attributed to uncontrolled illumination of the more peripheral surroundings of the test areas. That part of the curve below 0.013 millilambert results from rod vision only, and a somewhat abrupt change near that point is suggested by the data. It is sometimes more instructive to plot the differential threshold data as the contrast sensitivity ($I/\Delta I$), as shown in Fig. 8.

If smaller test and standard areas are used, the sensitivity is less, that is, the curve lies higher on the $\Delta I/I$ axis of the differential threshold graph. Also it is found that, if the luminosity of the surroundings outside of the test and standard areas is kept constant, and then that of the standard area is varied, the differential threshold is increased (sensitivity decreased), and the entire curve lies above the curve shown in Fig. 7. The luminosity of the surroundings of the test field is an important factor in the contrast sensitivity of the eye.

ADAPTATION. When one goes from a brightly illuminated room to one that is only dimly illuminated, several minutes must elapse before details in the room can be discerned. Likewise in going from the dark room into sunlight there are a few moments of blinding glare. In either case, the eyes become adjusted to the prevailing brightness of the visual field in a few minutes. The retinal process by which this occurs, as well as the final stationary state, is called *adaptation*. By the process of adaptation the sensitivity of the eye to contrast differences is automatically changed to meet changing luminosities of the surroundings. In light adaptation (photopic vision) the visual sensitivity of the eye decreases; in dark adaptation (scotopic vision) it increases. In this adaptation the eye adapts itself to changes of illumination of several thousand times.

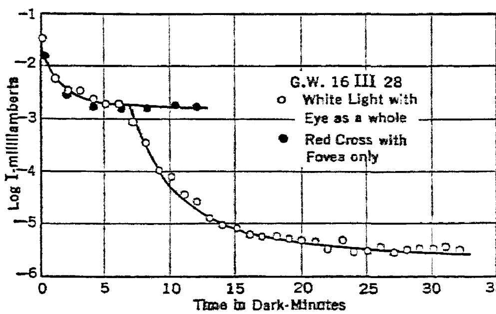

FIG. 9. The Dark-adaptation Curve of the Eye as a Whole and of the Fovea Showing the Behavior of the Cone and Rod Systems (Hecht, *J. Gen. Physiol.*)

Light and dark adaptations are opposing processes and are different for the cone and rod systems of the retina. To a small extent the pupil aids in the adaptation processes. A typical curve showing the progress of dark adaptation of the eye as a whole is shown in Fig. 9. The ordinates indicate the luminosity of the test object at the threshold of visibility at any given moment in the progress of the dark adaptation. The upper curve results from the activity of the retinal cones; the remaining part of the curve results from the rods. The data show that foveal (cone) dark adaptation is nearly complete in 2 to 10 min. For the rods the eye is essentially dark adapted in 40 min, though the sensitivity can still be shown to increase slightly for longer periods of time in total darkness. Anomalies in dark adaptation may be due to vitamin A deficiency.

The progress of dark adaptation varies somewhat with the size of the test object and especially with the intensity of the illumination in the previous light adaptation. There is evidence also that the rate of dark adaptation can be increased and the dark adaptation maintained when the observer wears dark red glasses, adequately shielded, in ordinary illuminations (Rowland and Sloan).

The rate of light adaptation is very much more rapid than dark adaptation. Though dependent upon the intensity of the adapting light, the sensitivity drops to a fraction of its initial value within the first few seconds, and the light adaptation is nearly complete in 1 min.

10. TEMPORAL ASPECTS OF PERCEPTION

PERSISTENCY OF VISION. From the instant the retina is stimulated to the moment the first sensation occurs, a brief interval of time has elapsed. This interval, called the *latent period*, which, in a sense, is a visual reaction time, depends upon the nature and strength of the light stimulus and upon the adaptation of the retina. Under ordinary light conditions, the latent period is roughly between 0.06 and 0.2 sec. As the intensity of the stimulus is increased, however, the latent period decreases to a minimum (0.065 to 0.130 sec), beyond which further increases in intensity will not shorten the latent period.

Above the minimum, this interval varies approximately inversely as the logarithm of the intensity. In dark adaptation, the latent period, for threshold conditions, may be 0.5 to 1 sec, depending upon conditions. The latent period is generally shorter in the peripheral parts of the retina than at the fovea, and shorter for blue light than for red.

With a flash stimulus, the sensation persists for some time after the stimulus has ended. The magnitude of the light sensation and its duration vary with the adaptation level of the eye, that is, the luminosity of the background upon which the stimulus is seen and the strength of the stimulus. Typical curves are shown in Fig. 10. The duration of the impressions from stimuli of equal brightness is longer for the fovea than for the peripheral parts of the retina and is generally increased as the eye is more dark adapted. An increased intensity of the stimulus results in a decreased duration time. For colored light the persistence of the sensation varies inversely to the apparent luminosities of the visibility curves and hence is shortest for yellow, longest for blue, and intermediate for red.

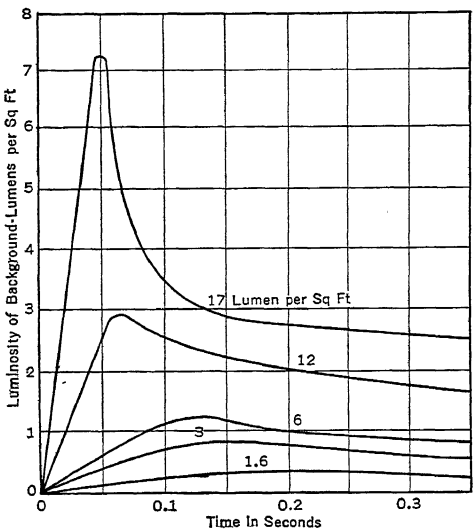

FIG. 10. Illustration of the Apparent Brightness and the Duration of the Light Sensation Following a Flash Stimulus (Data of Broca and Sulzer, from Luckiesh and Moss, *Science of Seeing*)

After the first sensation has faded away, several after-images may again appear at intervals depending upon the luminosity of the surroundings and the intensity of the stimulus. If the after-image corresponds to the original impression as regards contrast and color it is called positive; if the light-to-dark relationships are reversed and the colors are complementary to the original impression it is called negative. Considerable practice is sometimes necessary to see these images, for conditions of fatigue, adaptation, and inhibition may greatly affect their appearance. The typical sequence of after-images is illustrated in Fig. 11, where the ordinate represents the relative brightness of the after-images, positive above and negative below the abscissa.

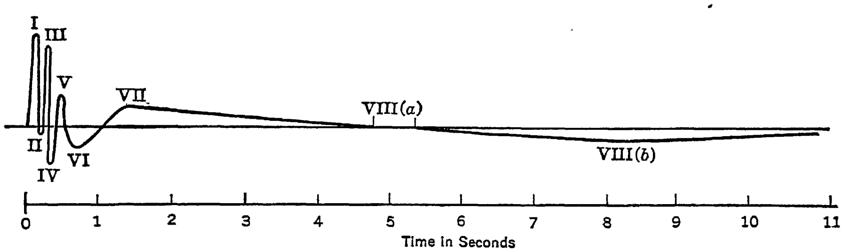

FIG. 11. Diagram of the Sequence of After-effects Following a Flash Stimulus in the Light-adapted Eye (after Tschermak-Bethe, *Handb. normal u. path. Physiol.*, 12/1, II)

PERIODIC STIMULI AND FLICKER. Periodic light stimuli may be perceived as discrete flashes, but if made sufficiently rapid, so that the persistent sensation from one stimulation curve overlaps the rise of the primary sensation from the succeeding stimulation, the sensation will be the same as that for a continuous illumination.

The brilliance of fused periodic stimuli which have different intensities is the same as the average intensity (Talbot's law), that is, the integral of the photometric luminosity of the periodic stimuli divided by time. This law holds accurately except for extremes of high and low intensities. That frequency at which periodic stimuli are first perceived as a steady illumination (fused) is known as the *critical flicker frequency*, which may be abbreviated to c.f.f. The critical flicker frequency varies with the illumination, the part of retina being stimulated, the area of the flickering field, the ratio of the light-to-dark intervals of the flashes, the retinal adaptation, the wavelength of the light, and the presence of other steady light stimuli also falling upon the retina. So reliable is the c.f.f. under controlled conditions that it is sometimes used to measure luminosities and adaptation levels.

The manner in which the c.f.f. for small test fields illuminated with white light varies with illumination and for different parts of the retina is shown in Fig. 12. In the rod-free area at the fovea, the c.f.f. varies proportionately with the logarithm of the illumination (Ferry-Porter law), except at the extremes of the illumination. The maximum critical frequency is about 53 cycles per second. The c.f.f. decreases for flicker stimuli on the peripheral parts of the retina. If the area of the flickering field is large, however, the

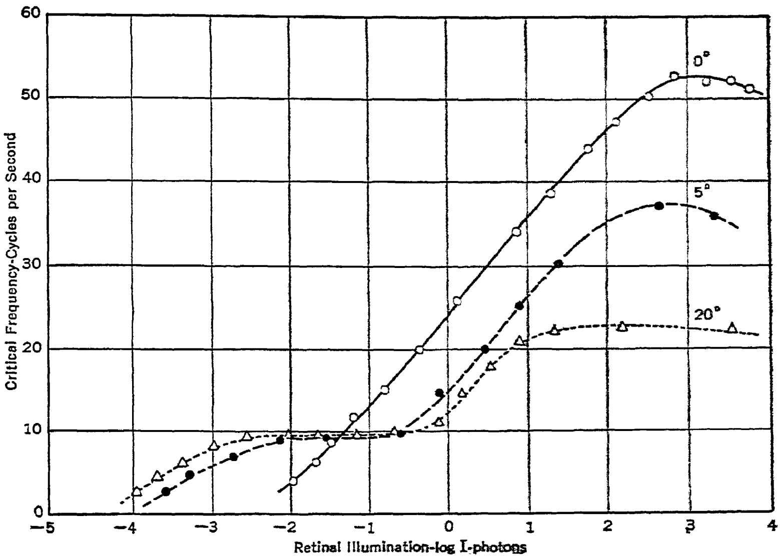

FIG. 12. The Relationship between the Critical Flicker Frequency and the Illumination, for Different Parts of the Retina (Hecht, *J. Gen. Physiol.*)

critical frequency may be found higher in the periphery, which indicates a spatial summation of the retina in the periphery. The curves generally appear to be in two parts, a division which is attributed to the rod and cone behavior. The c.f.f. for various colored stimuli is substantially the same as for white light if their apparent luminosity is the same as that of the white light and the intensity is above the cone threshold.

In the curves shown in Fig. 12, the duration of the light phase was equal to that of the dark. Where the dark phase is longer, generally higher critical frequencies are found, and when shorter, lower critical frequencies are necessary, especially in the ordinary ranges of illuminations. Only at high intensities of the light stimuli will this generalization be invalid. Rapid eye movements or rapidly moving periodic stimuli enhance the appearance of flicker, and under these conditions higher frequencies are necessary. A steady illumination of one part of the retina changes the c.f.f. of a periodic stimulus in another part if the separation of the two stimuli is not too great. In general the c.f.f. increases as the brightness of the steady stimulus is increased, until a maximum is reached, beyond which it then decreases.

Bartley found that for periodic stimuli below the c.f.f., and at about 8–10 flashes per second, there is a marked enhancement of the apparent brightness of the stimuli.

11. COLOR

A clear differentiation must be made between the *color stimulus* and the *color sensation.* The color sensation and all the associated phenomena are purely psychological (experiential). The stimuli measured in terms of energy and wavelength are physical. The color problem is fundamentally the finding of the relationships that exist between the color sensation and the physical stimuli. Moreover, relationships found for color mixtures from spectral light will not necessarily be true when colored pigments are mixed. This fact has led to much confusion and controversy. The spectral luminosities reflected from pigments, however, are subject to the same laws as those from spectral light.

Colors are ordinarily seen as properties of objects and hence are usually associated with the objects themselves. There are, therefore, many psychological constancy phenomena in which objects tend to retain their color and brightness when seen in varying conditions of light and shade. Photographic scenes in color projected in an otherwise darkened room tend to retain normal color relationships in spite of actual wide deviations. Under other conditions where these reproductions are viewed against backgrounds of stable color and contrast relationships, these deviations are more readily apparent. To study correlations between the quality of color experience and the physical composition of light, the test fields must be dissociated from known objects having spatial values. These psychological facts are important in dealing with color problems.

A given color sensation is said to have three dimensions: *hue, saturation,* and *brilliance.* Hue is associated with the dominant wavelength of the light stimulus. Saturation indicates the amount or degree of the hue present (deep-red as against pale-red) and represents the ratio of the luminosity of the pure spectral light to that of the white light present. Brilliance (apparent brightness, apparent luminosity) indicates the total intensity (energy) of the colored light stimulus. Frequently, hue and saturation are considered together under the term *chromaticity.*

SATURATION OF THE SPECTRAL COLORS. All spectral colors do not appear equally saturated, that is, some have a greater sensation of white than others. The ratio of the luminosity of the least perceptible spectral color to the luminosity of a background field defines the least-perceptible colorimetric purity for that color. Two halves of a test field are equally illuminated with white light. To one half a spectral color is added, and, in order that the brightness of the two fields shall be the same, the luminosity of the white light of that field is decreased as the spectral color is added. The intensity of this spectral color is then increased until the two halves of the field just appear different in color. From the luminosity of the added spectral colors the colorimetric purity of the spectrum can be found. Figure 13 illustrates data obtained in this manner. It is clear that a great deal

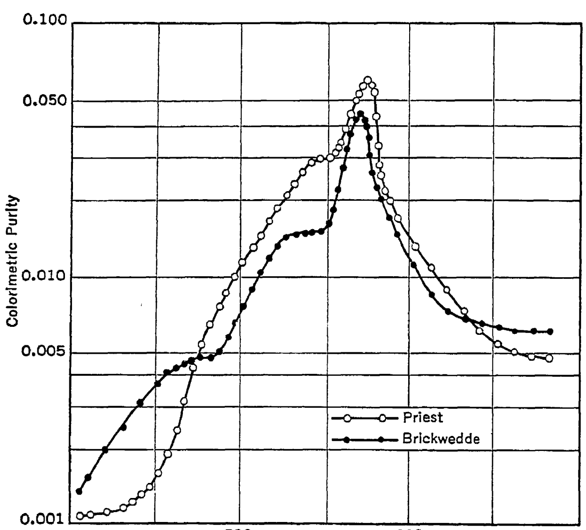

FIG. 13. The Least-perceptible Colorimetric Purity of the Visible Spectrum (Data of Priest and Brickwedde, after Hecht, *J. Gen. Physiol.*)

more of yellow than red or blue is required to produce a least-perceptible color, and yellow is therefore considered a less saturated color than red or blue.

HUE DISCRIMINATION THRESHOLD. The change in wavelength corresponding to a just-noticeable difference in color varies over the spectrum and also somewhat with the individual. In general, however, the data are similar, and the resultant curves show three maxima and three minima. In Fig. 14 are illustrated representative data for an individual with normal color vision. The discrimination is poorest at the ends of the spectrum, especially in the red.

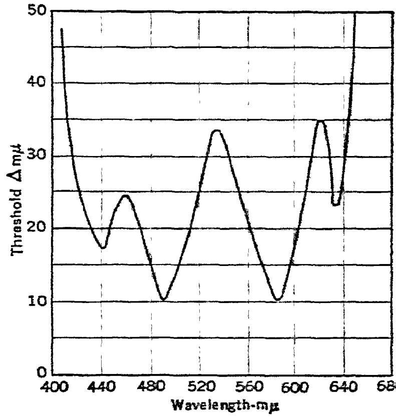

FIG. 14. The Least-perceptible Difference in Color for the Visible Spectrum (Data of Jones, *J. Optical Soc. Am.*)

COLOR SPECIFICATION. The color stimulus (as distinct from the color sensation) of any color field can be specified quantitatively by the luminosity of the radiation given off for each part of the spectrum. This can usually be measured by a spectroradiometer or a spectrophotometer. Under any condition, the objective color from a given surface can then be specified by a spectrophotometric curve obtained from those measurements.

The eye itself cannot analyze the radiation from a color stimulus as can the spectrophotometer, for it responds in a complex manner dependent not only upon the visual processes and their reaction to light stimuli but also upon certain psychological factors. There are, therefore, many different objective color stimuli, as specified by spectrophotometric curves, which will result in the same color sensation. It is possible, however, to transform the data from the spectrophotometric measurements by means of standard data from color-matching experiments, so that equal color sensations can be specified by three quantities derived from the objective stimulus.

The I.C.I. (International Commission on Illumination) system is that most used for accurate color specification. It is based upon the theory that the chromaticity (hue and saturation) of any color stimulus can be specified by three quantities, which represent the proportions of three selected primary light distributions that are necessary to match the color sensation evoked by a given stimulus. The amounts (luminosities) of each of three selected primary color sources that must be added together in order to match a given spectral color are determined by these color-matching experiments. These amounts are called the *tristimulus* values of the three primaries for that color. Three standard spectral distributions of equal energy, whose tristimulus values are $\bar{x} = f_x(\lambda)$, $\bar{y} = f_y(\lambda)$, and $\bar{z} = f_z(\lambda)$ (λ being wavelength), are especially selected, with dominant wavelengths in the red, green, and blue respectively. Cf. Fig. 15. These primary distributions are obtained by transformations from the experimental data with real primaries; they are specially selected to avoid negative tristimulus values and to meet other requirements for a convenient system. The $\bar{y}$ spectral distribution function has been made to correspond to the photopic visibility curve. Any homogeneous spectral radiation can be specified by the tristimulus values read directly from the curves or special tables (Hardy). For a spectral radiation objectively specified by a spectrophotometric

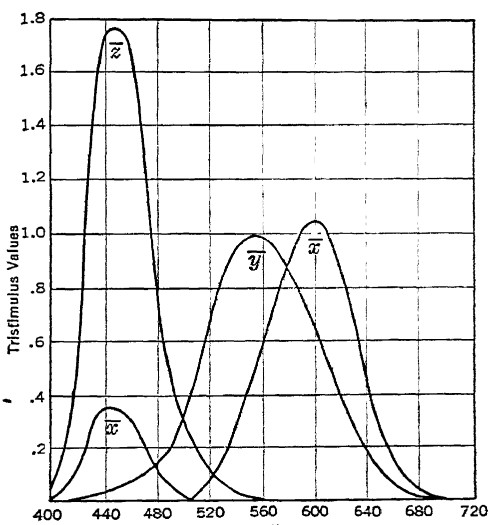

FIG. 15. Tristimulus Values for the Various Spectral Colors. The values $\bar{x}$, $\bar{y}$, $\bar{z}$ are the amounts of the three I.C.I. primaries required to match in color a unit amount of energy having the indicated wavelength. (Hardy, *Handbook of Colorimetry.*)

curve, the tristimulus values are found by summing up the products of the energy E_λ for all wavelengths by the corresponding tristimulus values from the standard primaries from the tables, viz.,

$$x' = \int_0^\infty \bar{x}E_\lambda \, d\lambda \qquad y' = \int_0^\infty \bar{y}E_\lambda \, d\lambda \qquad z' = \int_0^\infty \bar{z}E_\lambda \, d\lambda$$

Through the choice of primary standard distributions the second integral gives directly the relative luminosity (brightness) of the color stimulus on a black (zero) to pure white (100) scale. In practice, the tristimulus values for any spectrophotometric curve are computed by averaging the products of $\bar{x}E_\lambda$ (and $\bar{y}E_\lambda$ and $\bar{z}E_\lambda$) for equally spaced wavelengths.

The values of x', y', and z' do not necessarily measure the color sensation, but they do state the conditions under which different spectral stimuli will result in the same color sensation. It must be borne in mind that this sensation may vary slightly between individuals and even with other factors, such as size of field and conditions of the surrounding fields.

THE CHROMATICITY DIAGRAM. A convenient graphical representation of the chromaticity of any spectral stimulus is made by plotting the trichromatic coefficients which are defined by the ratios

$$x = \frac{x'}{x' + y' + z'} \quad \text{and} \quad y = \frac{y'}{x' + y' + z'}$$

and the third would be related to the other two by $x + y + z = 1$. The result is the standard chromaticity diagram in which colors of equal luminosity are represented in terms of dominant color and saturation. See Fig. 16. Color matches are known to be stable through wide limits of luminosity; hence, this representation is valid.

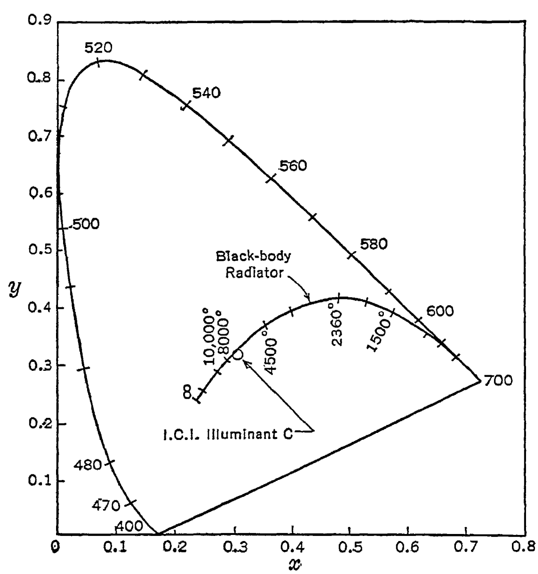

FIG. 16. The Chromaticity Diagram, Showing the Geometrical Arrangement of the Spectral Colors and the Locus of White Lights (after Hardy, *Handbook of Colorimetry*)

The visible spectrum arranges itself in a horseshoelike curve beginning with red (700 mμ) and passing counterclockwise through orange, yellow, green, blue to a deep purplish blue (400 mμ). The straight line joining the ends of the spectrum contains the purples. Clearly, this line is not part of the spectrum. White light is represented by various points on a curve near the center of the diagram, its exact position depending upon the temperature of the source. The luminant recommended by the International Commission on Illumination is shown on the diagram at C. Any given color stimulus will also be represented by a point within this curve. Figure 17 shows the approximate color names for the different portions of the diagram. The dominant wavelength of any stimulus will be given by the place where a straight line drawn through C and the point intersects the nearest part of the spectral curve. The complementary wavelength will be the intersection point on the spectral curve diametrically opposite. The saturation or excitation purity of a given color can be determined from the ratio of the distances of the point from C, and from the dominant wavelength on the spectrum curve. The resultant color of a mixture of any two colors represented by two points on the I.C.I. diagram will be represented somewhere on the straight line drawn between the two points. The advantage of this representation is its direct quantitative application to spectrophotometric data. Its disadvantage, however, lies in its graphical distortion of color differences.

OTHER SYSTEMS. The Ostwald and Munsell systems consist of orderly arrangements of colors based upon their visual relationships, and not dependent upon the mixture of pigments or upon the physical measurements of the light, and independent of the illumination. Both these systems are illustrated in carefully prepared charts with orderly arrays of colored patches, which vary in hue, saturation, and value according to the concept of the author.

COLOR TOLERANCE. Nearly as important to color specification is the necessity of knowing color tolerances. The most thorough study, to date, is that of MacAdam in which the color tolerances in changes in hue and in saturation were determined.

COLOR ADAPTATION. If the eyes are subjected to a large field of a spectral color for a period of time, the perception of hue of other colors becomes modified and distorted. This may be in the nature of an adaptation. Two electric lamps, one white and one colored, say red, are set in front of a large white screen several feet apart. Then an object is placed nearer the screen in between the lamps, so that two shadows, one from the white and one from the red lamp, are cast upon the screen. Upon continued observation it will be found that the shadow cast from the red lamp will appear green, complementary to the red color, while the shadow from the white light will appear red. In the general perception of colored objects in fields of familiar detail, the color relationships tend to remain the same, in spite of rather wide variations of illumination intensities and even color. If the visual fields are isolated and confined, however, to small areas, apart from the larger field, this color-constancy phenomenon tends to disappear.

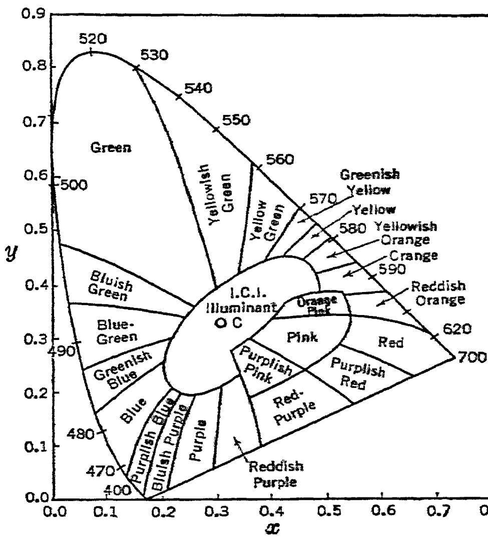

FIG. 17. Approximate Color Names for Various Parts of the Chromaticity Diagram (Kelley, *J. Optical Soc. Am.*)

12. THE SPACE SENSE

It is necessary to distinguish clearly between objective space, filled with real objects, and *visual space*, filled with *visual objects*. It is somewhat meaningless to ask whether the position of visual objects is identical to that of the real objects. It is only necessary that the relationships between visual space and objective space be sufficiently stable so that the organism can effectively operate within real space. The visual perception of space is essentially egocentric in that objects are localized with respect to the body. The final perception of space arises through a complex integration of (1) the visual clues inherent in the pattern of the dioptric images that fall on the retinas, (2) the simultaneous impressions from the other senses, (3) experiential factors that have been associated with visual, auditory, and tactile stimuli, and (4) the immediate attention of the individual. It is convenient to regard space perception in terms of (1) the discrimination of direction (egocentric and bidimensional), and (2) the discrimination of depth, that is, the third dimension.

DIRECTION LOCALIZATION. By virtue of the discrete make-up of the retina (the retinal mosaic), the various parts of the dioptric images on the retina can be differentiated through some type of "local signs" associated with the retinal elements, which, in this case, is a subjective visual direction. Resolving power and visual acuity are measures of the keenness with which this differentiation can be made. The fovea is the primary point of reference, and the subjective direction of objects is described in terms of "breadth" (right or left) and "height" (above or below) the point of fixation which is imaged on the fovea. The subjective visual directions then are relative to the fovea. By a reflex process associated with the eye, head, and body movements, the change in the subjective direction of the whole visual field that would occur with eye movements is counteracted, so that objects tend to appear in the same "absolute" direction in spite of the fact that the images move across the retina.

The precision of the relative subjective direction varies greatly with the character of the visual field, and in many cases estimations actually are inaccurate. Probably the highest precision is in the estimation of when lines are parallel or when they are straight, and in the comparison of angles whose corresponding sides are parallel. In the estimation of differences in length, a greater precision is found in the horizontal than in the vertical. Vertical distances, moreover, look longer than equal horizontal distances. In the estimation of lengths, accuracy varies with the lengths to be compared and their relative positions. When attempting to determine the center of line segments without eye movements, the eye tends to overestimate the portion on its own side (Kundt partition phenomenon), though frequently the reverse is found. Subdivided and filled spaces look longer than unfilled spaces. Acute angles are generally overestimated and obtuse angles are underestimated. Magnitudes are diminished in the presence of larger magnitudes and magnified in the presence of small ones. Many of the well-known illusions are examples of these errors in the perception of direction.

VISUAL ACUITY AND RESOLVING POWER. The *visual acuity* of the eye is the degree to which it is able to discriminate fine detail in the visual field, and this varies considerably with the type of detail, the contrast, illumination, surrounding brightness, adaptation level, etc. In a strict sense, *resolving power* is more definitive than visual acuity; it is measured as the reciprocal of the smallest visual angle (usually in minutes of arc) by which two objects can be seen separately. The theoretical limit of visual resolution would be determined by the size of the diffraction circles on the retina and the dimensions of the retinal elements. However, for pupils of normal and larger sizes the spherical and chromatic aberrations, together with small irregular astigmatism that is usually present, modify the nature of the light intensity distribution within the image, so that, with the contrasts ordinarily encountered, the resolution is better than that based upon diffraction alone. For small pupils a marked decrease in acuity is found, probably resulting from the increased size of the diffraction circles, but for pupils larger than 2 to 3 mm the acuity remains nearly constant (Cobb). Faint stars whose angular separation is 1 to $1\,{}^1/_2$ minutes of arc can usually be resolved. With small point light sources of low contrast with respect to the background, the minimum angle of resolution may be 100 seconds with a mean error of 5 seconds of arc. With repeating patterns such as lattices, grids, or checkerboard patterns the minimum angle of resolution varies between 50 and 75 seconds of arc, under optimum conditions.

The eye is, of course, capable of much finer discrimination of detail than that which would be obtained on the basis of resolving power alone. Experiments which indicate this fine appreciation of detail involve least-perceptible differences in contours. These differences have been expressed as the mean error of settings, or in the 50/50 point, in correct judgments. Typical results are shown in the table below.

Test	*Mean Error, seconds*	*Authority*
Widening of lower half of slit	10–12	Wulfing (1892)
Coincidence of vertical lines (the vernier)	8–12	Brian and Baker (1912)
Coincidence of vertical lines (the vernier)	13	Best (1900)
Coincidence of vertical lines (the vernier)	3	Langland (1929)
Coincidence of vertical lines (the vernier)	0.6	French (1920)
Coincidence of vertical lines (the vernier)	2	Wright (1942)
Error in contact of white disks on dark background	15	Dale (1920)
Alignment of edges of two rectangles	10	Hering (1899)
Error of setting range finders	2–6	von Hofe (1920)
Stereoscopic displacement of images	5–7	Florian (1930)

In general, where such fine discrimination can be seen, the retinal images of the detail (such as extended lines) involve the activity of a larger number of retinal elements. Except for monochromatic yellow light, visual acuity is decidedly poorer under colored illuminants than under white light. This is especially true of blue and only slightly less so under red illuminations. Part of this latter decrease in acuity is undoubtedly related to the chromatic aberration of the eye.

Visual acuity is usually measured by a test chart of letters of graded sizes, in spite of certain obvious inherent faults. Visual acuity is considered normal when letters can be identified the separation of adjacent parts of which subtend an angle at the eye of 1 minute of arc. A line of letters, each of which subtends a 5-minute visual angle, is printed on a chart in sequence for visual distances of 10, 15, 20, 25, 30, 40, 60, 100, and 200 ft. These letters are usually arranged with the smallest at the bottom of the chart, and with a single large E at the top. The acuity tests are usually made at a visual distance of 20 ft, and that line of letters which the subject can just read is then recorded relative to 20 ft. Thus 20/20 represents normal vision; 20/15 indicates that print which could ordinarily be read at 15 ft can be read at 20 ft and therefore the acuity is better than normal; and 20/100 indicates that that type which should be legible at 100 ft can be read only at 20 ft and therefore the acuity is much less than normal. Other test objects frequently used are the Snellen hook, the Landolt broken ring, and checker-board patterns.

Because of the increased size of the photosensitive elements toward the peripheral parts of the retina and the greater number of them associated with single conductor nerves, together with the increased magnitude of the optical aberrations toward the periphery of the eye, it is to be expected that the resolving power of the eye would fall off rapidly toward the periphery. Figure 18 shows this decrease in resolving power with the increase

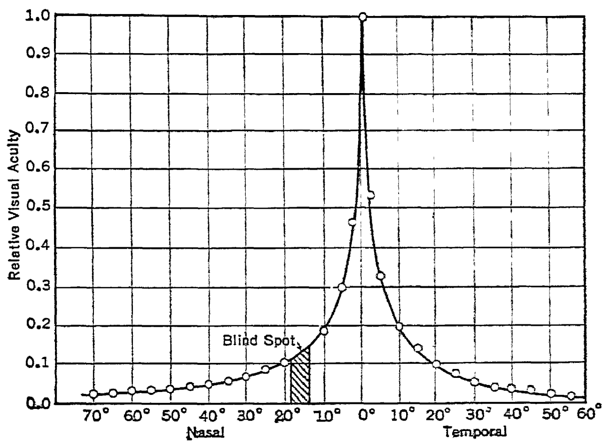

Fig. 18. The Decrease in Visual Acuity toward the Peripheral Parts of the Retina (Wertheim)

of the peripheral angle (data of Wertheim). A very rapid decrease in acuity occurs to about 5 degrees, and from there the decrease is much slower. This loss of acuity is not the same in all the meridians of the eye but is greater in the vertical meridian than in the horizontal. Figure 19 shows the isopters of the retina, that is, the curves of equal visual acuity (data of Wertheim).

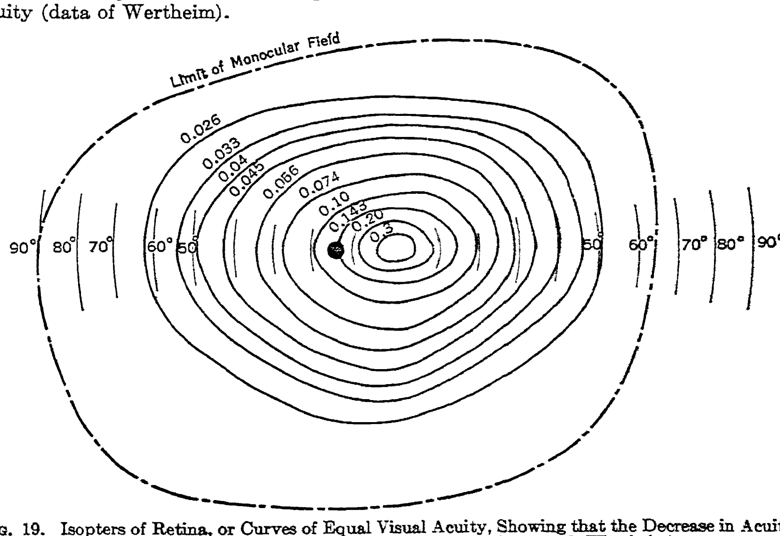

Fig. 19. Isopters of Retina, or Curves of Equal Visual Acuity, Showing that the Decrease in Acuity is Greater in the Vertical Meridian than in the Horizontal (Wertheim)

There has been evidence that visual acuity is greater for distant vision than for near vision. This phenomenon is believed to be dependent upon the type of test and the conditions under which the test is made, especially for peripheral vision, because opposite results have been reported.

IRRADIATION. Owing to the aberrations of the optical system of the eye, the images of discrete points are not defined with sharp boundaries. Rather, the intensity of the light in the image falls off in a bell-shaped curve. The perceived contour depends upon the differential sensitivity of the eye, but the image always corresponds to an object larger than the original. The position of the perceived contour will tend to be toward the less intense end of the light distribution curve. Accordingly, bright objects seen against a dark background appear larger than dark objects of equal size against a bright background. This phenomenon, called *irradiation*, depends upon the relative luminosity of the adjacent surfaces and varies with individuals because of differences in ocular aberrations. Objects of large angular size are increased proportionately only to a small extent, and their size can be said to remain constant. For small objects, however, the irradiation increases with decrease in angular size. On the other hand, the separation of small black lines against a bright background may actually appear larger than it is. This so-called negative "irradiation" is explained, however, by the influence of the mechanism of *simultaneous contrast*, whereby the apparent brightness (or color) of an area is influenced (enhanced) by adjacent areas of different brightness (or color).

VISUAL ACUITY AND ILLUMINATION. The visual acuity of the fovea of the eye increases markedly with an increase in the luminosity of the field, but that of the peripheral retina changes scarcely at all. In general, then, studies on visual acuity and illumination pertain to foveal vision. The data of König illustrated in Fig. 20 (as recomputed by Hecht) are among the most complete on this phenomenon. They were obtained with a black test object upon a white background and are therefore of maximum contrast. For illuminations from 0.013 to 10 lumens per sq ft the visual acuity is approximately proportional to the logarithm of the luminosity. The visual acuity obtained at lower illuminations decreases rapidly in the neighborhood of 0.001 lumen per sq ft, where scotopic vision begins. From here, for lower illuminations, only rod vision is involved and the change in visual acuity is small. Although König's data show a maximum for illuminations greater than 100 lumens per sq ft, and thereafter a constant visual acuity, more recent data have indicated that this maximum is due to the fact that the brightness of the field surrounding the background of the test object was low compared to that of the test object itself. In experiments where the brightness of the surrounding field is the same as that of the background for the test object, a maximum is not found and the visual acuity continues to increase at only a slightly lower rate with a continued increase of illumination. The visual acuity is lower for colored light than for white of the same brightness, being poorer in the order green, red, blue. In general, visual acuity is also reduced under conditions of glare.

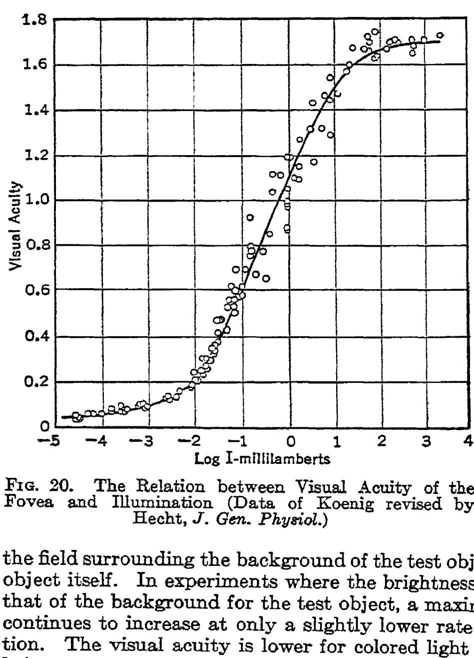

FIG. 20. The Relation between Visual Acuity of the Fovea and Illumination (Data of Koenig revised by Hecht, *J. Gen. Physiol.*)

When detail is exposed for short intervals of time (less than about 1 sec), and the luminosity of the background remains constant, the visual acuity varies roughly with the logarithm of the time of exposure. Below exposure times of about 0.01 to 0.03 sec, depending upon the illumination, the product of time and illumination is constant for the same visual acuity.

In König's data the contrast, defined as the ratio of the difference in luminosity of the background and the test object to the luminosity of the background, was very high. It has been shown that with lower contrasts the visual acuity is also lower. Figure 21 illustrates data from Cobb and Moss on the relationship between contrast and visual acuity. No data are available for bright detail against a darker background.

MINIMUM VISIBLE. Similar to the problem of visual resolution is that of the minimum visible. What is the angular size of the smallest detail that can be perceived? As in resolving power, this depends upon an intensity discrimination within the image on the retina and hence varies with the nature of the dioptric image, the contrast sensitivity of the eye, the size and form of the detail, exposure time, etc. Lines are more readily seen than dots, and repeating patterns of dots, lines, etc., are perceived even more readily. Small voluntary and involuntary eye movements also aid in the discrimination of fine detail. Under general illumination a line against a bright background can be seen when its width subtends a visual angle of 3 to 4 seconds of arc. Hecht and Mintz found that with a similar test object the angular width of a wire that could just be seen varied from 10 minutes to 0.5 second over the complete range of illuminations. The minimum value 0.5 second represents a discrimination of about 1 to 2 per cent difference in light intensity in the image on the retina. When a narrow illuminated slit that is exposed for short durations is just visible, it is found that (visual angle) × (duration of exposure) × (adapting luminosity of background) is approximately a constant for flashes of 0.004 to 0.189 sec of duration (Niven and Brown).

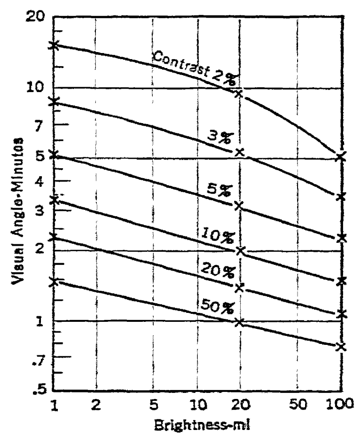

FIG. 21. Relationship between Minimum Angle of Resolution, Luminosity of Background, and the Contrast of the Test Object Relative to its Background (Cobb and Moss, *J. Franklin Institute*)

As indicated above it is now believed that the rate at which contrast sensitivity and visual acuity in the absence of glare increase with luminosity of background is not appreciably diminished with the very high luminosities (cf. Figs. 8 and 20). In other words, there is no optimum luminosity. The question arises then as to what the general illumination should be for adequate vision. Although this question cannot be answered specifically

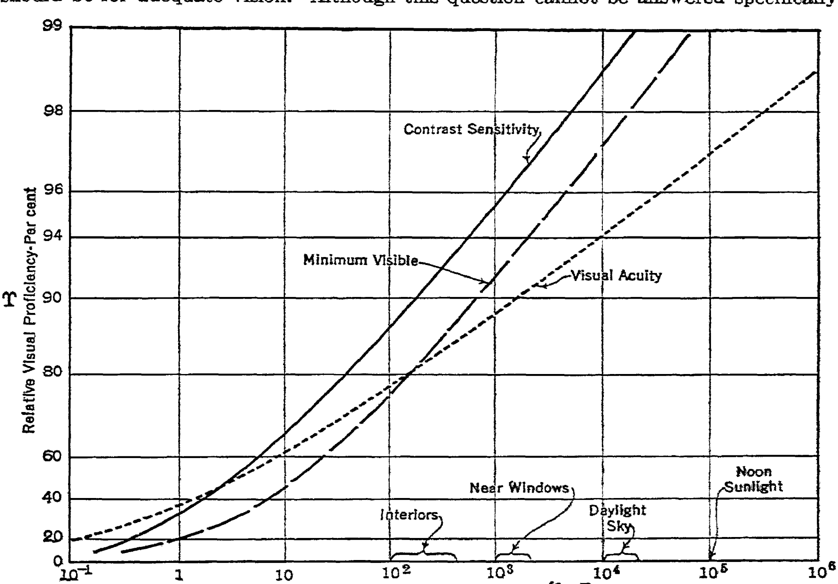

FIG. 22. Relative Visual Proficiency for Contrast Sensitivity, the Minimum Visible, and Visual Acuity, as a Function of Brightness of Background (after Moon and Spencer, *J. Optical Soc. Am.*)

it is of value to know the relative degree of visual efficiency for any given general illumination. A scheme for indicating this has been suggested by Moon and Spencer. In contrast sensitivity, the quantity Υ_c is defined as the ratio of the contrast sensitivity

$(I/\Delta I)$ for the given illumination (I) to the maximum contrast sensitivity that would be obtained with uniform fields and very high daylight luminosities. It represents the relative proficiency of contrast discrimination at any given illumination. Similar ratios Υ_v and Υ_a are defined for the minimum visible and for visual acuity. In Fig. 22 the theoretical values of each of these three visual functions are shown as dependent upon the luminosity of the background. For outdoor lighting the relative visual proficiency would range between 70 and 95 per cent, and for interiors with artificial lighting it would probably be less than 80 per cent.

PERCEPTION OF MOTION. The motion of objects in space is perceived as motion relative to the observer or as relative motion between the objects themselves. Under special circumstances the motion of objects seen with respect to each other and to the observer may be equivocal, for example, the apparent motion of the moon observed through moving clouds. In a field of large and small objects the larger objects are said to exhibit more stability and are less liable to apparent motion, while small objects exhibit apparent movement more readily and are said to be more mobile. Moreover, objects imaged on the peripheral parts of the retina appear less mobile than those falling on the fovea.

Perception of motion rests upon a temporal reaction to stimuli falling successively on neighboring points of the retina, but its appreciation appears only partially related to resolving power. It is thought to be a visual sensation resulting from experience. For objects whose visual angle of movement is small, motion is inferred from the apparent positions after lapses of time, for example, a moving train seen at a great distance. The true perception of motion, however, is a specific sensation, with both lower and upper thresholds of discrimination. The impression of motion can also occur (within definitely prescribed limits) from successive stimuli arising from separated stationary sources. This is called apparent movement by psychologists.

The threshold of the perception of true motion relates to the least angular displacement of an object that can be recognized in unit time. With comparison objects in the field of view the lower threshold is 1–2 minutes of arc per second. Without comparison objects this value must increase 10 to 20 times. The least angular movement that can be detected between two fixed points is sometimes called the movement acuity; under ordinary circumstances, this is found to be 10 to 20 seconds of arc, when stationary comparison objects are in the field of view. Without comparison objects this increases to more than 1 minute of arc. When the range of the movement (the distance between the beginning and end points) is fixed, the shortest lapse of time in which motion is seen has also been measured. Under ordinary circumstances, for example, the threshold for a 10-degree range varies between 0.027 and 0.079 sec. The upper limit for the discernment of motion, when the sensation becomes a meaningless blur, is 1.4 to 3.5 degrees per $^1/_{100}$ sec. The movement acuity decreases with increase in illumination.

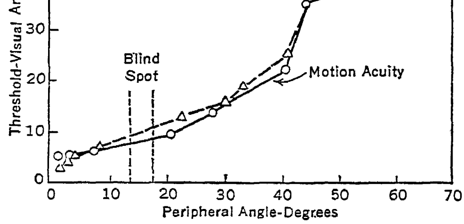

FIG. 23. The Thresholds for Form Acuity and Motion Acuity for Same Test Objects. The motion acuity is given in terms of the minimum distance required for perception of motion. (Data of Klein, *Arch. Psychol.*)

The threshold for the discrimination of movement is least at the fovea and increases rapidly out toward the periphery of the retina, though it has been thought that the increase is much less than the decrease of visual acuity toward the periphery. Figure 23 illustrates the data of Klein, which show, however, that the acuity and motion thresholds are essentially the same except at the fovea. It appears that the *discrimination* of motion is greatest at the fovea, but the *appreciation* of motion is most marked in the peripheral retina, to a degree beyond the actual resolving power. The discrimination of movement in the periphery is somewhat poorer above and below the fovea than to the right or left. There is a tendency to overestimate the extent of motion in the periphery, and, furthermore, the subjective direction of that motion is somewhat vague and uncertain. However, the sense of movement is highly developed.

THE PHI-PHENOMENON. The impression or illusion of movement can occur in certain situations without there being actual physical movement. The most important of the apparent movements is known in its purest form as the *phi*-phenomena, whereby apparent movement can occur, under certain conditions, when separated stationary points are illuminated successively. Usually the illusion of movement can be distinguished from real motion, however, and, as such, may be variously interpreted by different observers. Only in the neighborhood of an angular succession of 20 degrees per second are the two motions difficult to identify (de Silva). For the impression of motion there is a time relationship between the duration of the first stimuli, the separation of stimuli, the interval between successive stimuli, and the brightness of background, the impression depending also to a great extent upon the attitude of the observer. Under ordinary conditions, with a dark background, it has been found that, for two point stimuli 1 cm apart, the duration of each of which is 0.05 sec: (1) if the two stimuli are nearly instantaneous (0.03 sec) they will appear simultaneous; (2) if the time interval is greater than 0.2 sec the points will appear discrete and stationary; (3) for time intervals intermediate between these two there will be an apparent movement of the first point to the second, with an optimum at 0.06 sec. Of two light points of different intensity the weaker tends to move toward the brighter. Other examples of apparent movement are in the cinema, in neon signs, and in stroboscopic instruments.

THE PERCEPTION OF DEPTH. In the perception of depth one must distinguish between the perception of depth differences (how much one object appears in front of or behind another) and the absolute localization by which the actual distance of objects from the individual is estimated. Binocular vision, through the phenomenon of stereopsis, provides the most accurate means of relative depth discrimination.

The absolute localization of objects in space results from a complex process that involves both monocular and binocular perception. It has been usual to state that the perception of depth by monocular vision is a conception of depth (distance) attained through experience with certain relationships (clues) that will exist between parts of the retinal images of different objects in space. The more important of these visual clues are: (*a*) *Overlay*, by which the images of near objects overlap and tend to hide those of the more distant objects. (*b*) *Perspective*, which depends upon the fact that objects of equal size have smaller retinal images when at a distance than when near by. Linear perspective relates to the apparent convergence of parallel lines that recede in the distance (railroad tracks, etc.). Details within known objects are more readily seen when near than when distant. Thus, the size of retinal image related to known size provides the clue for estimation of distance. (*c*) *Aerial perspective*, through which the edges of objects at a distance are less clearly defined than those near by. Moreover, the more distant objects appear cooler (bluer) in color on account of atmospheric haze. Near objects appear brighter with more color saturation than those more distant. (*d*) *Light and shadow*, which give clues as to shapes and relative positions of objects. (*e*) *Parallax*, which results from head movements, for the relative alignment of more distant objects changes less than that for near objects with the same movement. This clue to depth perception is very strong, and the precision of depth estimation through it is nearly as great as that of stereoscopic depth perception (Tschermak). (*f*) *Height*, whereby objects seen above others are also judged more distant. (*g*) To a small extent accommodation and convergence, through a proprioceptive sense arising from the muscles of the eyes, may provide a clue for gross differences in depth.

As is well known it is impossible to present a single bidimensional picture which will have all the characteristics of the actual three-dimensional scene being portrayed. This is especially true when the picture is being viewed binocularly. As the eyes move over a painting, no change in accommodation or convergence is demanded and obviously no disparity clues are present for stereoscopic space localization of the details in the picture as there would be in the actual scene. The perspective in a pictorial representation of any scene, whether a photograph or a painting (except in certain art styles), refers to a fixed station point and in order to appear correct must be viewed from that point. A contact-print photograph should, then, be viewed at that distance that approximates the focal length of the camera that took the photograph. Viewed at other distances the perspective is exaggerated and unnatural. The viewing distance of an enlarged photograph will be equal to the product of the focal length of the camera and the magnification of the enlargement. This larger viewing distance explains the more pleasing effect derived from looking at enlarged photographs. It is desirable that pictures be viewed in such a way that the observer feels himself a part of the scene. The screen or plane of the picture itself should seem detached from the surroundings and preferably should appear indefinitely localized. To accomplish this is not always easy; usually it can be only approximated, especially for pictures viewed near by with binocular vision. It must be pointed out, however, that with the proper attitude on the part of the observer, and in the absence of distracting peripheral detail, the several psychological constancy phenomena tend to correct small distortions of form, of size, and of the color-brightness relationships.

13. BINOCULAR VISION

Binocular vision is the coordinated use of the two eyes, in which a single perception of external space is obtained, and by which the specific sensation of stereoscopic depth perception is made possible. The final perceptual images from the two eyes are normally said to *fuse* in the brain, and through the strength of the fusion impulse all movements of the eyes become coordinated in the process of fixating different points in space.

One differentiates between the binocular visual field, which will correspond to that portion of visual space for which the images of the two eyes will overlap, and the binocular field of fixation which is the maximum field swept over by the movements of the two eyes. Figures 24 and 25 illustrate the approximate angular dimensions of these fields.

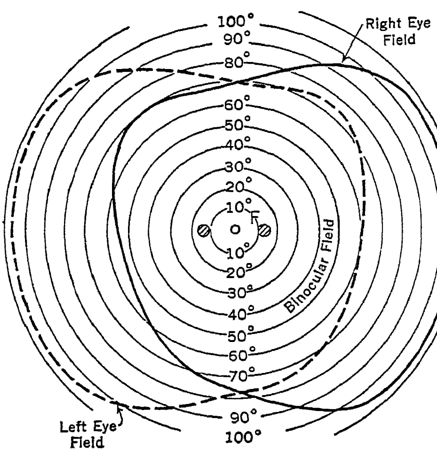

FIG. 24. The Binocular Visual Field (after Southall, *Introduction to Physiological Optics*)

The luminosity of objects is somewhat increased by the use of two eyes over that of only one, depending upon experimental conditions. Also the visual acuity of two eyes is usually found to be higher than that of one eye.

FUSIONAL AREAS. When the eyes are fixated upon one point in space, not all other points in space are perceived single. In fact, only those points will be seen single that are situated within a certain three-dimensional region determined by the distance of the fixation point and by the equivalent anatomical extent of certain areas on the retinas (Panum's fusional areas). See Fig. 25. Points in space outside these areas would ordinarily be seen double (physiological diplopia); however, unless attention is called to them, one is usually suppressed. The functional extent of Panum's area varies to some extent with visual conditions, and its measurement of size decreases somewhat with practice. The size increases away from the foveas toward the periphery. Near the fovea its minimum extent is about 6 to 12 minutes of arc in the horizontal meridian and about 6 minutes of arc in the vertical meridian. All objects beyond a fixation point at about 50 ft from the observer will generally be seen single. Double images exert compulsion innervations for the eyes to move so as to overcome the doubling. In the horizontal meridian, the actual eye movements, however, are usually subject to the will.

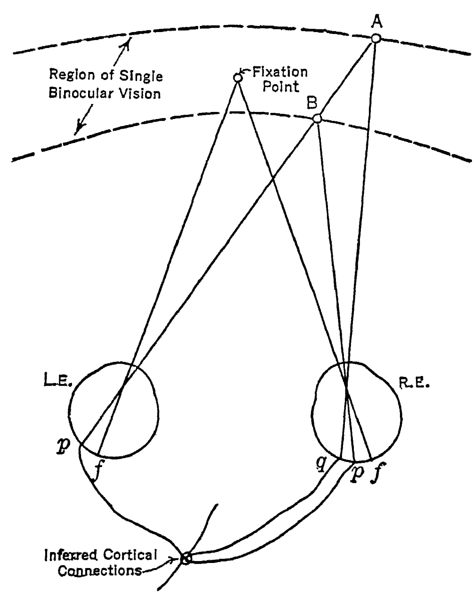

FIG. 25. The Spatial Region of Single Binocular Vision and the Geometrical Relations for the Disparity of Retinal Images in the Two Eyes

STEREOSCOPIC VISION. Stereoscopic vision rests upon the fact that each of the two eyes, by virtue of their separation,* sees objects in the visual field from a slightly different

* The variation of the interpupillary distance, in the general population, is between 55 and 75 mm, with a median at about 63 mm (measured while the eyes are looking at a distant object).

point of view, and hence the two retinal image patterns are slightly dissimilar. See Fig. 26. The angular separation of the retinal images, arising from two points in space, will be different in the two eyes, if one of the points is farther away from the observer. This difference in angular separation defines a *disparity* between the images. A disparity must always relate to two points in space. Referring again to Fig. 25, the double images from points at A and beyond are said to be *uncrossed* disparate with respect to the images of F, for if the right eye is suddenly closed the right half-image vanishes. Similarly the images of points at B and nearer are said to be *crossed* disparate with respect to the images of F, for if the right eye is suddenly closed the left half-image vanishes. Between the points A and B there will be some position for which the images from the two eyes will not be disparate, either crossed or uncrossed with respect to the image of F. This criterion defines the position of points on the horopter surface. Stereoscopic depth perception arises by virtue of the disparity between retinal images, uncrossed disparity being associated with the sense of distance away from the fixated point. Objects seen in crossed disparity are seen nearer than that point. Stereopsis is a specific sensation resting upon

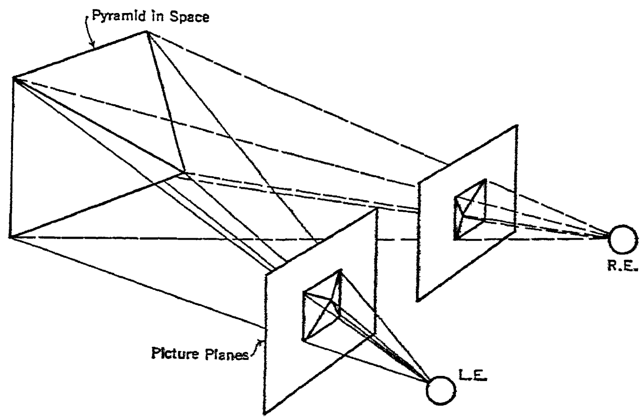

Fig. 26. Illustration of the Difference in the Image Patterns of the Two Eyes in Binocular Space Perception

the physiological and anatomical organization of the retinal elements of the two eyes. It usually occurs immediately for almost instantaneous illumination, and it exists within the entire binocular visual field.

The angular disparity between the images of two separated objects in depth in space will increase with the separation of the eyes and will decrease with their distance from the eyes. Though a sensation of greater depth will be associated with greater disparities of the images, the effect is not rigidly geometrical. For a given angular disparity, the apparent depth interval, to be quantitative, must vary with the square of the visual distance.

The visual acuity of the poorer eye must ultimately limit the threshold of stereoscopic vision. Likewise, the threshold of stereoscopic vision will depend upon those factors influencing visual acuity and, like visual acuity, will vary with the duration of the stimuli. For central vision and for durations longer than 3 sec, maximum acuity is obtained; for shorter durations down to 0.2 sec there is a 4 to 5 fold increase in threshold, after which the instantaneous threshold is nearly constant (Langlands).

Although varying with interpupillary distance and with individuals as well as with the nature of the detail in the visual field, the limiting threshold for stereopsis frequently is taken, on the average, as 30 seconds of arc. There is, correspondingly, a visual distance beyond which objects at greater distances cannot be seen stereoscopically. This limiting distance will roughly be 450 meters, or about a quarter of a mile. Under certain conditions, when the threshold of stereopsis may be as low as 6 seconds of arc, this distance will be exceeded several times. For the peripheral regions of the retina, this limiting distance will be much reduced, owing to the lowered acuity.

Two points separated vertically will have images in the two eyes which are vertically disparate if those points are located to the right or left of the plane perpendicular to the interpupillary base line. Vertical disparities do not give rise to the perception of depth, as do horizontal disparities, but they undoubtedly aid in the spatial localization of objects.

Since the invention of the stereoscope by Wheatstone in 1838, and the discovery of the bases for stereoscopic vision, various instruments have been devised whereby stereoscopic views could be obtained with pictures. In general, the procedure consists in presenting slightly different pictures or drawings before the two eyes which would correspond to the views that each of the eyes would perceive if they had been present when the photograph was taken. The devices include the mirror- and prism-stereoscopes, the haploscope, the red and green and polaroid anaglyphs, grid devices, and even motion pictures where the left- and right-eye views are projected alternately. The problem of projecting pictures for stereoscopic vision, so as to preserve correct disparity relationships and the correct perspective features, is a difficult one, especially for a group of observers (Rule).

RIVALRY. If the fields presented to the two eyes are greatly different, for example in radically different colors or in detail, instead of fusion or even a simultaneous perception of both patterns taking place, *retinal rivalry* occurs. In this, either one field or the other is seen, usually alternately. In the case of dissimilar patterns sometimes sections of each are seen simultaneously, but seldom both in the same region of the visual field. The period of alternation of the two visual fields varies between 2 and 12 sec, depending upon differences in luminosity, area, distinctness of detail within the fields, and central or peripheral vision. One field may prevail over the other for longer periods if there is a great difference in luminosity, or if intelligible detail exists on one and not the other, etc. Ocular dominance may also be a factor in the field that prevails the longer. Only in the case of certain color differences can fusion and therefore the emergence of a mixed color arise.

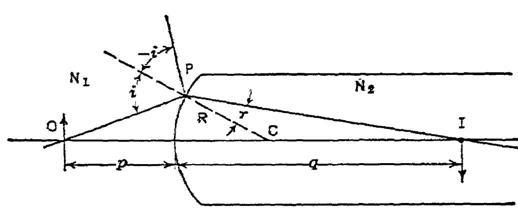
ELECTRON OPTICS

By D. W. Epstein

GENERAL CONCEPTS. Electron optics has become a branch of applied physics. The term "electron optics" was chosen because of the similarity between the path of an electron, or any charged particle, moving through electrostatic and magnetostatic fields and that of a ray of light passing through refracting media. Because of this similarity, such concepts of optics as lens and focal length may be transferred to electrostatic and magnetostatic fields.

The subject of optics is generally divided into: (1) geometrical optics, which treats only of the geometrical relations of the propagation of light; and (2) physical optics, which, utilizing the wave theory of light, is capable of dealing with any problem in light. A similar division is made in electron optics. This chapter will concern itself exclusively with non-relativistic geometrical electron optics of static fields; that is, relativity, wave mechanics, and electron optics of high-frequency phenomena will be excluded.

The analogy between electron optics and light is indicated in Figs. 1 and 2. Figure 1 shows the trajectory of a ray of light refracted and reflected at a spherical interface separating two regions of different indices of refraction. The analogous electron optical case is shown in Fig. 2. Assume that by some means (such as two closely spaced meshes at different electrostatic potentials) a space in vacuum is divided into two regions by a sphericocylindrical surface as shown in Fig. 2, the region to the left of the spherical surface being at the electrostatic potential V_1 and the region to the right of the spherical surface being at the electrostatic potential V_2. An electron emitted with zero initial velocity by a cathode (located to the left of the V_1 region) at zero potential will move in the V_1 region at a constant velocity v_1 given by



$$N_1 \sin i = N_2 \sin r$$

$$\frac{N_2}{q} - \frac{N_1}{p} = \frac{N_2 - N_1}{R} = -\frac{N_1}{f_1} = \frac{N_2}{f_2}$$

$$\frac{f_2}{f_1} = -\frac{N_2}{N_1}$$

$$m = \frac{N_1}{N_2}\frac{q}{p}$$

FIG. 1. Trajectory of a Ray of Light Refracted and Reflected at a Spherical Interface Separating Two Regions of Different Indices of Refraction

$$v_1 = \sqrt{2\frac{e}{m}V_1} = 5.95 \times 10^5 \sqrt{V_1} \text{ meters per sec} \tag{1}$$

where $e = 1.59 \times 10^{-19}$ coulomb is the charge of the electron and $m = 9.04 \times 10^{-31}$ kg is its mass. As long as the electron stays in the region of constant potential V_1 there is no electrostatic force acting on it and it will move in a straight line, say OP in Fig. 2; this corresponds to the law of rectilinear propagation in light optics.

When the electron crosses the spherical surface at P its velocity is changed to v_2 corresponding to V_2, i.e., to $v_2 = 5.95 \times 10^5 \sqrt{V_2}$ meters per second. The force being normal to the surface, only the component of velocity v_R normal to the surface will change; the tangential component of velocity v_T will be the same on both sides of the surface. It thus follows (see Fig. 2) that

$$v_T = v_1 \sin i = v_2 \sin r \tag{2}$$

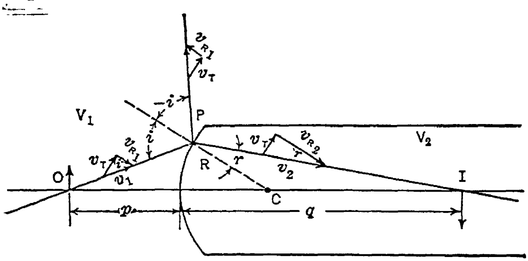
where i and r are the angles of incidence and refraction, respectively. Equation (2) may also be written

$$\sqrt{V_1} \sin i = \sqrt{V_2} \sin r$$

or

$$\frac{\sin i}{\sin r} = \frac{v_2}{v_1} = \frac{\sqrt{V_2}}{\sqrt{V_1}} = \frac{N_2}{N_1} = N \tag{3}$$

so if N_1 and N_2 are identified as the indices of refraction of the left region and right region respectively and N as the relative index of refraction then eq. (3) becomes the well-known law of refraction. The focusing properties of a spherical refracting surface then follow as indicated in Fig. 2.



$$v_1 = \sqrt{2\tfrac{e}{m} V_1} \qquad v_2 = \sqrt{2\tfrac{e}{m} V_2}$$

$$v_T = v_1 \sin i = v_2 \sin r$$

$$\sqrt{V_1} \sin i = \sqrt{V_2} \sin r$$

$$\frac{\sqrt{V_2}}{q} - \frac{\sqrt{V_1}}{p} = \frac{\sqrt{V_2} - \sqrt{V_1}}{R} = -\frac{\sqrt{V_1}}{f_1} = \frac{\sqrt{V_2}}{f_2}$$

$$\frac{f_2}{f_1} = -\sqrt{\frac{V_2}{V_1}}$$

$$m = \sqrt{\frac{V_1}{V_2}}\ \frac{q}{p}$$

$$V_2 < V_1$$

$$|V_2 - V_1| > \frac{1}{2} m (v_1 \cos i)^2$$

FIG. 2. Electron Optical Analogy of Fig. 1

If $V_2 < V_1$, then $e(V_2 - V_1)$ is negative, and if in absolute magnitude it is greater than $1/2\ m\ (v_1 \cos i)^2$—the part of kinetic energy of the electron corresponding to the normal component of its velocity—then the electron will be shot back from the surface with its normal velocity component reversed. The path of the reflected electron will make with the normal to the surface the same angle i which its path made on incidence (see Fig. 2). Thus the law of reflection also holds in electron optics.

The different rays of a beam of light do not affect one another. The various electrons in an electron beam repel one another; this, of course, is the well-known effect of space charge. However, for low electron beam intensities the effect of space charge is negligible, and it will be so assumed in what follows.

It is generally customary to deduce the laws of geometrical optics especially for nonhomogeneous media from Fermat's principle of shortest optical path.

This principle states that the path of a ray of light from a point A to a point B is always such as to make the integral an extremum (usually a minimum) with respect to all neighboring paths for rays of the same frequency. The principle is usually stated as

$$\delta \int_A^B N\, ds = 0 \tag{4}$$

where N, the index of refraction, may be a function of direction as well as position and ds is an element of path length.

In particle dynamics there is the similar principle of least action stating that

$$\delta \int_A^B p\, ds = 0 \tag{5}$$

where p is the momentum of the particle. A comparison of eqs. (4) and (5) shows that an electron in an electrostatic and magnetostatic field will follow the same trajectory as light would if the index of refraction at every point were made proportional to the momentum of the electron at the point. The momentum of an electron moving in an electrostatic and magnetostatic field is

$$p = mv - eA \cos \theta$$

where θ is the angle between the direction of motion of the electron and the direction of magnetic vector potential A. The index of refraction for an electron moving in a combined electrostatic and magnetostatic field is

$$N = k\left[v - \frac{e}{m} A \cos \theta\right] \tag{6}$$

Equation (6) shows that owing to the magnetostatic field N is a function not only of the position of the electron but also of its direction of motion so that combined electrostatic and magnetostatic fields behave like non-homogeneous anisotropic media.

It was noted in Fig. 2 that the index of refraction for an electron at a point in an electrostatic field is proportional to its speed at the point, i.e., $N = kv$, but it must not be assumed that the index of refraction in a magnetostatic field is $ke/mA \cos \theta$ but rather

$$k\left[v_0 - \frac{e}{m} A \cos \theta\right] \tag{7}$$

where v_0 is the constant speed with which the electron moves through the magnetic field.

14. ELECTROSTATIC LENSES

The electrostatic lens of Fig. 2 is an example of a relatively impractical case. Practical electrostatic lenses are generally formed by the application of electrostatic potentials to axial symmetric electrodes. Figure 3 shows a cross-section through the axis of such an electron focusing system. The double lines represent cylindrical, hollow conductors at the potentials V_1 and V_2; the single lines represent the equipotential surfaces in the space (vacuum) between the electrodes. From eq. (3) it follows that each equipotential surface represents a surface of constant index of refraction. Here are shown only a few of the equipotential surfaces; actually, of course, there is an infinite series of equipotential surfaces having a common axis. This electron focusing system may, therefore, be considered as a very large number of coaxial refracting surfaces. Most optical systems for light consist of a series of spherical refracting surfaces having a common axis of symmetry called the optic axis. For light, the optical systems are usually such that the index of refraction changes abruptly as light passes from one medium to the other. In electron optics, the index of refraction is a continuous function of position. Optically speaking, this means that an electrostatic field constitutes an isotropic non-homogeneous medium for electrons, corresponding to a medium of continuously variable density for light rays.

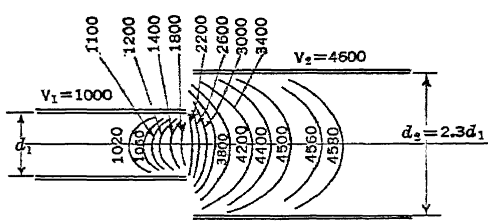


FIG. 3. Equipotential Line Plot in Charge-free Space Due to Potentials Applied to Coaxial Cylindrical Electrodes

The potential distribution $V(r, z)$—the potential at a radial distance r from the axis and an axial distance z from the origin—in charge-free space due to potentials applied to axial symmetric electrodes is given in cylindrical coordinates by the Laplace equation

$$\frac{\partial^2 V(r, z)}{\partial r^2} + \frac{1}{r}\frac{\partial V(r, z)}{\partial r} + \frac{\partial^2 V(r, z)}{\partial z^2} = 0$$

subject to the boundary conditions that $V(r, z)$ at the electrodes assumes the values of the potentials applied to the electrodes. Except for some special cases it has not been possible to obtain mathematical solutions subject to the actually existing boundary conditions. The solutions are generally obtained experimentally by means of an electrolytic tank. The potential distribution of Fig. 3 was thus determined.

The equations of motion of an electron moving in a meridian plane, i.e., a plane containing the axis, are

$$\begin{aligned} m\frac{d^2 z}{dt^2} &= e\frac{\partial V(r, z)}{\partial z} \\ m\frac{d^2 r}{dt^2} &= e\frac{\partial V(r, z)}{\partial r} \end{aligned} \tag{8}$$

The trajectory of a meridional electron traversing an axially symmetric electrostatic field $V(r, z)$ and with a velocity $v = \sqrt{2(e/m)V(r, z)}$, namely, an electron emitted with zero velocity from a cathode at zero potential, is given by the differential equation

$$\frac{d^2r}{dz} + \frac{\left[1 + \left(\frac{dr}{dz}\right)^2\right]}{2V(r, z)} \frac{\partial V(r, z)}{\partial z} \frac{dr}{dz} - \frac{\left[1 + \left(\frac{dr}{dz}\right)^2\right]}{2V(r, z)} \frac{\partial V(r, z)}{\partial r} = 0 \tag{9}$$

The distribution of potential in space is uniquely determined if the distribution along the axis together with its even derivatives are known. Thus

$$V(r, z) = V(0, z) - \frac{r^2}{2^2} V''(0, z) + \frac{r^4}{2^2 4^2} V^{\mathrm{IV}}(0, z) + \cdots \tag{10}$$

where $V(0, z)$ is the distribution of potential along the axis, $V''(0, z)$ is the second derivative of axial potential with respect to z, $V^{\mathrm{IV}}(0, z)$ is the fourth derivative, etc.

It may be shown by using eq. (10) that the equipotential surfaces in the neighborhood of the axis are hyperboloids with a radius of curvature of

$$R = \frac{2V'(0, z)}{V''(0, z)} \tag{11}$$

This shows that, in electron optics, index of refraction and curvature cannot be varied independently as they can in light optics. Consequently, the correction of some lens aberrations is extremely difficult if not impossible in electron optics.

An optical system is usually described in terms of paraxial or first-order imagery. Actual imagery departs from paraxial imagery. Such departures are described as aberrations.

The focusing action of an electrostatic field is similarly described to a first approximation by considering only paraxial electrons. Paraxial electrons are characterized by the fact that in calculating their paths it is assumed that their distances from the axis, r, and their inclination toward the axis, dr/dz, are so small that the second and higher powers of r and dr/dz are negligible.

The differential equation for the trajectory traversed by a paraxial electron becomes from eq. (9)

$$\frac{d^2r}{dz^2} + \frac{V'}{2V}\frac{dr}{dz} + \frac{V''}{4V} r = 0 \tag{12}$$

or

$$\sqrt{V}\frac{d}{dz}\left(\sqrt{V}\frac{dr}{dz}\right) + \frac{1}{4} V'' r = 0 \tag{13}$$

where V, V', and V'' are the axial distribution of potential $V(0, z)$ and its first two derivatives with respect to z respectively. Equation (12) or its equivalent eq. (13) may be taken as the fundamental equation of paraxial electron optics of axially symmetric electrostatic fields.

The general solution of the second-order differential equation (12) or (13) may be written

$$r(z) = c_1 r_1(z) + c_2 r_2(z) \tag{14}$$

where $r_1(z)$ and $r_2(z)$ are any two linearly independent solutions and c_1 and c_2 are arbitrary constants. Equation (14) states that the trajectory of any paraxial electron is simply the linear combination of two independent trajectories. Hence the complete paraxial focusing action of an axially symmetric electrostatic field is determined by calculating the trajectories of only two electrons. The trajectories of two electrons entering the lens parallel to the axis from the object and image sides are chosen as the two solutions $r_1(z)$ and $r_2(z)$ and are called the two *fundamental trajectories*. These trajectories determine the location of the cardinal points of the focusing system, i.e., the location of the focal and principal points, and thus the focusing action of the lens.

Referring to Fig. 4 let S_1 and S_2 be two equipotential surfaces such that the space to the left of S_1 is equipotential and is at potential V_1 and the space to the right of S_2 is equipotential and at the potential V_2. The potential in the region between S_1 and S_2 varies continuously, as shown in Fig. 3. Then the paraxial electron moving parallel to the axis in the equipotential space to the left of S_1 will follow the trajectory $r_1(z)$ and after passing through the focusing system will move in a direction inclined at an angle to the axis and will pass through the axial point F_2. All paraxial electrons moving parallel to the axis in the V_1 or object space will pass through F_2. The point F_2 is the second focal point. The plane passing through the second focal point and perpendicular to the axis of symmetry is the second focal plane.

The plane perpendicular to the axis and passing through the point of intersection of the original and final directions of motion of the electron is the second principal plane. The point of intersection H_2 between the second principal plane and the axis is the second principal point. The distance H_2F_2 denoted by f_2 is the second focal length.

Similarly, a paraxial electron moving parallel to the axis in the V_2 or image space will after passing through the focusing system move in a direction inclined to the axis and will

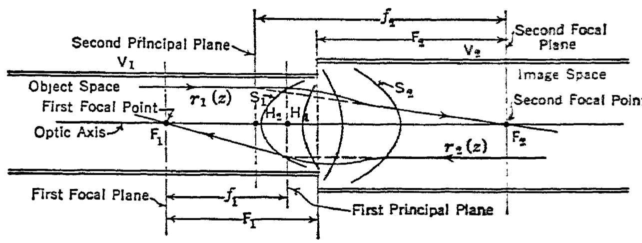

FIG. 4. Fundamental Trajectories and Cardinal Points of an Electrostatic Lens

pass through the point F_1 in the object space. F_1 is the first focal point. F_1 may also be considered that axial point in the object space from which all electrons, after passing through the focusing system, are parallel to the axis in the image space.

The plane perpendicular to the axis of symmetry and passing through the first focal point is the first focal plane. The plane perpendicular to the axis and passing through the point of intersection of the original and final directions of motion of the electron is the first principal plane. The point of intersection, H_1, of the first principal plane and the axis is the first principal point.

It is to be noted that in Fig. 4 the principal planes are crossed. This is a characteristic of lenses having indices of refraction different on the two sides.

In Fig. 5 let A_1B_1 be an object (say, an aperture through which electrons are passing) located in the equipotential region V_1. Then a paraxial electron coming from A_1 and moving parallel to the optic axis will after passing through the lens go in the direction F_2A_2. A paraxial electron issuing from A_1 in the direction A_1F_1 will after passing through the lens move parallel to the optic axis and will intersect the trajectory of the other electron at A_2. Similarly the trajectories of all paraxial electrons coming from A_1 will intersect at A_2, the image of A_1. The same is true of every point on A_1B_1, and so the inverted image

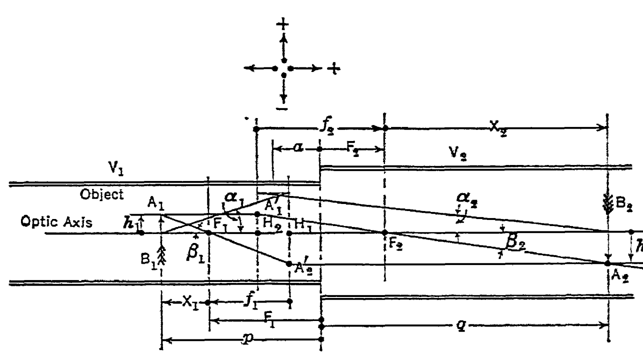

FIG. 5. Image Formation in a Direct Bipotential Electrostatic Lens

A_2B_2 is obtained. The ratio A_2B_2/A_1B_1 or h_2/h_1 gives the magnification. The electron image of A_1B_1 becomes visible if a fluorescent screen is placed in the plane of A_2B_2.

From eq. (12) or (13) and Fig. 5 it may be shown that the following relations hold:

$$\frac{f_2}{f_1} = -\sqrt{\frac{V_2}{V_1}} \tag{15}$$

$$X_1X_2 = f_1f_2 \tag{16}$$

$$\frac{f_1}{f_1 + X_1} + \frac{f_2}{f_2 + X_2} = \frac{f_1}{p + (f_1 - F_1)} + \frac{f_2}{q + (f_2 - F_2)} = 1 \tag{17}$$

$$\frac{1}{[q + (f_2 - F_2)]} - \frac{1}{\sqrt{\frac{V_2}{V_1}}\,[p + (f_1 - F_1)]} = \frac{1}{f_2} \tag{18}$$

$$m = \frac{h_2}{h_1} = -\frac{f_1}{X_1} = -\frac{X_2}{f_2} = \sqrt{\frac{V_1}{V_2}}\frac{[q + (f_2 - F_2)]}{[p + (f_1 - F_1)]} = \sqrt{\frac{V_1}{V_2}}\frac{\beta_1}{\beta_2} = \sqrt{\frac{V_1}{V_2}}\frac{\alpha_1}{\alpha_2} \tag{19}$$

$$p = (F_1 - f_1) + f_1\frac{(m - 1)}{m} \tag{20}$$

$$q = (F_2 - f_2) - f_2(m - 1) \tag{21}$$

The complete paraxial focusing action of an electrostatic lens is determined by means of the above relations when the positions of the cardinal points or f_1, f_2, F_1, and F_2 are known.

Electrostatic lenses are classified according to (*a*) electrode symmetry, (*b*) thickness, and (*c*) the potentials on the sides of the lens.

Spherical lenses are formed by applying different voltages to two or more electrodes having axial symmetry such as apertures and cylindrical and conical tubes. Spherical lenses are used in cathode-ray tubes, television pick-up tubes, and electron microscopes.

Cylindrical lenses are formed by applying different voltages to two or more pairs of electrodes having a plane of symmetry such as pairs of wires or pairs of strips. Cylindrical lenses are used in some receiving and transmitting tubes.

Thick lenses are characterized by the fact that the axial extension of the electrostatic or refracting field is of the same order of magnitude as or even larger than the focal length. It is necessary to know the positions of all four cardinal points in order to determine the focusing action of a "thick lens."

Thin lenses are characterized by the fact that the axial extension of the refracting field is negligible compared with the focal length. In a thin lens the principal planes coincide, and the focusing action of the lens is determined by its location and focal lengths. For estimating purposes it is sufficiently accurate to consider most lenses "thin."

The focal lengths of a "thin" spherical lens may be calculated from the relations

$$\begin{aligned} \frac{1}{f_2} &= \frac{3}{16}\left(\frac{V_1}{V}\right)^{1/4}\int_a^b \left(\frac{V'}{V}\right)^2 dz \\ \frac{1}{f_1} &= -\frac{3}{16}\left(\frac{V_2}{V_1}\right)^{1/4}\int_a^b \left(\frac{V'}{V}\right)^2 dz \end{aligned} \tag{22}$$

where V_1 and V_2 are the potentials of the equipotential regions on the two sides of the lens, V and V' the axial distribution of potential and its first derivative with respect to z, and the integral is taken over the axial extension of the field.

Equations (22) also apply to "thin" cylindrical lenses, if the numerical factor $^3/_{16}$ is replaced by $^1/_2$.

Unipotential lenses are characterized by having identical equipotential regions on the object and image sides, $V_1 = V_2$, and hence $f_1 = -f_2$. Figure 6 shows a few electrode arrangements and axial distributions of potential of unipotential lenses. Figures 7 and 8 * give the focal length of several thin unipotential lenses as a function of V_c/V_0. The dotted curves of Fig. 8 give the focal length of a unipotential lens where the central aperture has been replaced by a fine metal screen or an electron-permeable conducting membrane. It should be noted that this lens is divergent, i.e., f_2 is negative, when V_c/V_0 is less than unity. In the case of thin unipotential lenses eqs. (15) to (21) simplify to

$$f_1 = -f_2 \tag{15'}$$

$$X_1X_2 = -f_2^2 \tag{16'}$$

$$\frac{1}{q} - \frac{1}{p} = \frac{1}{f_2} \tag{18'}$$

$$m = \frac{h_2}{h_1} = \frac{f_2}{X_1} = -\frac{X_2}{f_2} = \frac{q}{p} = \frac{\beta_1}{\beta_2} = \frac{\alpha_1}{\alpha_2} \tag{19'}$$

$$p = -f_2\left(\frac{m - 1}{m}\right) \tag{20'}$$

$$q = -f_2(m - 1) \tag{21'}$$

* Figures 7 and 8 were plotted from data calculated by Dr. E. G. Ramberg of RCA Laboratories.

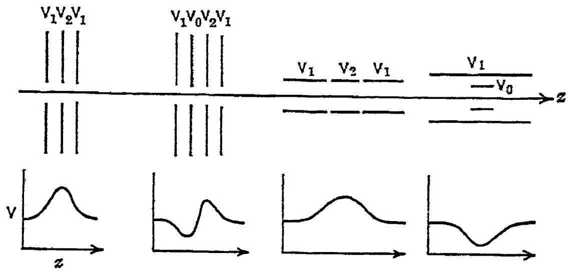

FIG. 6. Electrode Arrangements and Axial Distribution of Potential of Some Unipotential Lenses

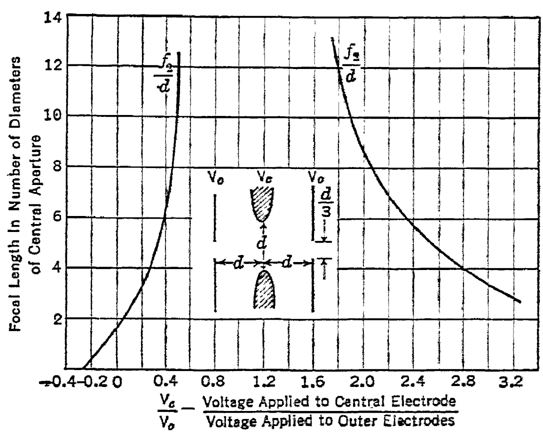

FIG. 7. Variation of the Focal Length (Measured as the Number of Diameters of the Central Aperture) with the Ratio of the Voltages Applied to the Central and Outer Electrodes

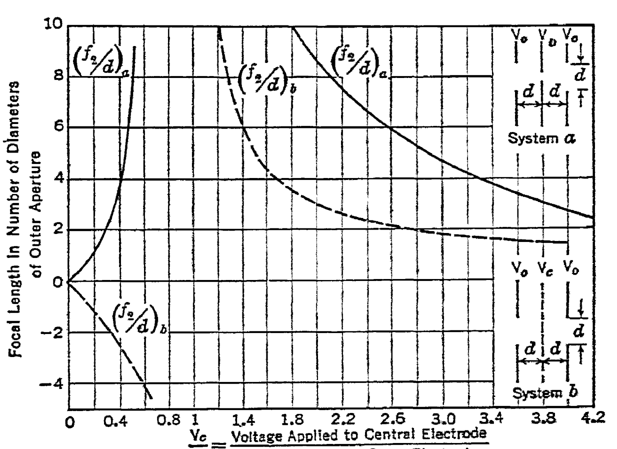

FIG. 8. Variation of the Focal Length (Measured as the Number of Diameters of the Outer Electrodes) with the Ratio of the Voltages Applied to the Central and Outer Electrodes. The solid curves apply to system (*a*) with a small central aperture. The dotted curves apply to system (*b*) with a central electrode consisting of a fine metal mesh or an electron-permeable conducting membrane.

Bipotential lenses are characterized by having different equipotential regions on the object and image sides, or $V_1 \neq V_2$. In the *direct bipotential* lens the potential of the image space is greater than that of the object space ($V_2 > V_1$). In the inverted bipotential lens $V_2 < V_1$. Figure 9 shows a few electrode arrangements and axial distributions of potential of some bipotential lenses. Figures 10*a* to 10*e* give the focal lengths and positions of

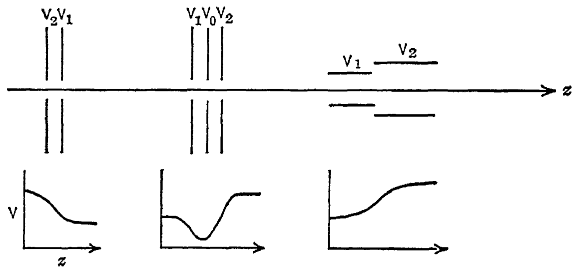

FIG. 9. Electrode Arrangements and Axial Distribution of Potential of Some Bipotential Lenses

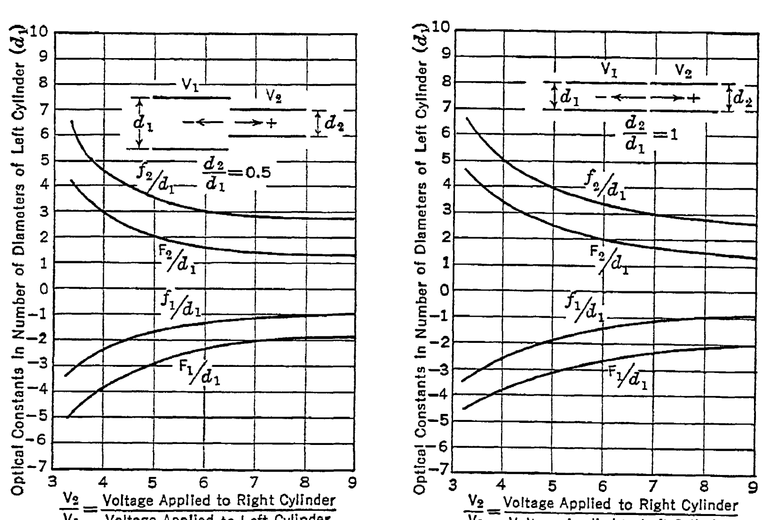
the focal points (thus giving the positions of the four cardinal points, see Fig. 5) as a function of V_2/V_1 for 5 different diameter ratios d_2/d_1. Figure 11 shows f_1, f_2, F_1, and F_2 as a function of d_2/d_1 for $V_2/V_1 = 5$.

The focusing characteristics of a "thick" bipotential lens are given by eqs. (15) to (21). Their use in conjunction with Fig. 10*c* will be illustrated by the following simple example (see Fig. 5 for sign convention). Given the lens with $d_2/d_1 = 1.5$, $V_2/V_1 = 5$, then, from Fig. 10*c*, $f_1 = -2.1d_1$, $(F_1 - f_1) = -1.1d_1$, $f_2 = 4.7d_1$, and $(F_2 - f_2) = -1.8d_1$. It is desired to obtain a real image of an object with a magnification $m = -5$ (since a real image of an object is inverted). Then by eqs. (20) and (21)

$$p = (F_1 - f_1) + f_1\left(\frac{m-1}{m}\right) = -1.1d_1 - 2.1d_1\left(\frac{-5-1}{-5}\right) = -3.6d_1$$

$$q = (F_2 - f_2) - f_2(m-1) = -1.8d_1 + 4.7d_1(-5-1) = 26.4d_1$$

and thus the object is located at a distance of $3.6d_1$ to the left of the cylinder ends and the image $26.4d_1$ to the right of the cylinder ends.



(*a*) (*b*)

FIG. 10. (See facing page.)

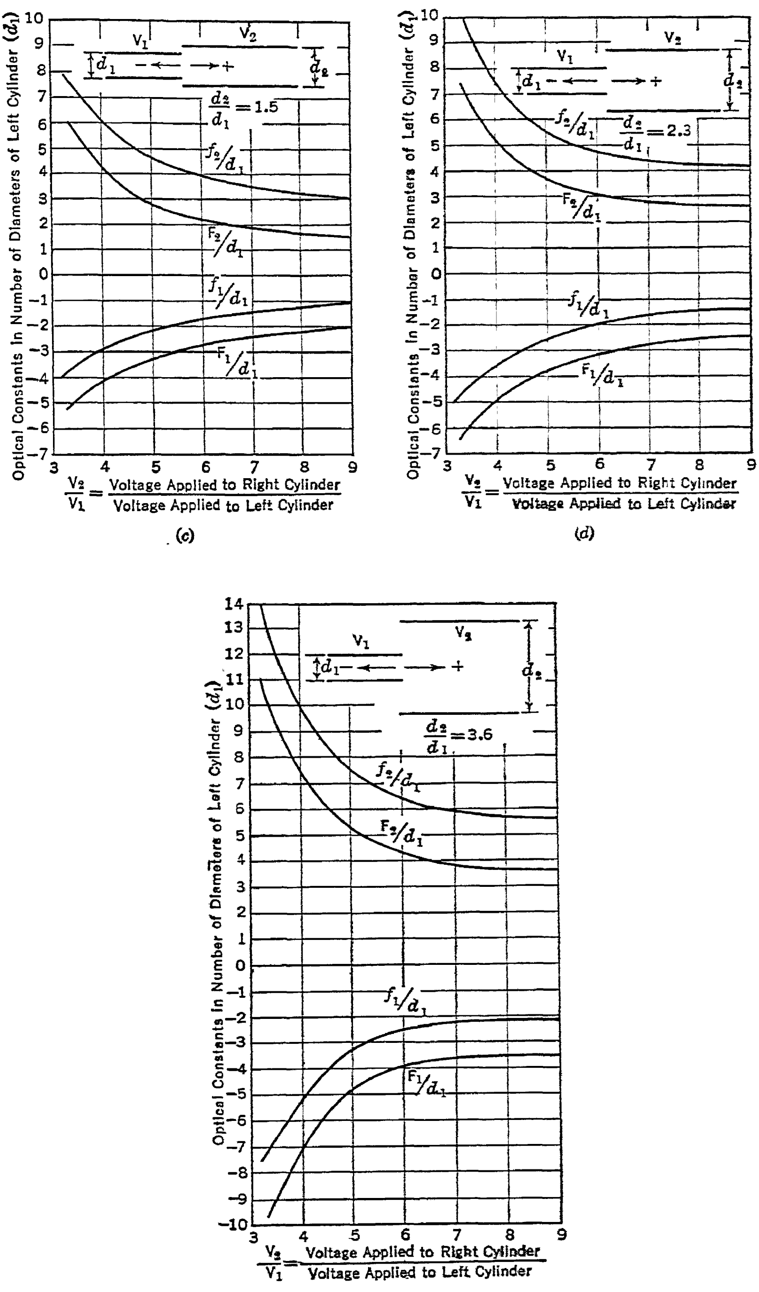


FIG. 10. Variation of Focal Lengths, f, and Distance of Focal Points from End of Cylinder, F (Measured as the Number of Diameters of the Cylinder on the Left), with the Ratio of the Voltages Applied to Right and Left Cylinders

In the case of a "thin" bipotential lens eqs. (18) to (21) simplify to

$$\frac{1}{q + a} - \frac{1}{\sqrt{(V_2/V_1)}(p + a)} = \frac{1}{f_2} \tag{18''}$$

$$m = \frac{h_2}{h_1} = \sqrt{\frac{V_1}{V_2}}\frac{(q + a)}{(p + a)} \tag{19''}$$

$$p = -a + f_1\left(\frac{m - 1}{m}\right) \tag{20''}$$

$$q = -a - f_2(m - 1) \tag{21''}$$

where a is the distance between the position of the equivalent thin lens and cylinder ends as indicated in Fig. 5.

Bipotential lenses are most generally used in cathode-ray tubes.

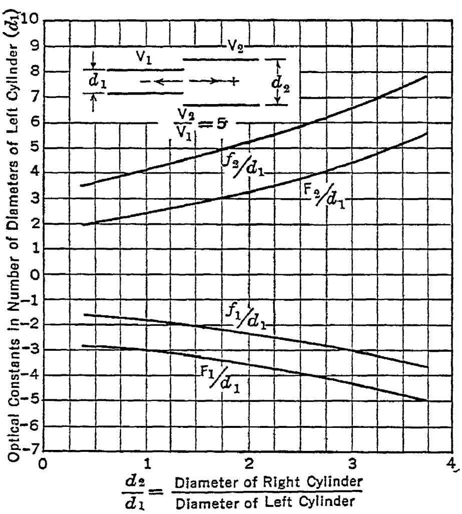

FIG. 11. Variation of Focal Lengths, f, and Distances of Focal Points from End of Cylinders, F (Measured as the Number of Diameters of Cylinder at Left), with the Ratio of Diameters of the Right and Left Cylinders

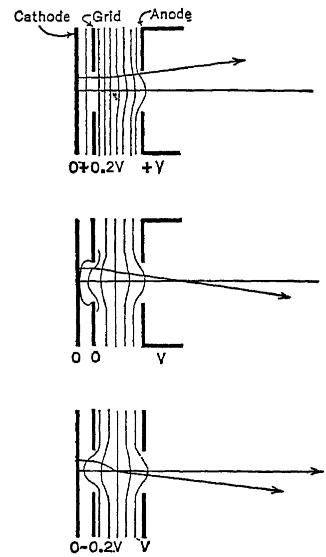

FIG. 12. Electrode Arrangement and Approximate Distributions of Potential (for Three Values of Grid Bias) of One of the Most Commonly Used Cathode Lenses

Cathode lenses are characterized by having a plane of zero potential (cathode) normal to the optic axis. The cardinal points of a cathode lens are of less significance than in case of the other lenses because of the distribution of initial velocities of the electrons emitted by the cathode. Figure 12 shows the electrode arrangement and approximate distribution of potential of one of the most commonly used cathode lenses. Figure 12 also shows the approximate trajectory of an electron emitted normal to the cathode for grid voltages of +0.2, 0, and −0.2 V. The grid is so named since it is also used for controlling the current going to the anode aperture. The cathode lens is the most widely used since it exists in all types of electronic devices.

Electrostatic lenses suffer from the defects or aberrations known as spherical aberration, coma, astigmatism, curvature of field, distortion, and chromatic aberration. They also suffer from defects due to misalignment and malconstruction of electrodes, space charge, relativity effect, etc.

Spherical aberration is in general the most troublesome, especially in instruments requiring a fine focused spot (or line) as in cathode-ray tubes, television pick-up tubes, and electron microscopes. Figure 13 shows the increase in spot size caused by the spherical aberration of a bipotential lens. The increase in spot size is given as a function of the beam diameter at the end of the first cylinder measured in terms of the first-cylinder diameter. Figure 14 shows the decrease in voltage ratio required to focus a beam of diameter d/d_1. In general the spherical aberration of the unipotential lens is greater than that of the bipotential lens and the equidiameter bipotential lens has less spherical aberration than a lens with $(d_2/d_1) > 1$ or $(d_2/d_1) < 1$. In general the aberrations in electron lenses are much more severe than they are in light lenses (this also applies to magnetostatic lenses). This is primarily due to the connection between radius of curvature and index of refraction—see eq. (11)—which exists in electron optics and not in light optics.

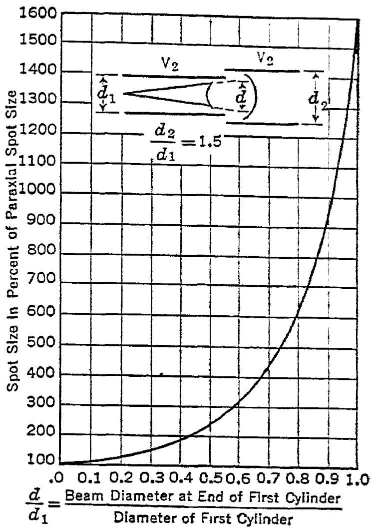

FIG. 13. Increase in Spot Size Caused by the Spherical Aberration of a Bipotential Lens as a Function of the Beam Diameter at the End of the First Cylinder

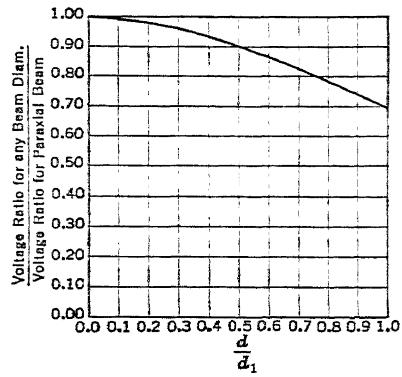

FIG. 14. Decrease in Focusing Voltage Ratio Caused by the Spherical Aberration of a Bipotential Lens as a Function of the Beam Diameter at the End of the First Cylinder

15. MAGNETOSTATIC LENSES

Any axially symmetric magnetostatic field acts as a "lens" for electrons. Such fields are generally created by passing direct current through coils with axial symmetry.

As already noted, a magnetostatic field is an electron-refracting medium whose index of refraction is a function not only of position but also of the *direction* of travel of the electron. Consequently magnetostatic lenses differ in their behavior from electrostatic and ordinary light lenses. In general the differences are made evident by a rotation of the image and the irreversibility of object and image. Thus, a real image, produced by a magnetostatic lens, is not inverted (as it is in an electrostatic lens), but is rotated through an angle θ relative to the inverted image. Similarly, if the image is made the object, then its image will not coincide with the original object (as it would in an electrostatic lens) but will be rotated through an angle 2θ relative to the original object. Magnetostatic focusing is generally accomplished by long or short lenses. The image rotation of a magnetosattic lens is, for a given focal length, reduced as the extent of the field along the axis is reduced. Thus the image rotation is practically zero for an extremely short lens and is 180° (image erect) for a very long lens.

The long lens generally extends over the entire length of the electron beam and is formed by the uniform field of a long solenoid. It is used in such television pick-up tubes as the image dissector, orthicon, and image orthicon. The uniform field of the long lens produces a sequence of uniformly spaced, real, erect (rotation 180°) images with unity magnification of an object which is placed normal to the field and which emits electrons of uniform speeds. This follows from the fact that an electron injected into a uniform magnetostatic field, B, with a speed v, and a corresponding voltage V and at an angle α with the field, describes a helix, the radius of the helix being

$$r = \frac{v \sin \alpha}{(e/m)B} = \frac{3.38 \times 10^{-6}\sqrt{V}}{B} \sin \alpha \text{ meters} \tag{23}$$

$$= \frac{2.69\sqrt{V} \sin \alpha}{H} \text{ meters}$$

The time taken by the electron in describing 1 revolution is

$$T = \frac{2\pi}{(e/m)B} = \frac{3.56 \times 10^{-11}}{B} = \frac{2.84 \times 10^{-5}}{H} \text{ sec} \tag{24}$$

which depends exclusively on B or H and is independent of V or α. The pitch of the helix or the distance that the electron has traveled in time T is

$$s = \frac{2\pi v \cos\alpha}{(e/m)B} = \frac{21.1 \times 10^{-6}\sqrt{V}\cos\alpha}{B} \text{ meters}$$

$$s = \frac{16.8\sqrt{V}\cos\alpha}{H} \text{ meters} \tag{25}$$

If the angles α at which electrons from a point source are injected into the field are small, then their speeds along the lines of force, $v \cos\alpha$, are essentially constant ($\cos\alpha = 1$) and all electrons will reunite at the following distances from the source

$$s_n = \frac{21.1 \times 10^{-6} n\sqrt{V}}{B} = \frac{16.8n\sqrt{V}}{H} \text{ meters} \tag{26}$$

where n is an integer. Since any line of force is an axis of symmetry in a uniform field, an extended electron-emitting (or "illuminated") source placed perpendicular to the field will be imaged at the distances s_n of eq. (26) (see Fig. 15).

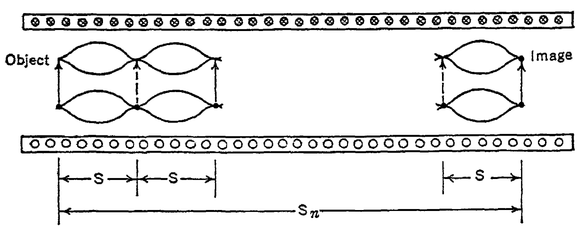

FIG. 15. Image Formation by a Uniform Magnetostatic Field

The short magnetostatic lens extends over a limited region of the beam and is generally formed by the non-uniform field of an iron-encased coil with a narrow slit in the iron shell or pole pieces (Fig. 16). Short lenses are used in electron microscopes and television

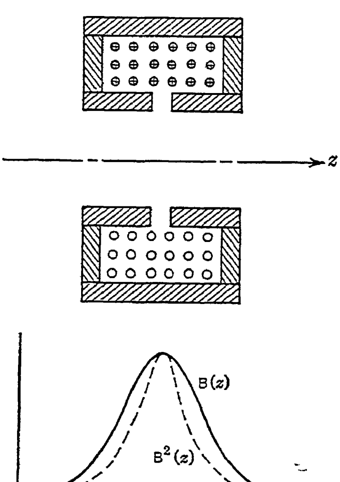

FIG. 16. Short Iron-clad Magnetostatic Lens and Approximate Distribution of Axial Flux Density

cathode-ray tubes. Except for some image rotation the short lens behaves like a thin unipotential electrostatic lens so that its focusing characteristics are given by eqs. (15') to (21′). The focal length of a short lens is given by

$$\frac{1}{f} = \frac{1}{8}\frac{e}{m}\frac{1}{V}\int_a^b B^2\,dz = \frac{2.2 \times 10^{10}}{V}\int_a^b B^2\,dz \quad \text{meters}^{-1}$$
$$= \frac{3.5 \times 10^{-2}}{V}\int_a^b H^2\,dz \quad \text{meters}^{-1} \tag{27}$$

where B is the axial component of the flux density along the axis of the lens, and V is the potential of the equipotential region in which the lens is located.

The image rotation is given by

$$\theta = \sqrt{\frac{1}{8}\frac{e}{m}\frac{1}{v}}\int_a^b B\,dz = \frac{1.5 \times 10^5}{\sqrt{V}}\int_a^b B\,dz \quad \text{radians}$$
$$= \frac{0.19}{\sqrt{V}}\int_a^b H\,dz \quad \text{radians} \tag{28}$$

Integrating eqs. (27) and (28) for a wire loop of diameter d and carrying a current NI results in

$$\frac{f_2}{d} = \frac{8 \times 10^{14} V}{3\pi^3 (e/m)(NI)^2} = 48.5\,\frac{V}{N^2 I^2} \tag{29}$$

$$\theta = \sqrt{2\pi^2 \times 10^{-14}\frac{e}{m}}\,\frac{NI}{\sqrt{V}} = 0.19\,\frac{NI}{\sqrt{V}} \quad \text{radians} \tag{30}$$

To a fair approximation, eq. (29) also applies to a short coil of mean diameter d, of N turns, and carrying current I. Figure 17 is a plot of eq. (29) giving, graphically, the focal length

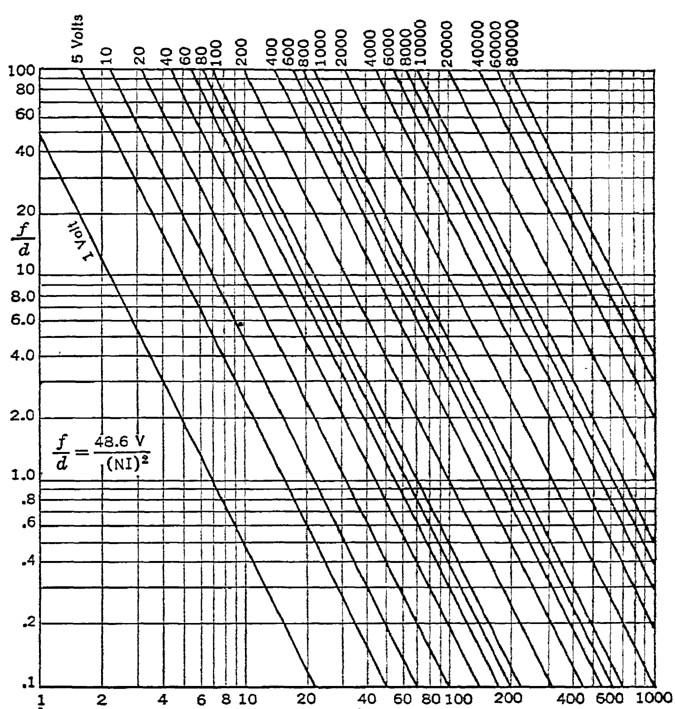

FIG. 17. The Focal Length of a Short Coil as a Function of Ampere-turns and Beam Voltage

as a function of voltage and ampere-turns. Figure 17 may be used, for estimating purposes, in the case of an iron-encased coil if the ampere-turns are small and if d is taken as the clear diameter of the pole pieces. Since the iron-clad coil concentrates the field more than the air coil, the iron coil produces the smaller image rotation.

Besides the usual 5 third-order aberrations of spherical aberration, coma, astigmatism, distortion, and curvature of field, the images produced by magnetostatic lenses usually suffer from three other aberrations. These are generally known as anisotropic distortion, anisotropic curvature of field, and anisotropic coma. Anisotropic distortion is often called the "S effect," since this aberration distorts a straight radial line on the object into an elongated letter S on the image.

16. ELECTRON PRISMS

A uniform electrostatic field and a uniform magnetostatic field constitute the two basic types of electron prisms. Electron prisms are used for deviating (deflecting) beams of electrons of uniform speed as in cathode-ray tubes and pick-up tubes, and for dispersing a beam of charged particles so as to separate particles of differing mass or speed as in the ion trap of a cathode-ray tube and mass spectrograph.

Electrostatic prisms are generally formed by the approximately uniform field between the charged plates of a condenser (see Fig. 18).

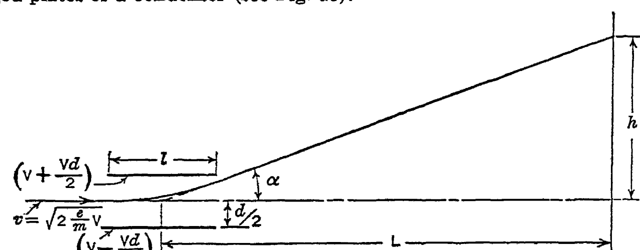

FIG. 18. Deviation (Deflection) of an Electron Beam by an Electrostatic Prism (Deflecting Plates)

A charged particle moving initially perpendicularly to a uniform electrostatic field, E, with a velocity v (corresponding to a potential drop V), follows a parabolic trajectory while in the field. On leaving the field the charged particle is deviated into the direction of the field (see Fig. 18) through the angle α given by

$$\tan \alpha = \frac{lE}{2V} = \frac{lVd}{2dV} \tag{31}$$

where l is the extent of the field or approximately the length of the plates, d the distance between the plates, and Vd is the difference in potential between the plates. The apparent center of deflection is located approximately at $l/2$ from the ends of the plates, and the amount of deflection at the distance L from the center of the plates is

$$h = \frac{lL}{2d}\frac{Vd}{V} \tag{32}$$

Magnetostatic prisms are generally formed by the approximately uniform field between two current-carrying coils or pole pieces of a magnet.

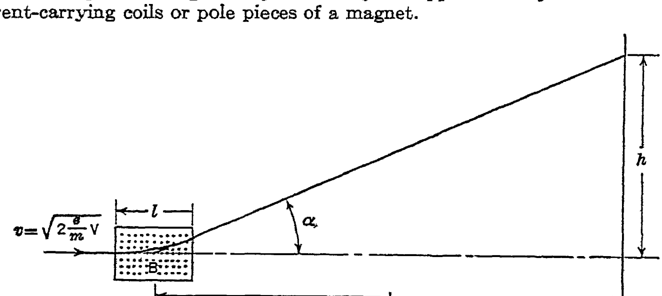

FIG. 19. Deviation (Deflection) of an Electron Beam by a Magnetostatic Prism (Deflecting Coils)

A charged particle moving initially perpendicularly to a uniform magnetostatic field with the velocity v follows a circular trajectory in a plane at right angles to the field. On leaving the field the charged particle is deviated in a direction perpendicular to the field (see Fig. 19) through the angle α given by

$$\sin \alpha = \frac{\sqrt{e/m}\, lB}{\sqrt{2V}} \tag{33}$$

which becomes in the case of electrons

$$\sin \alpha = 2.97 \times 10^5 \frac{lB}{\sqrt{V}} \tag{34}$$

The apparent center of deflection is located approximately at the center of the field, and the amount of deflection at the distance L from the center of the field is

$$h = L \tan \alpha \cong 2.97 \times 10^5 \frac{lLB}{\sqrt{V}} \tag{35}$$

17. GENERAL THEOREMS ON ELECTRON OPTICAL SYSTEMS

Electron optical systems generally consist of a cathode lens and one or more electrostatic and/or magnetostatic lenses and electron prisms (deflecting plates or coils).

The following general theorem applies to an electron optical system using electrostatic and magnetostatic elements. The trajectory of a charged particle remains similar, as long as the quantity $(e/m)(B^2L^2/V)$ is kept unchanged. Thus, if the voltages on all the electrodes are increased by a constant factor n, it is necessary to increase B by the factor $\sqrt{n}$ in order to keep the trajectory the same. If all the linear dimensions (L) of the system, i.e., of all the electrodes, coils, object distance, image distance, etc., are increased by the factor n, it is necessary either to increase all the voltages by n^2 or to decrease B to $1/n$ in order to keep the trajectory similar.

The following theorems apply to any purely electrostatic electron optical system:

1. The trajectory is independent of e/m. Hence all like charged particles emitted by a cathode will be identically focused and deflected by any electrostatic optical system.
2. The trajectory of any charged particle emitted by a cathode is unchanged if the voltages on all the electrodes are increased by the same factor.
3. If all the linear dimensions of all the electrodes are increased by a constant factor n, the trajectory remains unchanged (if measured in units n times larger).

All electron lenses which are free of space charge and conductors within the field of the lens and are bounded by uniform potential regions on both sides are always convergent, i.e., will form a real image of an object located beyond the focal point of the lens.

The maximum current density, J_2, obtainable in an electron spot or image, regardless of the electron optical system employed, is given by

$$J_2 = J_1 \frac{eV_2 + kT}{kT} \sin^2 \alpha_2 \cong J_1 \frac{11{,}600}{T} V_2 \sin^2 \alpha_2 \tag{36}$$

where J_1 is the specific emission of the cathode, kT is the initial kinetic energy of an electron emitted by a thermionic cathode at the absolute temperature T, $k = 1.38 \times 10^{-23}$ erg per degree, $eV_2 + kT$ is the final kinetic energy, and α_2 is the angle of maximum convergence of the electron trajectory at the spot or image.

Equation (36) may be deduced from the fact that, for a perfect optical system which accepts and focuses all the electron current emitted by a thermionic cathode, $J_2 = J_1/m^2$ (m = magnification), and $m = \frac{v_1}{v_2}\frac{\sin \alpha_1}{\sin \alpha_2}$ (see eq. [41], p. 14-08), where v_1 and v_2 are the initial and final velocities of an electron and $\alpha_1 (= 90°)$ is the angle of maximum convergence at the cathode.

ELECTRO-OPTICAL DEVICES

ELECTRO-OPTICAL DEVICES

PHOTORESPONSIVE DEVICES

By Herbert E. Ives

1. RADIATION, PROPERTIES, AND MEANS OF DETECTION

Photoelectric tubes, or cells, belong to the general class of instruments responsive to radiant energy, or *radiation*. An intelligent use of such instruments demands a knowledge of the more important characteristics of radiation, which may be summarized as follows: Radiant energy consists of electromagnetic waves, of a vast range of wavelengths, extending from radio waves, many meters long, to x-rays and γ-rays less than a millionth of a millimeter in length (see Section 11, article 5). The portion of this extended spectrum which is effective in photoelectric tubes and similar devices is confined to a small region centering around that group of wavelengths commonly called light, or the *visible spectrum*, which extends roughly from 0.8 micron (1 micron = 10^{-4} cm) to 0.4 micron. (Other units of measurement frequently encountered are the angstrom unit, 10^{-8} cm, and the millimicron, 10^{-7} cm.) The adjacent region of longer wavelength is called the *infrared;* that of shorter wavelength, the *ultraviolet*. The radiations in the visible spectrum vary greatly in their ability to produce the sensation of light, the relationship between energy value, or radiant intensity, and luminous value being indicated by the *luminosity curve* of the spectrum which has a maximum at approximately 0.5 micron, dropping to zero at the ends of the visible spectrum. Radiant energy is measured in energy units, namely, ergs or joules; and radiation or radiant flux is measured in ergs per second or watts: The *irradiation* of a surface, such as that of a phototube, is measured in ergs per second incident per unit area, or watts per unit area. Luminous flux is radiant flux evaluated according to its luminosity (the integral of the product of the radiation spectrum and the luminosity curve of the spectrum). Its unit is the lumen. One lumen is radiated in unit solid angle by a point source of luminous intensity of 1 candle. The *illumination* of a surface is measured in lumens incident per unit area. The *meter-candle* or *lux* is an illumination of 1 lumen per square meter.

All instruments which respond to radiation do so because they absorb some of the energy of the radiation and transform it into some form susceptible of practical measurement or utilization. *Thermal* instruments become heated by the incident energy, and indicate by changes of dimensions, position, or the production of electrical currents. *Photoelectric* instruments depend primarily upon the fact that the incidence of radiation on matter causes the emission or release of electrons, setting up electromotive forces or causing electrical currents to flow.

CLASSIFICATION OF PHOTORESPONSIVE DEVICES. It is convenient to divide photoresponsive devices into two broad groups, namely, *thermal* devices and *photoelectric* devices. In the group of thermal devices are included thermojunctions, bolometers, and radiometers. In the group of photoelectric devices are included photoemissive cells, photoconductive cells, barrier photocells, and photovoltaic cells.

The *thermal* instruments in general respond to a wide region of the spectrum, corresponding to the thermal absorbing power of the materials of which they are constructed or with which they are coated. Since they are frequently coated with a "black" of high and substantially uniform absorbing power through the infrared, visible, and ultraviolet portion of the spectrum they are often termed "non-selective." They are generally less sensitive than the photoelectric instruments in the spectral region to which the latter respond; they are much slower in response and, being usually of relatively low resistance, are not easily adapted to methods of electrical amplification.

The *photoelectric* instruments are in general sensitive to relatively narrow regions of the spectrum (are strongly selective), but they are far more sensitive in these regions than the thermal instruments. They have also the great practical advantage that they are readily adaptable to the various modern methods of electrical amplification.

2. THERMAL DEVICES

THERMOJUNCTIONS. When two different metals are joined and the junction is maintained at a temperature different from the rest of the circuit, a potential is generated whose magnitude is dependent on the temperature difference and on the materials of the junction. When this difference is very small the potential will be proportional to the temperature. Bismuth and antimony and some of their alloys give large potentials compared with most other metals, and many thermopiles have been made of them. Good, durable combinations of high sensitivity commonly used at present are bismuth against silver, bismuth-tin against bismuth-antimony alloys, and Constantin against Manganin.

Other requirements beyond high thermoelectric power are a low internal resistance and heat capacity and low thermal conductivity between the hot and cold junctions, and in practice a compromise has to be made between these factors. Thermoelements are used in three principal forms: the single junction, the multiple-junction thermopile, and the radiomicrometer, the last being a galvanometer with a thermojunction built directly into, and forming a part of, the moving coil. Multiple junctions are preferable where the illumination extends over some area; for example, where spectral lines are to be measured a linear arrangement of couples is often used, a diagram of which is shown in Fig. 1. The warm junctions, *a*, which receive the radiation to be measured, are commonly flattened or covered with small, thin disks or squares of metal to present a large receiving area. These disks are usually blackened, for instance, with a layer of lampblack, in order to make them uniformly absorptive to a long range of wavelengths. The connection to the cold junctions, *b* and *b'*, must conduct as little heat as possible and at the same time not have too high an electrical resistance. In order to secure the maximum stability it is desirable to shield these cold junctions thoroughly from scattered radiation and to maintain their temperature substantially equal to that of the walls of the surrounding enclosure. This is accomplished by attaching fins of relatively large area to the cold junctions.

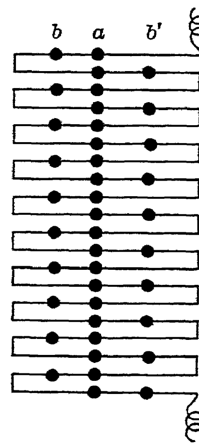

Fig. 1. Linear Thermopile

The galvanometer should have a resistance not far from that of the thermopile, usually from 10 to 50 ohms. There is no advantage in increasing the number of junctions beyond a certain point, and in fact with a given flux the overall sensitivity may be the largest with a few junctions of small heat capacity especially if they are enclosed in a vacuum which eliminates the loss of heat by conduction and convection to the atmosphere and reduces the disturbing effect of drafts. The sensitivity of thermopiles is expressed in volts per unit of irradiation, in some cases, in terms of the response from a stated source at a given distance, commonly a Hefner candle at 1 meter. Values for some of the standard thermopiles are given in Table 1.

Table 1. Sensitivity of Thermopiles

	Ohms Resistance	Volts per Erg per Second per Square Centimeter
Moll linear	20	0.75×10^{-8}
Hilger linear	10	0.7×10^{-8}
Moll large surface	50	5.0×10^{-8}
Moll sensitive vacuum couple	45	0.46×10^{-8}
Moll quick vacuum couple	20	0.13×10^{-8}
Coblentz vacuum couple	14.8	0.7×10^{-8}

For the sensitivity in watts per square centimeter multiply the above figures by 10^7, and for gram calories per second per square centimeter multiply by 4.186×10^7. One Hefner standard lamp with 14 by 50 mm diaphragm opening gives, at 1 meter, 9.6×10^{-5} watt per sq cm or 9.6×10^2 ergs per sec per sq cm.

If a thermopile is to be used with weak radiation, as it frequently is, it is very important that the thermopile and the galvanometer be adapted to each other in order to secure a high sensitivity of the system, i.e., the ratio of the scale reading to the flux. Besides high voltage sensitivity of the pile previously mentioned, other requirements are that the galvanometer should have a low internal resistance, high voltage sensitivity, and a critical damping resistance equal to that of the pile inclusive of the leads. Such galvanometers are made by the Leeds and Northrup Company, Philadelphia, and Kipp and Zonen, Holland.

The sensitivity of the system can sometimes be greatly increased by concentrating the radiation on the junctions and also by using one of the numerous optical devices for amplifying the galvanometer deflections. These are arrangements whereby a light beam reflected from the galvanometer mirror actuates a photocell, the output of which in turn produces an increase in the deflection or operates a second galvanometer. In the Moll thermorelay made by Kipp and Zonen, or the similar Zernike differential couple, the reflected light beam determines the relative temperatures of two opposing thermojunctions, the net output of which controls a second galvanometer. In this manner the readings can be increased up to the inherent instability of a galvanometer, but care must be taken to preserve the linearity of the entire system.

BOLOMETER. The bolometer is essentially a sensitive resistance thermometer of very small heat capacity; that is, the electrical resistance of a fine wire or strip of metal is increased by the heating due to the radiation. It was used extensively before the development of the modern high-sensitivity, quick-acting thermopile, which is more convenient and stable under ordinary conditions. In its practical form two bolometer elements form two arms of a Wheatstone bridge, which the radiation unbalances. It is essential that a material such as platinum be used which has a high temperature coefficient of resistance as well as a low heat capacity and conductivity. Unless unusual precautions are taken the entire bridge network is subject to temperature fluctuations which render the readings uncertain. The sensitivity of bolometers is about one-millionth of a degree per millimeter deflection of a galvanometer used without intermediate amplification. For example, a bolometer of 2.8 ohms resistance and using 40 mils current gave a deflection of 45 cm when exposed to 1 candle at 1 meter with a galvanometer sensitivity of 1.5×10^{-10} amp per mm, the scale being at 1 meter.

THERMISTOR BOLOMETER. A more recently developed form of bolometer is one made of thermistor materials, that is, semiconductors whose resistance varies rapidly with temperature. Combinations of oxides of nickel, manganese, and cobalt change their resistance about 4 per cent per degree centigrade, or about ten times as much as platinum. The oxides are prepared in the form of thin flakes cemented to glass or quartz. A typical flake 3 mm long, 0.2 mm wide, and 0.01 mm thick has a resistance of 4×10^6 ohms and with 250 volts applied gives a sensitivity of 300 volts per incident watt or 18 volts per watt per sq cm. The spectral response is determined by the optical properties of the oxide constituents, which may show regions of relative transparency in the infrared. Because of the high resistance the output of the thermistor bolometer is well adapted to electrical methods of amplification.

RADIOMETER. The Nichols radiometer is a self-contained instrument consisting of two similar vanes of blackened mica or platinum on a horizontal arm and suspended in a vacuum. It is a development of the toy known as Crookes' radiometer frequently seen in optical shops, which consists of four vanes, each blackened on one face, on arms balanced on a needle-point, which rotate when illuminated. The behavior of the radiometer is dependent on the gas pressure; at higher values the blackened sides of the vanes are drawn in turn toward the window; at lower pressures the warming of the blackened faces by the radiation causes the residual gas molecules to rebound from their surface directly to the cooler window and push the vanes away from it and the radiating source. All practical instruments have the gas pressure so adjusted that they work by the latter method. The Nichols radiometer is used by measuring the deflection of the vanes by means of a small mirror attached to the cross-arm supporting them, its rotation being observed by the usual telescope and scale. The sensitivity of the radiometer to radiation is of the same magnitude as that of the bolometer with a sensitive galvanometer.

SPEED OF RESPONSE OF THERMAL DEVICES. The thermal devices are in general slow to respond to variations in signal strength and hence are not well adapted for following rapidly fluctuating radiation, such as radiation modulated at speech frequencies. The time constant, defined as the interval in which the response declines to $1/e$ value, is for the fastest devices of the order or 5 milliseconds.

3. PHOTOEMISSIVE CELLS

STRUCTURE. In photoemissive cells an electropositive metal surface is placed in a highly evacuated enclosure, usually of glass or quartz, together with another metal plate, the electropositive material constituting the sensitive cathode, the other plate the anode, and both plates are connected with terminals led through the glass. The action of the cell is as follows: When light falls on the cathode, electrons are emitted into the space above. These pass over to the anode, and, if the terminals outside the cell are connected through a current-measuring device, a current is observed which varies with the total illumination. Although some current will flow without a battery being connected in series, it is common practice to use one, and then the cells act primarily as valves, the illumination controlling the amount of current which is permitted to pass.

Practically all photoemissive cells use alkali or alkaline-earth metals as their light-sensitive materials, and the structure is largely influenced by the problem of introducing these metals into the glass or quartz enclosure. In early types of photoemissive cells an alkali metal, such as sodium or potassium, was introduced in molten form into a simple spherical bulb provided with one leading-in wire in contact with the pool of alkali metal, and a

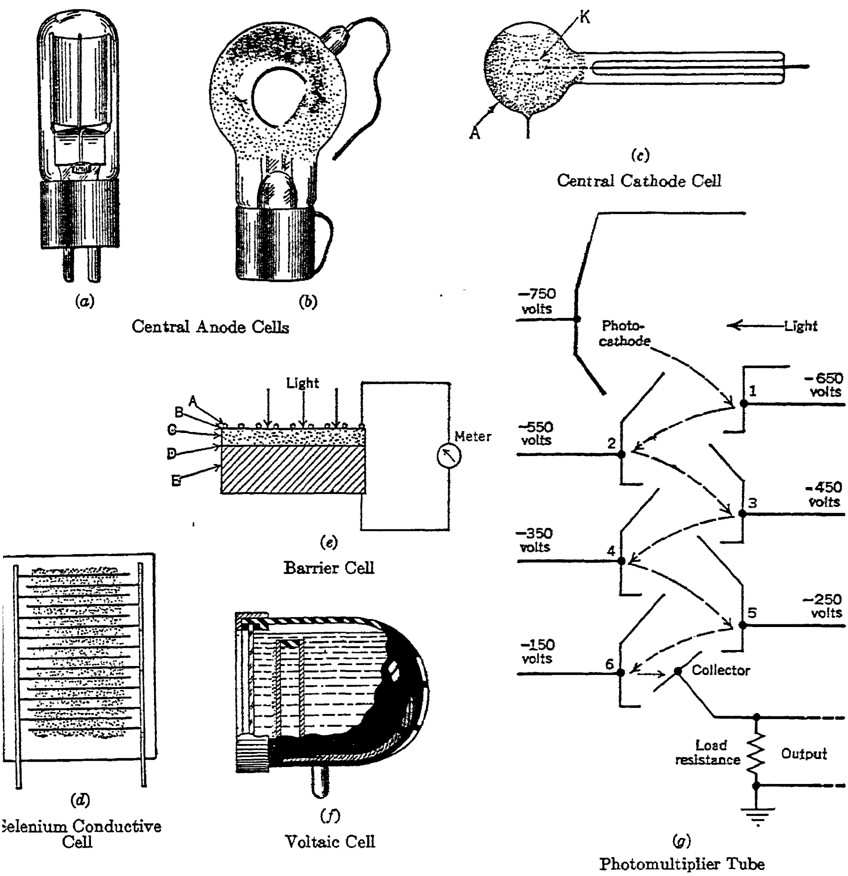

FIG. 2. Types of Photo-responsive Cells

second wire to serve as an anode. This type has been almost entirely superseded by cells in which the alkali metal forms a thin film upon some other metal. Two general types of structure are common, respectively, the central-anode and the central-cathode types. The central-anode type is represented by cells (*a*) and (*b*), Fig. 2. In these the alkali metal has been distilled upon a metal plate or on the walls of a bulb with an opening left for a window for the light. The central anode consists of a wire loop or grid. The central-cathode type, which is illustrated in (*c*), Fig. 2, consists of a metal plate, on which the alkali metal has been deposited, more or less surrounded by a grid or metal covering on the bulb wall serving as the anode.

ELECTRODE MATERIALS. The most commonly used photosensitive materials are the alkali metals, sodium, potassium, rubidium, and cesium, whose intrinsic sensitiveness increases in the order given. The sensitiveness of the pure metals is, however, far below that of the same metals when given various special treatments, such as being exposed to a glow discharge in hydrogen or being put down upon an oxidized base and given special heat treatments. The most generally used cell at present consists of a silver plate which is oxidized and subsequently exposed to cesium vapor and heat treated. A later development has been the combination of antimony with cesium, which produces a high sensitivity localized in the blue region of the spectrum. Other materials, such as barium and cadmium, are occasionally used when sensitiveness to particular regions of the spectrum is required.

VACUUM AND GAS-FILLED CELLS. Photoemissive cells are commonly made up either as high-vacuum cells or as gas-filled cells. In high-vacuum cells, the photoelectric current consists entirely of the electrons emitted from the cathode. In gas-filled cells, an inert gas such as argon is introduced at a pressure of several tenths of a millimeter of mercury, and, when a sufficient voltage is applied, the photoelectrons by collision with the gas produce ionization, whereby the current is amplified several times. This process of gas amplification is limited by the ignition voltage, at which a visible glow discharge takes place, which is self-perpetuating and will injure the surface of the cathode.

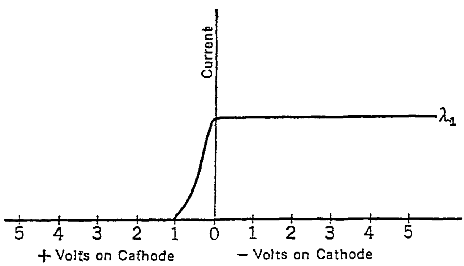

FIG. 3. Current-voltage Relation for a Central Cathode Cell

VOLTAGE-CURRENT CHARACTERISTICS. The relationship between voltage and photoelectric current under constant illumination depends upon the physical structure of the cell, particularly upon the size and arrangement of the electrodes. The structure best adapted for studying the fundamental phenomena of photoelectricity is the central-cathode arrangement. The voltage-current relation for a vacuum central-cathode cell, in which the dimensions of the cathode are negligibly small compared with those of the anode which encloses it as completely as is possible while allowing space for the entrance of light and mechanical parts, is shown in Fig. 3. In this figure, the abscissas represent voltages applied to the cathode and show that, at a certain positive voltage, that is, with a field which opposes the emission of electrons, the photoelectric current makes its appearance. This point, which is a measure of the maximum energy given to the photoelectrons by the incident light, is called the "stopping potential." As the positive voltage is decreased, the photoelectric current increases until it reaches a steady value at the saturation voltage. This voltage will be zero if anode and cathode are of the same material, but it will be displaced by the contact difference of potential between the anode and cathode where the materials are different.

In Fig. 4 is shown the corresponding characteristic for a vacuum central-anode cell. Here, because of the small target presented by the anode, saturation is reached only at high voltages. In Fig. 4 is also shown the voltage-current relationship for a gas-filled cell of the same construction. At low voltages this characteristic is essentially that determined by the structure of the cell, whether it be central anode or central cathode, but at higher voltages the current increases rapidly up to the ignition voltage of the gas which is, in general, of the order of magnitude of several hundred volts. Beyond this point, a sustained discharge occurs with a negative voltage-current characteristic.

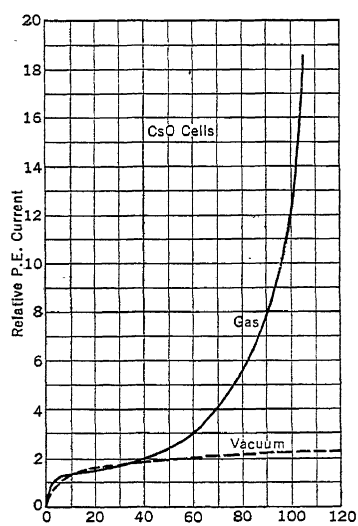

FIG. 4. Current-voltage Relation for Gas and Vacuum Central Anode Cells

ILLUMINATION-CURRENT RELATIONSHIP. With an ideal cell structure, the number of electrons released by the light, and consequently the photoelectric current, are directly proportional to the illumination. In all practical cells, however, this strict relationship is departed from to a slight extent because of charging effects of exposed glass walls and other obscure phenomena. For this reason, photoelectric cells are applicable to precision photometric measurement only if their exact characteristics are determined by experiment, or if a substitution method is used. In gas-filled cells, the illumination-current relationship departs from strict proportionality whenever, as is common, a high series resistance is used either as part of the measuring system or for protection against the occurrence of a glow discharge. The photoelectric current flowing through this series resistance uses up part of the applied potential, thereby lowering the voltage across the cell itself, which accordingly works upon a lower point in the voltage-current characteristic of Fig. 4. Typical illumination-current curves for a gas-filled cell with various series resistances are shown in Fig. 5.

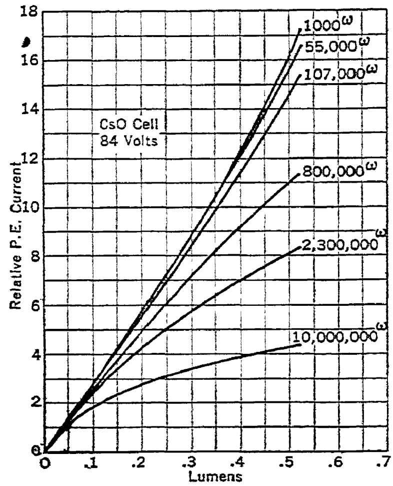

FIG. 5. Current-Illumination Relation for Gas Cell with Various Series Resistances

WAVELENGTH RESPONSE. The photoelectric current per unit of incident radiation varies greatly with wavelength and in different ways, depending on the characteristics of the sensitive material employed.

Figure 6 shows the equi-energy response curves for several typical cells compared with the average eye. These exhibit maxima of emission strongly localized in different parts of the spectrum. The maximum lies in the blue for the potassium hydride cell, in the infrared for the cesium-silver oxide cell, and in the near ultraviolet for the cesium-antimony cell. The type of cell to choose for a given purpose to secure the maximum response depends on the characteristics of the light source used. Sources like the tungsten lamp, whose emission is greatest in the infrared, evoke a maximum response from cells of the cesium oxide type, as illustrated in Fig. 7, where two cells of Fig. 6 are excited by tungsten lamplight instead of an equal-energy spectrum. Daylight and the quartz mercury arc, on the other hand, evoke a greater response from cells whose sensitiveness is farther toward the blue end of the spectrum.

SENSITIVITY. The luminous sensitivity of photoemissive cells is ordinarily defined by their output in microamperes per lumen of steady light. For gas cells which have some

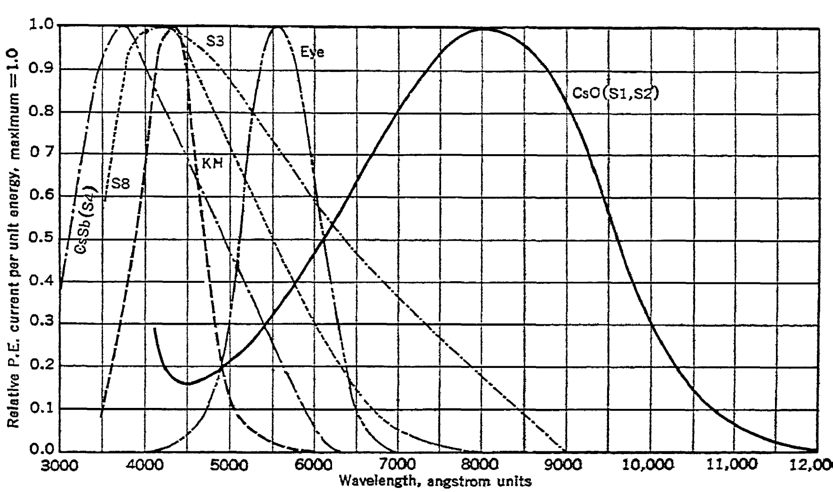

FIG. 6. Equi-energy Spectral Response for Some Types of Blue- and Red-sensitive Cells and the Average Eye

inertia at acoustic frequencies this sensitivity is often stated in terms of the cell's ability to follow a sinusoidally varying light at one or more stated frequencies within this range.

In general the sensitivity depends on the cell voltage, the flux intensity and its color, the resistance in the external circuit, and the distribution of the flux over the cathode if it is non-uniform, as it frequently is to some extent. No allowance is ordinarily made for the glass bulb or any absorbing films on its interior as they must be tolerated in using the cell.

Since the output is dependent on the spectral composition of the light, this should be specified; as tungsten lamps are ordinarily used in rating cells, it is done by stating their color temperature. There is no general agreement on a standard color temperature, but 2870 deg abs has been suggested and is used by some manufacturers. Figure 8 shows how the sensitivities of the red-responsive cesium oxide and the blue-responsive potassium hydride cells vary with this temperature. The sensitivity should not be confused with the total output obtainable from a cell as the filament temperature of the lamp is raised; this output always increases rapidly. The current per lumen of light, however, decreases with highly red-sensitive cells because there is relatively less red to blue or total light. Typical sensitivities are given in Table 2.

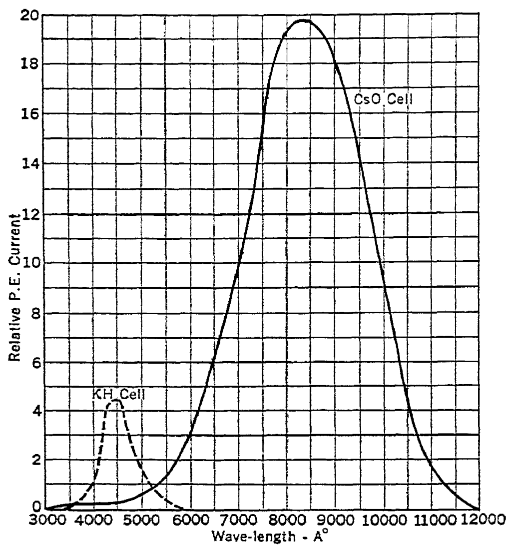

FIG. 7. Tungsten Spectral Response for KH and CsO Cells

The sensitivity of photocells is also defined by the magnitude of their response per unit radiant flux at a given wavelength. For example, the cells in Fig. 6 may be so evaluated by their microampere output per microwatt of irradiation at the wavelengths of maximum response. Typical values for unamplified commercial cathodes are: S1, 0.002 at 7500 Å; S2, 0.002 at 8000 Å; S3, 0.002 at 4400 Å; S4, 0.04 at 3750 Å.

In evaluating photoemissive cells the permanence and stability of the sensitivity must be considered along with its absolute value. Commercial emissive cells are usually permanent and stable provided that excessive voltages are not used (particularly on gas cells)

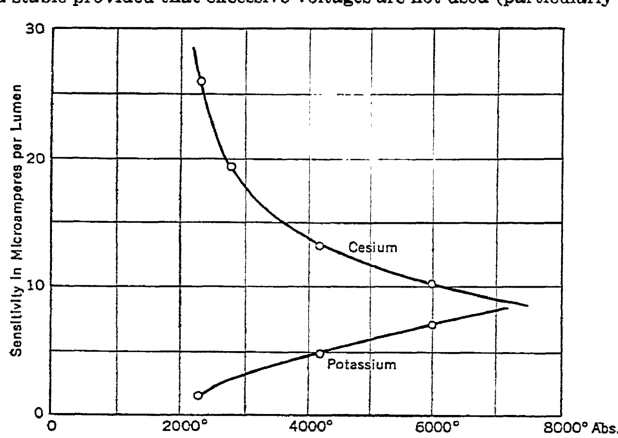

FIG. 8. Variation of Sensitivity with Color Temperature

and provided that they are not subjected to excessive heating or too concentrated illumination. Any ionization even of residual vapor or gas must be avoided for maximum stability so that in precision use anode voltages as low as 20 volts are recommended.

Leakage, due to a conducting film around the stem or to thermionic emission from the cathode, may render high sensitivity more or less useless. Cathodes deficient in red sensitivity, such as cesium-antimony, have greatly reduced thermionic emission.

FREQUENCY RESPONSE. The emission of electrons in the photoelectric effect is practically instantaneous, and accordingly the emission should be capable of following intermittent illumination up to exceedingly high frequencies, such for instance as those required for television. In practice, the frequency response drops off at high frequencies, owing either to the presence of the gas in gas-filled cells or in vacuum cells to the presence of the high series resistance, which is ordinarily used for coupling purposes, or to the electrostatic capacitance of the cell considered as a condenser. Typical frequency-response curves are given in Fig. 9.

Table 2. Sensitivity of Photoemissive Materials

(Tungsten lamp source)

	Microamperes per Lumen *	Filament Color Temperature, deg Kelvin
Potassium hydride	0.5–1.0	2848
Potassium-sulfur	1.8	2848
Sodium-sulfur	2.4	2848
Sodium-sulfur-oxygen	6–8	2848
Cesium antimony (S4)	30–45	2870
Cesium oxide on silver (S1, S2)	10–50	2870
S3	6.5	2870
S5	15.0	2870
S8	3.0	2870

* Intrinsic sensitivity of the cathode; amplification by gas or by secondary emission may increase these figures by several times or by several orders respectively.

In a gas cell the frequency response is dependent on the applied voltage, and if this is near the breakdown the loss of response may considerably exceed the values shown. It is not advisable to exceed the voltage recommended by the manufacturer.

MEASURING CIRCUITS FOR USE WITH PHOTOEMISSIVE CELLS. There are two general methods of measuring photoelectric-cell output: first, the measurement of the current directly; and second, the measurement of the voltage drop across a series resistance. The photoelectric current is measured by inserting a sensitive galvanometer in series with the cell and a battery, and the method is limited in sensitiveness only by the sensitivity of available galvanometers. The voltage drop across a high resistance is measured by means of an electrometer or of special vacuum tubes designed to function in the same manner. For extremely minute illuminations, the high resistance may be made infinite, and the current may be ascertained by the rate at which the electrometer or equivalent device charges up.

A number of d-c galvanometers are made which are suitable for use with photoemissive cells, ranging in sensitivity down from about 10^{-10} amp; this can be extended to about 10^{-12} amp with a device like the Moll thermorelay. The resistance of the galvanometer is immaterial, provided that it has a high current sensitivity, because the resistance of the cell will ordinarily be enormously greater. It is not desirable for several reasons to use an instrument that is much more sensitive than the work demands, but the testing of various types of cells of widely varying characteristics with different colors and intensities of illumination may require a very flexible galvanometer system. In this event, shunts can be used if they are so arranged as not to interfere with the critical damping. A good method is to insert various sections of the damping resistance in the cell circuit. The Leeds and Northrup type 2285-F galvanometer is suitable for this purpose. Where considerable current is available and portability is desired, microammeters of the Rawson or Weston type are convenient, especially when provided with a dial or other means of securing various scale sensitivities.

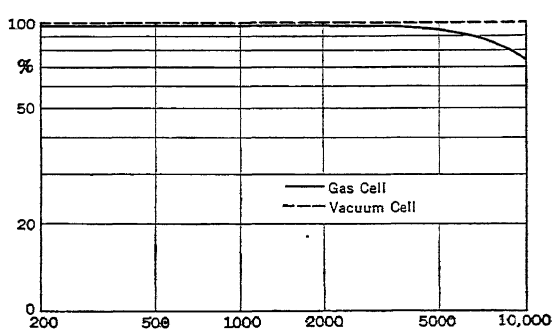

FIG. 9. Frequency Response for Gas and Vacuum Cells

In all cases, great care must be taken to protect any instrument from a breakdown of the cell by inserting sufficient series resistance, at the same time, if possible, retaining linearity of response. For work of the highest sensitivity it is necessary to resort to an electrometer such as the Compton type, the applied potential being secured by the drop across several megohms in series with the cell, or by using the cell as a constant current source and measuring the rate of charging of the electrometer placed in series. Effective use of the electrometer requires a permanent laboratory installation. Where greater portability is desired practically equivalent results can be secured by amplifying the very small currents by an "FP.54 pliotron" and measurement on a moving-coil galvanometer such as the Leeds and Northrup type R. For the methods of using an electrometer see Hughes and DuBridge's *Photoelectric Phenomena*, 1932, pp. 435–444, and for the corresponding technique of amplification see DuBridge, *Physical Review*, Vol. 37, Feb. 15, 1931, pp. 392–400. For descriptions of the more common electrometers see the catalog of the Cambridge Instrument Company, and for galvanometers consult catalogs of Leeds and Northrup Company and Kipp and Zonen.

AMPLIFICATION OF PHOTOEMISSIVE-CELL OUTPUT. Photomultiplier Tube. The initial current produced by illumination of a photocathode may be greatly amplified by utilizing the phenomenon of secondary emission. In the photomultiplier tube the electrons emitted from the cathode are directed by a suitable high-voltage field onto another, usually similar, electrode where they cause the emission of secondary electrons which are greater in number than the impinging electrons. This process may be repeated a number of times. Present commercial multiplier tubes have as many as nine such stages, and even larger numbers have been used in special tubes. The overall current amplification thus produced is of the order of several hundred thousand times. A typical electron multiplier structure is shown in (*g*), Fig. 2, and commercially available models are listed in Table 3, p. 15-16.

Circuits for Amplifying Photoemissive-cell Output. The photoemissive cell, because of its exceedingly high internal resistance, is admirably adapted for use in connection with vacuum-tube amplifying devices. In the simplest arrangement, the electrometer described in the previous section is replaced by the grid of a three-electrode tube, and the potential acquired by it modulates the current through the vacuum tube, which may be further amplified by successive stages.

Circuits for amplifying photoemissive-cell output are determined by the type of application of the cell. These can be put largely into three classes: trigger operation, d-c linear operation, and a-c linear operation. The first class is concerned with merely a qualitative response, and there is no particular requirement for linearity. A large number of uses come under this classification, such as the operation of relays in various counting and sorting processes. The usual circuit for amplification consists in feeding the voltage drop across the cell load into a thyratron tube which in turn actuates a relay (see Section 21). The necessity for supplementary amplification will depend on the light variation available and the marginal requirements of the relay. It is necessary to provide for the release of the thyratron, and this can be easily done by using alternating current on its cathode or interrupting the direct current. The sensitivity of trigger systems can ordinarily be increased by the use of large load resistances in the cell circuit.

A method of use closely allied to the preceding in the characteristics demanded of the cell is as a null device in substitution photometry, where the only requirement is a suitable recorder with enough amplification to give the necessary precision. If the test and comparison lights are rapidly alternated on the cell, the method permits of a-c amplification with its attendant advantages of great efficiency and simplicity, the match being given by zero a-c output.

The second class, d-c linear operation, covers the direct-reading method of photometry, an example of which is the recording of daylight intensity. This method has the disadvantage of requiring stable cells of reproducible, linear characteristics, a requirement not always easy to meet for precision photometry. For many purposes, however, the requirements are not rigid and commercial cells are suitable for the purpose. Several methods of amplification are possible. One is to use straight d-c resistance-coupled amplification, preferably at low cell currents, with an electrometer tube as the first stage. In order to minimize the tendency to instability inherent in d-c amplification, use is sometimes made of balanced d-c amplification. At low light intensities these direct methods require much care to guard against leakages in and around the cell, and, for some purposes, specially constructed cells are necessary. Another precaution that must be taken is to insure the linearity of response of the amplifier. A third method of amplification that is sometimes applicable is to interrupt the illumination of the cell and use a-c amplification (see Section 7). This has the advantages of greater stability, of minimizing leakages, and of securing the efficiency of interstage coupling by transformers.

Such uses of photocells as for picture transmission and sound pictures may be classed as a-c linear operation. Here the response must be not only linear but also uniform over a range of frequencies which may, as in television, be very large. This imposes certain restrictions on the load impedance in the cell circuit. Since a large value is necessary in order to secure a high voltage output into the amplifier, the shunting capacitance becomes very important and severely limits the useful value of the impedance that can be used.

Noise Limit to the Use of Amplification. Broadly speaking, any photoelectric current, however minute, can by successive amplification be raised to any desired high value. A limit is set to the effectiveness of this process by the noise in the cell or its associated circuits, which is amplified along with the signal. The significant specification of sensitivity of a photocell thus becomes the signal which can override the noise. Noise in a photocell exists because of natural fluctuations of current at low values and by the thermal agitation of electrons in the coupled resistances, and it is a function of temperature, frequency, and band width. In addition there are many extraneous sources of noise from such causes as the ionization in gas tubes, interference, microphonic contacts, power supplies, and dielectric leakages. These can usually be diminished to secondary importance by careful shielding and design of the circuits. Where considerable amplification of weak photocurrents of wide bandwidth is required there will be a gain in the signal-to-noise ratio by using a multiplier phototube for the initial stages.

4. PHOTOCONDUCTIVE CELLS

The fact that light could directly change the electrical resistance of a substance was first discovered about 1880 by observation of the effect in metallic selenium, and since that time some 2000 papers have been published concerning its behavior and use. Nevertheless, the mechanism whereby light releases electrons remains obscure. Furthermore, many of its characteristics depend to a considerable extent on the method of construction as well as the conditions under which they are measured. Two types of construction have been used for such cells: one in which a thin layer of selenium is sandwiched between two electrodes, one of which must be translucent to permit illumination of the layer; and one in which two interlocking metallic grids or combs are bridged by a layer of selenium. Modern cells are usually of this second type, although the barrier cells described below use the first. An example of a conductive selenium cell of comb construction is shown in Fig. 2(*d*). Other materials which exhibit similar properties are thallium sulfide and lead sulfide. The former is used in a cell known commercially under the name of "Thalofide." Both these newer cells possess properties which render them superior to selenium.

Current-illumination Relationship. If a selenium cell is placed in series with a battery and meter and is illuminated with increasing intensity, the resulting current will usually be of the shape shown in Fig. 10. In general the change in conductance, G, follows the equation

$$G = \frac{1}{r_i} - \frac{1}{r_0} = gF^x$$

where g and x are constants, F the light flux, r_0 the dark resistance, and r_i the light resistance. The constant x is frequently about 0.5, so that the photocurrent varies approximately as the square root of the illumination. The dark resistances of different grid cells vary greatly but usually are from 100,000 up to several megohms; those of the sandwich type are much lower and may be only a few hundred or thousand ohms. The current-illumination relation of thallium sulfide differs from selenium in not being curved as strongly toward the illumination axis.

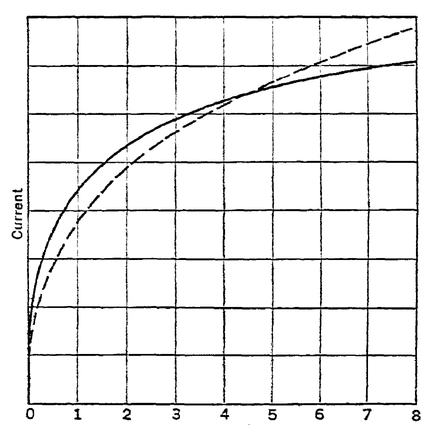

FIG. 10. Current-illumination Response for Selenium Conductive Cell

Photoconductive cells are made to operate on a variety of applied voltages, and in general the recommendations of the maker should be followed. If not hermetically sealed the cells should be protected from excessive moisture and corrosive gases such as sulfur fumes. High illumination also causes deterioration of some cells.

WAVELENGTH RESPONSE. Typical curves of the spectral response for both selenium and thallium sulfide are shown in Fig. 11. It is characteristic of the former to have a peak at 7000 or 7500 angstroms, the sensitivity up through the visible region being variable with different cells and frequently rising again as the ultraviolet is approached. Thallium sulfide is much more infrared-sensitive than selenium, with a maximum around 10,000 angstroms, after which it falls off rapidly, whereas lead sulfide has a maximum at 25,000 angstroms and falls to 20 per cent at 4000 and 33,000 angstroms.

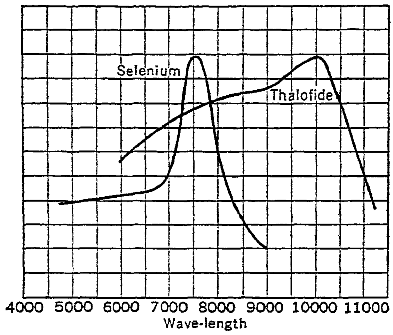

FIG. 11. Spectral Response for Selenium and Thallium Sulfide Conductive Cells

FREQUENCY RESPONSE. Many oscillographic observations have been made on the speed with which the photocurrent builds up when a selenium cell is suddenly illuminated and on the rate of decay of the current when the light is removed. This method of observing its inertia, however, is ordinarily not so useful as the method of measuring its response to continuously interrupted light of known frequencies. Figure 12 shows such a measurement starting at very low and extending to nearly 10,000 interruptions per second, the ordinates being the a-c response relative to the flat portion as unity. The most recently developed Thalofide cells fall off much more slowly with frequency and are useful up to the lower voice frequencies; the frequency performance of lead sulfide is notably better than that of thallium sulfide, remaining practically constant up to 5000 cps.

SENSITIVITY. Photoconductive cells are commonly rated by their ratio of dark-to-light resistance at a stated illumination and voltage. Thus a cell may be stated to have a ratio of 6 at 100 ft-c using a battery of 100 volts. As there is no agreement on a standard light intensity or color, care must be exercised in comparing cells from different manufacturers. The d-c sensitivities may be divided into two classes according to whether the load in series with the cell is a relay to be operated directly, or a resistance, the voltage drop across which is in turn required to operate the grid of a thermionic tube. In the latter case the expression for the voltage sensitivity, σ, of selenium is

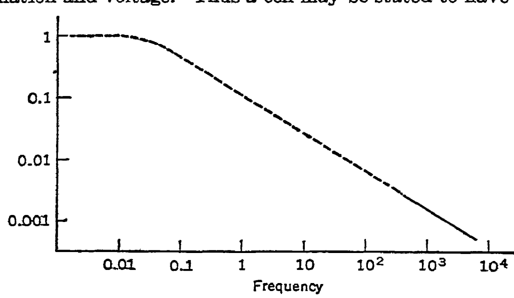

FIG. 12. Frequency Loss for Selenium Conductive Cell

$$\sigma = \frac{dE_g}{dF} = \frac{Er_ig}{8\sqrt{F}} = \frac{Er_0g}{8\sqrt{F}(1 + r_0g\sqrt{F})}$$

where E_g = voltage across load effective on grid.
E = battery voltage.
F = light flux.
r_0 = dark resistance of cell.
g = constant of the cell, its light conductance being $g\sqrt{F}$.
r_i = light resistance of cell.

This is the equation for the maximum voltage sensitivity at light flux F, where the load resistance is equal to the light resistance of the cell r_i, under the condition of operation. If the load is a relay to be operated directly in series with the cell the ampere-turn sensitivity must be used instead of the above. This is equal to the voltage sensitivity given above multiplied by $1/t$, where t is the resistance per turn of the relay.

If a photoresistance cell is operated between dark and a given light intensity as the limits, the maximum voltage change across the load resistance, r_a, is secured when

$$r_a = \sqrt{r_0r_i}$$

the voltage change being

$$Er_a\left(\frac{1}{r_i + r_a} - \frac{1}{r_0 + r_a}\right)$$

The same condition for r_a applies for the current-turn sensitivity, and its change is equal to the voltage change multiplied by $1/t$.

AMPLIFICATION OF PHOTOCONDUCTIVE-CELL OUTPUT. The amplification of the output of these cells is fundamentally the same as for the emissive cells, and the same types of amplifiers can be used. Since conductive cells have much lower impedances, it is possible in many cases to match the load to the cell and thereby secure the maximum efficiency of operation. Since the cell resistance may vary rapidly with illumination, care must be taken that the match be made at the average light intensity at which the cell is to be operated. If an intermittent or variable illumination is used such that the cell must respond to some range of frequencies it may be necessary to equalize the output in order to preserve fidelity of reproduction. Since there is an increasing loss as the frequency of response is increased, it is necessary to compensate for it by introducing attenuation of the lower frequencies by a filter network at some convenient point in the amplifier. The highest frequency at which one desires to work will then determine the effective loss of a cell.

5. BARRIER PHOTOCELLS

STRUCTURE. The fact that, under certain conditions, photoconductive selenium cells could produce an emf on illumination without any applied potential has been known since the late nineteenth century. The discovery of the effect in cuprous oxide revived interest in it and led to the development of cells of commercial importance. They are of the sandwich type of construction referred to above and illustrated in Fig. 2(*e*). A photosensitive material such as selenium or cuprous oxide *C* is formed on a suitable metallic base *E* and covered with a translucent conductor such as a wire mesh *A* or a thin metallic film. If the photosensitive layer is itself partially transparent, as, for example, cuprous oxide, a photo emf may appear at junction *D*, where it is called a "back-wall effect," or at *B*, where it is called a "front-wall effect." The location and degree of sensitiveness are dependent on the method of preparation, the heat treatment, rate of cooling, gas content, and treatment of the boundary surface. If an attempt is made to pass current across such a photosensitive boundary by inserting a battery of a few volts in the meter circuit, it is customarily found that the current can flow much more easily in one direction than in the other, and this directional resistance behavior or rectification is illustrated in Fig. 13 for a typical commercial cell in the dark, the unit here being of the front-wall type. As a photocell without the external battery, the effect of illumination is to make the top become negative and the base positive; that is, the electrons released by the light flow in the high-resistance direction. If the active layer is at the back wall *D*, Fig. 2(*e*), the behavior is primarily the same except that the polarities are reversed with respect to the top and bottom. In this case the light must penetrate much more material, which reduces the optical efficiency and alters the spectral response curve.

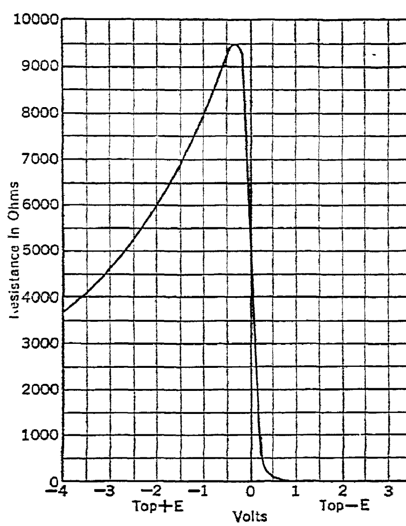

FIG. 13. Dark Resistance-voltage Relation for Selenium Barrier Cell

When a barrier cell is illuminated, its dark resistance at zero applied voltage is decreased by the photoconductive effect in the layer, and at high intensities it may be much reduced for a cell of the characteristics shown in Fig. 13.

ILLUMINATION RESPONSE. The current-illumination response of a typical cell is shown in Fig. 14 with various series resistances. With very low resistance or short-circuited current the relation is linear or very nearly so, gradually becoming more curved as the resistance is increased until the open-circuit voltage relation is reached. Figure 15 shows the two extremes for comparison. Care must therefore be taken not to use too much series resistance if a linear response is desired.

WAVELENGTH RESPONSE. In Fig. 16, *A* shows the spectral response for a typical selenium cell; *B* and *C* are for front- and back-wall cuprous oxide cells, respectively. In general, cells of this type have most of their sensitivity in the visible region. Back-wall cells of cuprous oxide, however, are deficient in this region owing to the absorption of the red oxide so that their response is confined largely to the visible red and some distance beyond into the infrared. Cells equipped with optical filters to make their response closely that of the eye are now supplied by manufacturers.

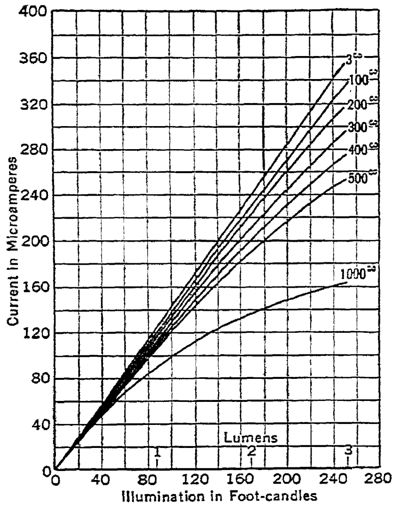

FIG. 14. Current-illumination Relation of Barrier Cell with Different Series Resistances

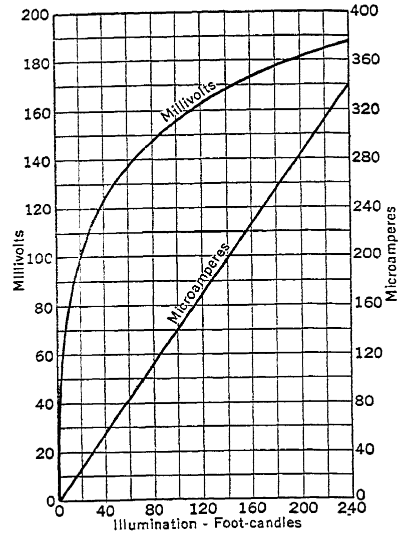

FIG. 15. Short-circuit Current and Open-circuit EMF-illumination Relations for Barrier Cell

SENSITIVITY. Barrier cells are rated according to their microampere-per-lumen output, and the same qualifications apply to them as were stated for emissive cells concerning the color of the light source and resistance in series. On account of the warping of the linearity of the current curve by comparatively small resistances, care must be taken in its measurement to use a sufficiently low-resistance meter. It is also frequently useful in certain applications to have a statement of the open-circuit voltage in millivolts per lumen. From Fig. 15 it is clear that this ratio is high at low illuminations and rapidly diminishes as the illumination is raised, and for this reason it is necessary to state the illumination at which the measurement is made.

Calculations of the maximum power and voltage sensitivities are complicated by the fact that the internal resistance decreases with illumination, especially with the selenium type. For this reason, it is necessary to know the characteristics of the individual cell, and it is advisable to consult the manufacturer regarding the particular use to which it is to be put or to determine the proper load experimentally. For the cuprous oxide type the internal resistance is commonly assumed constant, and in this case the maximum voltage sensitivity, dE_g/dF, is equal to Sr, S being the sensitivity constant and r the internal resistance, the load, r_L, being relatively very large. In this case the maximum power sensitivity is $S^2rF/2$, where $r_L = r$. These values of r_L will ordinarily be sufficient to cause departure from linearity of current response so that a compromise must be made by sufficient reduction in the load resistance. Barrier cells are liable to deteriorate, and direct-reading instruments utilizing them such as foot-candle and photographic exposure meters should be checked occasionally and the cell replaced if necessary. Poor contact with the clamping rings may also develop. This

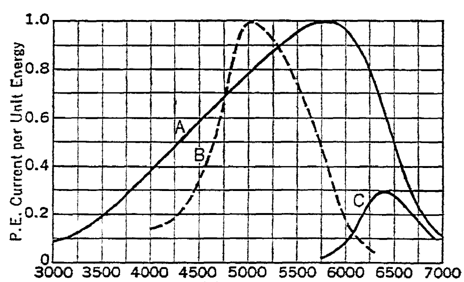

FIG. 16. Spectral Response of Barrier Cells. *A*, selenium. *B*, cuprous oxide, front wall. *C*, cuprous oxide, back wall.

type of cell is subject to a fatigue which causes a decrease in the response when first illuminated. Recovery takes place in the dark, but the reproducibility of readings is somewhat dependent on the duration and intensity of illumination. This type has no dark current.

FREQUENCY RESPONSE. Exact information on the various commercial cells is not available. Barrier cells have a relatively large internal capacitance which diminishes their output with increasing frequency. The "Photronic cell" is stated to give a satisfactory response to light interrupted at 60 cycles per second, and if this output is assumed 100 per cent then at 120 cycles it will be about 58 per cent, at 240 cycles 30 per cent, and at 1000 cycles 6.4 per cent. It is also stated that, if an equalized response is produced up to 5000 cycles, the power level is reduced approximately 35 db. The response of the cell to single interruption is more rapid than that of a relay, so that for this use they may be considered instantaneous.

AMPLIFYING CIRCUITS. If constant illumination is to be used, a d-c amplifier is demanded, which may be troublesome to build and operate. In general it is therefore recommended that the light be interrupted at a low frequency of, for example, about 60 cycles, and that a good a-f amplifier capable of transmitting this frequency efficiently be used.

The remarks previously made concerning the amplification of emissive and conductive cells also apply to this type. Barrier cells have lower impedance than either of these, and are well within the range of practical transformers, so that they can be directly coupled and the output used in an a-c amplifier. Equalization of frequency response may be necessary as with the conductive cells.

6. PHOTOVOLTAIC CELLS

In the middle of the nineteenth century it was discovered that if two similar electrodes of certain materials, such as platinum or silver coated with silver halide, were immersed in dilute electrolytes and one electrode was illuminated, a voltage appeared between them. These are referred to as photovoltaic cells, although some writers broaden this name to include also the barrier cells previously described and refer to them as wet and dry cells respectively. Various combinations of electrodes, coatings, and intervening liquids have been employed, but, apart from experimental studies of the effect, the usual materials are oxides, sulfides, or halides in an acid or inorganic salt electrolyte. Cuprous oxide gives a large effect and has frequently been used in attempts to commercialize this type, the non-sensitive electrode being some durable material such as lead with an electrolyte of lead nitrate in water; see Fig. 2(*f*).

CHARACTERISTICS. The behavior of the open-circuit voltage and the short-circuit current responses with illumination for a cell of the Cu, Cu_2O, $Pb(NO_3)_2$, Pb construction are similar in shape to the corresponding characteristics for barrier cells (see Fig. 15), the former showing a tendency to voltage saturation and the latter being linear. The effect of increasing external resistance is also qualitatively similar; see Fig. 14.

The spectral response of the cuprous oxide cell is high in the visible spectrum, being a maximum in the blue or blue-green.

These cells are subject to polarizing effects which make them more unstable than the other types, and there is a gradual deterioration of the sensitive layer which greatly shortens their useful life. It is claimed that this deterioration can be inhibited to some extent by using a depolarizer such as hydrogen peroxide in the electrolyte to oxidize the free hydrogen which reduces the cuprous oxide.

The response to illumination and the recovery afterward are not as rapid as the cuprous oxide barrier effect.

7. CHOICE OF CELLS FOR VARIOUS PURPOSES

Although the applications of photocells are frequently classified according to marginal or linear operation, this does not have so much to do with the choice of the cell as the method of its use and of the amplification of its output. Ordinarily the selection of a cell is dominated by considerations of high sensitivity to tungsten or daylight, the requirements of precision photometry, a particular spectral response, or convenience, all of which involve the relative evaluation for the purpose at hand of such factors as magnitude of output, frequency loss, fidelity of color and intensity response, permanence, stability, leakage, and absence of external battery.

¶ Some ultraviolet tubes not listed are WL767, WL773, WL775, WL789 by Westinghouse and 935 by RCA.

The cesium oxide cell is particularly efficient for use with tungsten light because its maximum sensitivity is near the optimum energy emission of the high-brilliancy gas lamps. This renders it suitable for sound pictures, telephotography, television, and numerous marginal applications such as counting and control operations. The color response is also sufficiently extended over the spectrum to permit its use in many sorting operations and in colorimeters. In some technical applications it is necessary or, at least, highly desirable that the cells be used with infrared light to avoid detection of the beam by the wary or curious, and the cell has sufficient infrared response to permit the tungsten light to be concealed by filters which transmit only this region with very little visibility of the interrupted beam. The cesium-antimony cathode is finding increasing application. Its high efficiency to tungsten light makes it competitive with cesium oxide and considerably superior with bluer modern illuminants. For colorimetric applications, a surface such as the S3 is more suitable because of its broad spectral response through the visible region which more nearly simulates the eye.

The requirements of precision photometry vary greatly according to the intensity and color of the light to be measured and according to whether the measurements are relative or in visual units. For example, in stellar photometry where very little light is available and high amplification is necessary, leakage in and around the cell must be reduced to the minimum and high sensitivity and color response may not be as important. On the other hand, in the ordinary routine photometry of tungsten light, leakage may be relatively unimportant. In precision photometry it is essential that cells be used in a manner which gives an assured calibration for each reading and that their constancy be not assumed without adequate proof. Cells to be used for measurements in visibility units require either a filter to modify their color response or a calibration by a source whose spectral emission is the same as that to be measured. If sources such as tungsten lamps through a moderate range of color temperature are to be measured, requirements of commercial photometry may be met by calibrating with a similar source within the range, combined if necessary with a visual filter that approximately matches the eye.

The increasing use of ultraviolet for therapeutic and photochemical purposes has created a demand for cells to measure intensities in this region, the response for therapeutic purposes being of such shape as to evaluate the radiation directly in erythema units or in time of exposure. This region is from 2800 to 3200 angstroms approximately, the shorter wavelengths of questionable value being excluded by filtering the source. A number of materials are intrinsically sensitive to this region, but it is undesirable to use those of considerable visible sensitivity because of the difficulty of suppressing sufficiently the larger amount of energy in the longer wavelengths even in the mercury arc, which would mask the ultraviolet response. Consequently it is desirable to use only those materials which are not naturally sensitive much beyond 3200 angstroms. Cadmium, uranium, and lithium have been proposed, and the first two have been used practically. In order to limit the response to the proper wavelength on the short-wavelength side, these metals can be mounted in bulbs of Corex D glass instead of quartz. If, for other purposes, it is desired to broaden the region of response up toward or into the visible blue, thorium and cerium have been suggested.

The glass bulbs of ordinary commercial cells are more or less opaque to radiation beyond about 3200 angstroms, so that, in any event, a special glass or quartz is necessary. The cesium oxide cathode, however, is very sensitive to the longer ultraviolet up to 2000 angstroms as far as measurements are available.

For certain purposes where an external battery is undesirable, cells of the barrier type are finding application, an example being as a photographic exposure meter. It is necessary, of course, to interpret the readings in terms of exposures for the various color sensitivities of emulsions by charts or suitable scales on the meter.

Table 3 lists the better-known commercial cells.

TELEVISION PICK-UP TUBES

By V. K. Zworykin and E. G. Ramberg

8. REQUIREMENTS

The purpose of the television pick-up tube is to convert an optical image of the scene to be transmitted into an electrical signal descriptive of the light distribution in the image. In all the pick-up tubes here considered the signal is obtained by scanning in sequence a rectangular image area along a fixed number (e.g., 525) of adjoining horizontal scanning lines; with an ideal transmission system and viewing device the instantaneous signal output of the pick-up tube determines the brightness of a particular picture element (i.e., a square whose length and height are equal to the separation of two scanning lines) in the reproduced image, scanned in synchronism with the transmitted image.

A satisfactory pick-up tube must be capable of furnishing a signal that can be converted into an image with adequate detail, free from objectionable random fluctuations in brightness (noise), and faithful in geometry and tonal values over its entire area, at a reasonable illumination of the transmitted scene. Similar requirements regarding resolution, signal-to-noise ratio, uniformity, and sensitivity must also be fulfilled by the 35-mm negative film employed in commercial motion-picture production, whose properties may reasonably be taken as a standard. This is all the more appropriate since the comparison of television with motion pictures appears inescapable.

SENSITIVITY. A suitable figure of merit for the sensitivity is given by the ratio $f^2/(BA)$, where f is the f-number of the lens employed, B the brightness of the scene required to yield a good picture (in lumens per square meter), and A the area of the picture on the film (in square meters); through the factor f^2/A the figure of merit is proportional to the square of the depth of focus. Employing figures derived from motion-picture studio practice, $f = 2$, $B = 5500$ (lumens/m^2), and $A = 0.00032$ m^2 (0.5 in.^{2}), $f^2/(BA) = 2.3$.

RESOLUTION AND SIGNAL-TO-NOISE RATIO. Thirty-five-millimeter film is generally capable of resolving 1000 to 1500 lines per picture height; on the other hand, at this level the photographic grain or noise interferes seriously with the picture detail (i.e., the signal). For a ratio of the signal to the root-mean-square noise amplitude of 30–40, required to render the grain unobjectionable, the resolution must be reduced to about 500 lines. It should be noted that the root-mean-square noise amplitude employed throughout in the present discussion is only about one-sixth as great as the peak-to-peak noise amplitude, which may be observed directly on an oscilloscope screen. It is found experimentally that the signal-to-noise ratio for film remains approximately constant throughout the useful exposure range. It differs in this from the more sensitive television pick-up tubes, for which the noise is constant and the signal-to-noise ratio, hence, is lower in the low lights than in the high lights.

UNIFORMITY. The film image is geometrically faithful and uniform in response over the entire image area.

It will be seen that certain pick-up tubes exhibit higher sensitivity and signal-to-noise ratio for equal resolution than film. To this extent they enable television cameras to function more favorably than studio and news motion-picture cameras.

9. THE IMAGE DISSECTOR

The Farnsworth image dissector is shown, in schematic cross-section, in Fig. 1. At one end of the tube there is a photocathode on which a lens projects an optical image of the scene; at the other, a positive electrode with a tiny aperture, equal to a picture element in size. The magnetic field of a solenoid focuses the photoelectrons so as to form, in the plane of the aperture, a charge image of the picture on the photocathode. This charge image is swept across the aperture by the magnetic deflecting fields so that, at any instant, photoelectrons from just one picture element on the photocathode pass through the aperture. These accelerated photoelectrons fall on the first stage of an 11-stage multiplier (see article 4) built into the tube and eject a larger number of secondary electrons which are drawn through an accelerating screen to the second target electrode, leading to a further secondary-emission multiplication of the current. The output of the multiplier, finally, may be coupled by a resistance to the input of a standard video amplifier.

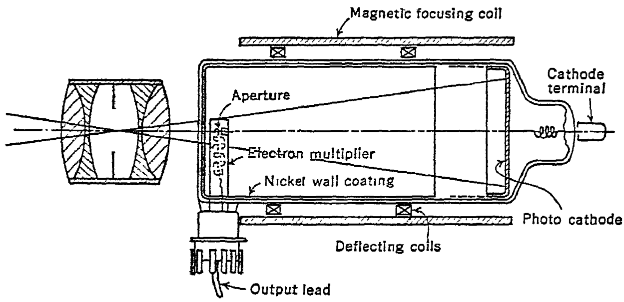

FIG. 1. The Image Dissector

The current passing through the aperture is simply the photocurrent emitted by a picture element on the photocathode. Thus, if p is the photosensitivity of the cathode in amperes per lumen, L its illumination in lux (lumen/m²), A the effective area of the photocathode in square meters, and N the number of picture elements, the signal current becomes

$$i_s = \frac{pLA}{N} \tag{1}$$

Denoting the transmitted band width by F, the shot-noise amplitude for this current is

$$\overline{i_n^2}^{1/2} = (2ei_sF)^{1/2} \tag{2}$$

Assuming $F = 5 \cdot 10^6$ sec^{-1} and a 525-line picture ($N = (525)^2 \cdot 4/3$),

$$\overline{i_n^2}^{1/2} = 2.1 \cdot 10^{-9}(pLA)^{1/2} \tag{3}$$

Hence the signal-to-noise ratio is

$$S = i_s/\overline{i_n^2}^{1/2} = 1.3 \cdot 10^3(pLA)^{1/2} \tag{4}$$

If it is assumed that $p = 20 \cdot 10^{-6}$ amp/lumen, $A = 0.01$ m² (15 in.²)

$$S = 0.58L^{1/2} \tag{5}$$

A signal-to-noise ratio of 100 would thus demand a cathode illumination $L = 29{,}000$ lux.

The multiplication provided by the multiplier should be such that the multiplied shot noise exceeds the amplifier input tube noise current, which may be estimated at $2 \cdot 10^{-9}$ amp. Since

$$\overline{i_n^2}^{1/2} = 1.6 \cdot 10^{-12}S \tag{6}$$

the multiplier gain will suffice for all recognizable picture detail ($S > 1$) if it is equal to a few thousand. The actual gain is made larger than this, reducing the required amplifier gain.

SENSITIVITY. From the above figures it follows that, in order to transmit a picture with a signal-to-noise ratio of 100, an image dissector provided with an $f/4.5$ lens would require (for an effective cathode area of 0.01 m²) a high-light brightness of the scene equal to $29{,}000\ (2 \cdot 4.5)^2 = 2.3 \cdot 10^6$ lumens/m². The figure of merit of the dissector, calculated in the same manner as for film, hence becomes

$$\frac{4.5^2}{0.01 \cdot 2.3 \cdot 10^6} = \frac{1}{1100} \tag{7}$$

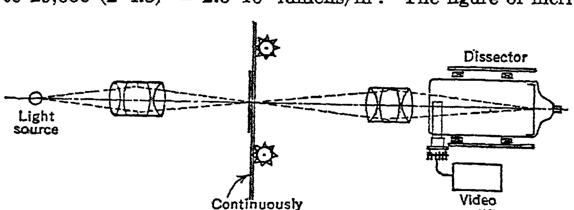

FIG. 2. Motion Picture Transmission with Image Dissector

Thus the sensitivity of the dissector is less than that of film by a factor of two or three thousand. This is a drawback for direct pick-up but is of secondary importance for motion-picture transmission. For the latter purpose, continuously moving film is generally employed (Fig. 2). The film motion provides the vertical deflection, so that only the horizontal deflection coil need be actuated. Special types of image dissectors, designed specifically for the transmission of black and white and of color film, are available. Since the standard projection speed for motion pictures is 24 frames per second and the television field frequency is 60 per second, the arrangement shown in Fig. 2 is generally modified by the insertion of an optical compensation system between the continuously moving film and the dissector tube. This causes the motion-picture frames to be scanned two and three times in alternation.

RESOLUTION. Under normal circumstances the aperture size determines the resolution of the image dissector. Change of focus with deflection is readily compensated by applying the proper correcting signals to the focusing current or the accelerating voltage in synchronism with the deflection. Fundamentally, the resolution of this type of tube is limited by the unsharpness of focus arising from the initial velocities of the photoelectrons. An increase in the number of picture elements demands, hence, either the employment of a larger photocathode, leaving the length of the tube unaltered, or a higher operating voltage and stronger focusing field.

SIGNAL-TO-NOISE RATIO. The signal-to-noise ratio of the image dissector is proportional to the square root of the scene brightness. Hence, for equal signal-to-noise ratio in the high lights, the noise will be more prominent in the low lights than for film, though less prominent than for most of the remaining pick-up tubes to be considered, for which the noise is independent of the light level. It is therefore necessary to demand a higher signal-to-noise ratio in the high lights than for film (e.g., 100 in place of 30–40). The fact that the noise becomes more noticeable in the low lights is accentuated by the circumstance that the signal output of the dissector is strictly proportional to the element brightness, i.e., that the tonal scale is not compressed by the pick-up device.

UNIFORMITY. The image dissector has excellent uniformity properties, both with regard to constancy of response over the entire picture and to the absence of geometric distortions.

10. THE ICONOSCOPE

The iconoscope, the orthicon, and the image orthicon may be classed together as storage pick-up tubes. In all of them the charge released photoelectrically from a picture element by the incident light is stored in the period intervening between two successive scannings of the element. This leads to a very great gain in sensitivity in comparison with nonstorage pick-up systems such as the image dissector.

Figure 3 shows the construction of a standard iconoscope (type 1850-A) with magnetic deflection. It is seen to consist of an electron gun whose beam is deflected across the surface of a photosensitive "mosaic" by two pairs of external deflecting coils, and the mosaic, all enclosed in a dipper-shaped envelope. An image of the scene to be transmitted is projected by a lens through an optically clear face of the envelope onto the mosaic plate whose dimensions are 4 $^3/_4$ × 3 $^9/_{16}$ in.[2]

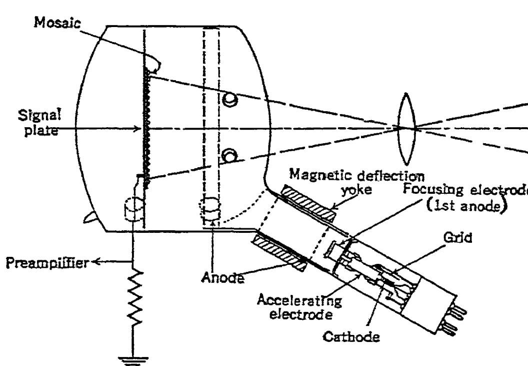

FIG. 3. The Iconoscope

A typical gun structure consists of an indirectly heated cathode enclosed in a grid cylinder with a 0.040-in. aperture, a closely spaced cylindrical accelerating electrode at full anode voltage with a defining aperture 0.002 in. in diameter, a focusing electrode or first anode, and the final anode in the form of a platinum coating on the inner wall of the gun tube. The defining aperture, which coincides approximately with the cross-over, is imaged by the equipotential electron lens formed by the two cylinders at full anode potential and the intermediate focusing electrode on the mosaic, forming a spot 0.005 in. or less in diameter; this design minimizes the current striking the focusing electrode or first anode and hence prevents disturbing secondary emission from the gun. In practice the anode is maintained at approximately 1000 volts, the focusing electrode at 300 volts, and the grid bias may be varied from −30 to −50 volts. The optimum Iconoscope beam current ranges from 0.05 to 0.2 microampere, increasing with the illumination of the mosaic.

The mosaic is a thin sheet of mica, covered, on the side facing the lens and the electron beam, with an array of minute silver globules, small compared with a picture element. These have been rendered photosensitive by a process involving oxidation, cesiation, and the subsequent evaporation of silver. On the other side the mica sheet is coated with a continuous metal film, the signal plate, which is electrically connected to the coupling resistor and the grid of the first stage of amplification. The capacitance between the signal plate and the photosensitive mosaic is of the order of 1 $\mu f/m^2$; the total capacitance between signal plate and anode coating, 10 $\mu\mu f$. The photosensitivity of the mosaic is 4–10 μa/lumen; its spectral response is shown in Fig. 4. For a mosaic illumination of 10 to 50 lux a coupling resistance of 0.1 megohm is recommended. At very low light levels (and a beam current of the order of 0.05 μa) it is proper to increase this to 1 megohm.

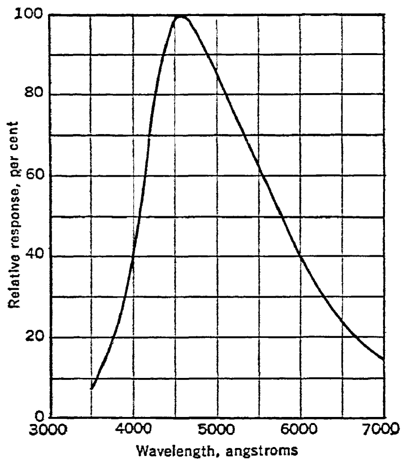

FIG. 4. Spectral Response of the Type 1850-A Iconoscope

Figure 5 shows a smaller Iconoscope (type 5527), with electrostatic deflection and transparent signal plate, which is designed primarily for industrial and amateur use. It has a 1.4-in. mosaic and operates with a beam voltage of 800 volts and a first-anode voltage between 125 and 250 volts. The cut-off voltage for the control grid is about −75 volts, and the horizontal and vertical deflection voltages are in the neighborhood of 100 volts.

OPERATION. Superficially, the operation of the Iconoscope may be described as follows: The mosaic functions as an array of minute photoelectric cells with a common anode, whose cathodes are capacitatively coupled to the signal plate. The elementary condensers so formed charge up, as the mosaic is exposed to light, by an amount proportional to the light intensity. Whenever the beam, acting as a commutator, sweeps across them, the cathode elements are returned to their equilibrium potential by collecting the requisite number of electrons from the beam, and an equal electron current passes through the signal lead. For an illuminated element on a generally dark mosaic (for which the total photocurrent would be very small), the signal current would be given by

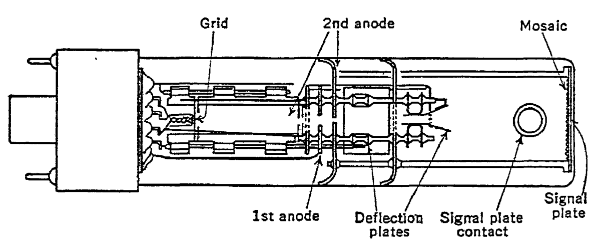

FIG. 5. Small Iconoscope with Electrostatic Deflection (Type 5527)

$$i_s = pL\frac{AT}{Nt_e} = pLA \tag{S}$$

employing the following notation:

- p photosensitivity of mosaic.
- L luminous flux/unit area of mosaic.
- A area of mosaic.
- N number of picture elements.
- T frame time.
- t_e time required to sweep over one picture element.

This would represent a gain in sensitivity relative to non-storage devices (without secondary-emission multiplication of the signal) which is equal to the number of picture elements.

The above representation is greatly oversimplified. Thus, it assumes that a mosaic scanned in darkness has a uniform potential. The actual, measured, potential distribution, at the moment when the scanning beam is approximately a third from the top of the mosaic, is as represented in Fig. 6. Figure 7 shows the variation of the potential of a particular illuminated and unilluminated element in the course of a frame time. This behavior arises in the following manner. Considering the unilluminated mosaic, an element directly under the beam emits secondary electrons whose initial kinetic energy varies from zero to a few electron volts. The secondary-emission properties of the mosaic are such that, on the average, about 4 secondary electrons are emitted for every primary electron incident from the beam. These will be able to leave the element only if the field conditions in front of it are favorable; as the element becomes, as the result of secondary emission, more positive with respect to the anode and the remainder of the mosaic, a larger proportion of the electrons will return to the element. When the element reaches a potential V_1 of the order of 3 volts positive with respect to the anode coating, only one secondary electron will leave the element for every incident beam electron and no further charging will take place. The beam current is chosen large enough to bring the picture element to the equilibrium potential V_1 in every transit.

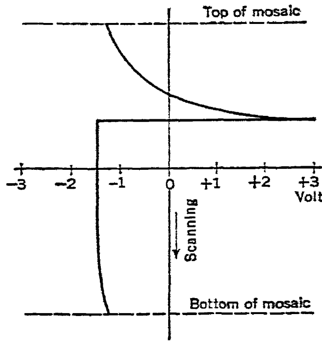

FIG. 6. Voltage Variation over Iconoscope Mosaic Scanned in Darkness

Since the mosaic is insulated, on the average only one of all the secondary electrons (and photoelectrons) which leave the element for every incident beam electron arrives at the second anode; the rest are redistributed over the remainder of the mosaic. This redistribution is influenced by the potential distribution over the mosaic (and hence, for an illuminated mosaic, also, to some extent, by the light distribution in the image) and the geometry of the tube—in particular the location of clear glass surfaces relative to the mosaic. The redistribution quickly reduces the potential of the elements immediately behind the beam and more gradually that of the more remote elements. When the elements have attained a potential V_2, of the order of $-1\ {}^1/_2$ volts, no further redistributed electrons reach them. This, thus, represents the equilibrium potential of elements not under the beam.

Consider, next, an illuminated element of the mosaic. Immediately after the beam has rendered the element about 3 volts positive with respect to the second anode, no photoelectrons are able to reach the second anode; however, an appreciable number may find their way to the elements ahead of it which have been under the beam even more recently and hence are more positive. Thus the element becomes negative less rapidly than an unilluminated element. However, the photoemission is far from saturated, a large proportion of the photocurrent returning to the element of origin. Although a larger proportion of the photocurrent will reach the anode as the element becomes more negative, the condition of incomplete saturation generally persists practically up to the succeeding passage of the scanning beam, at which point the illuminated element may have a potential V_3, a fraction of a volt above V_2. At low light levels the average photocurrent leaving a small illuminated region, with the rest of the mosaic in darkness, is approximately 20 per cent of the saturated photoemission.

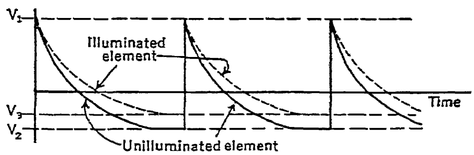

FIG. 7. Voltage Variation of an Illuminated and an Unilluminated Picture Element on the Iconoscope Mosaic

As the beam passes over the illuminated element, it returns it to the positive equilibrium potential V_1. For a small illuminated area on a dark background, the signal current is equal to the difference in the fraction of the secondary-emission current from the element which reaches the anode for the illuminated and for an unilluminated region. This is simply the current reaching the anode as an unilluminated element is raised, under the beam, from the potential V_2 to the potential V_3 (see Fig. 7). Since for both these potentials the secondary emission is, in general, saturated, and the current collected by the anode must equal the beam current, only a fourth of the stored charge can be utilized for the signal current if the secondary-emission ratio is 4. Thus the total operating efficiency at low light levels is of the order of 5 per cent (${}^1/_4$ of 20 per cent), and the signal current is given by

$$i_s = kpLA \qquad k \cong 0.05 \tag{9}$$

It may be noted that the photoelectric efficiency can be improved appreciably by illuminating slightly the photosensitive clear glass walls of the tube (backlighting), since this raises their potential.

At high light values the efficiency becomes much less; regardless of the degree of illumination, photoemission will drive an illuminated region only positive enough relative to its surroundings to prevent the departure of additional photoelectrons. Thus the Iconoscope signal is compressed in the high lights. The preferred collection of the redistributed electrons by the more positive areas of the mosaic enhances this effect. At very high light levels the Iconoscope signal is determined by the photoelectric charge stored during the line scan of the beam preceding the scanning of the picture element considered: Since under the beam an element becomes positive by 3 volts relative to the second anode, the photoemission of the neighboring element on the line ahead of the scanned line is saturated even if it is positive by several volts relative to its other neighbors ("line sensitivity"); an opposing voltage of 1–2 volts suffices to suppress the photoemission.

The signal output characteristic of the 1850-A Iconoscope is shown in Fig. 8.

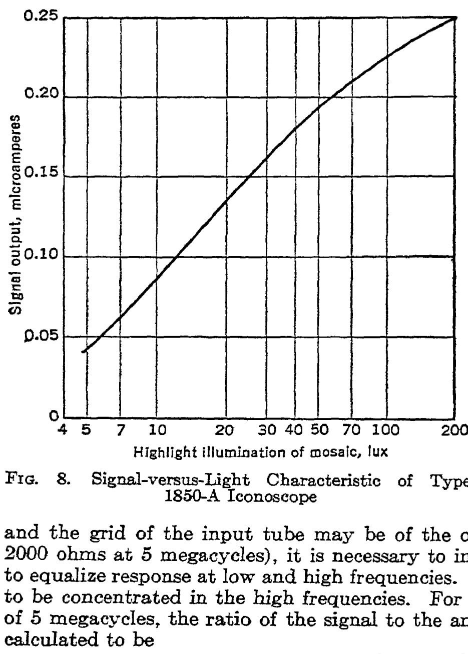

FIG. 8. Signal-versus-Light Characteristic of Type 1850-A Iconoscope

SIGNAL-TO-NOISE RATIO. The principal source of noise in the conventional Iconoscope pick-up system is the noise introduced by the input tube of the signal amplifier, which may be represented as thermal noise from an equivalent resistor r_T added to the resistive component of the coupling network between the Iconoscope and the amplifier. Since, for coupling resistances of the order of 0.1 to 1 megohm, the coupling impedance is primarily capacitative for the high frequencies of the video band (the combined capacitance to ground of the signal plate and the grid of the input tube may be of the order of 15 $\mu\mu$f, corresponding to about 2000 ohms at 5 megacycles), it is necessary to insert a peaking network in the amplifier to equalize response at low and high frequencies. This network causes the noise spectrum to be concentrated in the high frequencies. For low-noise input tubes and a video band of 5 megacycles, the ratio of the signal to the amplitude of the integrated noise may be calculated to be

$$S = 5 \cdot 10^8 i_s \tag{10}$$

i_s being measured in amperes. It should be noted that about 2 or 3 times as much of this peaked noise can be tolerated by the observer as shot noise (e.g., from a multiplier) distributed uniformly over the spectrum.

SENSITIVITY. In practice a scene brightness from 6000 to 17,000 lumen/m² is found to give satisfactory pictures with an 1850-A Iconoscope used in conjunction with a lens of f/5.6 or smaller aperture. The target area of the mosaic is approximately 0.011 m² (17 in.²). Employing the lowest values both for the illumination and the f-number, the figure of merit used as a measure of the sensitivity becomes

$$\frac{5.6^2}{6000 \cdot 0.011} = 0.48 \tag{11}$$

This is about $^1/_5$ that for film; the formula for the signal-to-noise ratio yields a value of 100, in harmony with direct measurements. This is greater than for film by a factor between 2 and 3. Such a factor is needed to render the noise unobjectionable in the low lights, since the noise does not decrease in proportion with the signal. The fact that the signal output of the Iconoscope has less contrast than the original image, i.e.,

$$\frac{\Delta i_s}{i_s} = \frac{1}{k}\frac{\Delta L}{L} \quad \text{where } k = 2 - 3 \tag{12}$$

a condition which is generally compensated in the viewing tube, leads to a useful reduction in the difference between the signal-to-noise ratios for the high lights and the low lights.

RESOLUTION. The resolution of the Iconoscope, as for the other pick-up tubes here considered, may be extended to better than 1000 lines; for the 525-line standard it is customary to peak the high-frequency response electrically so as to keep the response level up to 500 lines.

UNIFORMITY. The description of the operation given above makes it evident that the signal output for any picture element is not simply related to its brightness; the redistribution of the secondary and photoelectrons makes it dependent both on the geometrical position of the element and on the light distribution in the remainder of the picture. Hence spurious signals—"shading"—are introduced and must be compensated electrically with the aid of shading controls. They become particularly troublesome when large dark areas are present in the scene.

11. THE MONOSCOPE

The monoscope is not, strictly speaking, a pick-up tube. It merely serves to supply a standard picture signal, whose character is prescribed by the preparation of the target electrode. As such it has found application primarily in the testing and aligning of the components of a television system other than the pick-up tube itself.

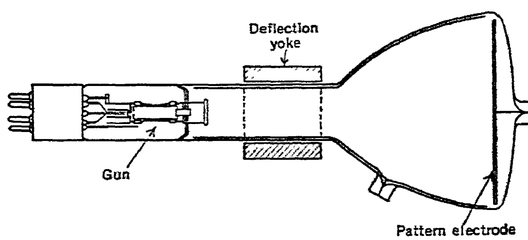

FIG. 9. The Monoscope

Figure 9 shows the construction of a type 2F21 monoscope. It consists of an Iconoscope gun and a target plate (3 1/16 by 2 5/16 in.), normal to the axis of the gun, mounted in a pear-shaped envelope. The target plate consists of sheet aluminum on which a pattern has been printed with a carbon ink (Fig. 10). The magnetic beam deflection and the circuit connections are the same as for an Iconoscope, with the distinction that the anode coating is maintained at a potential 50–200 volts positive with respect to the target plate.

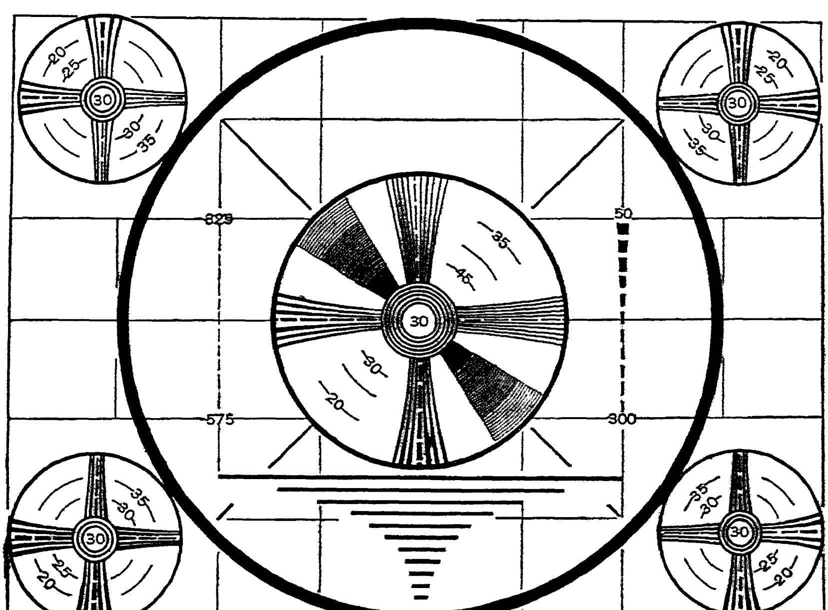

FIG. 10. Pattern on the Type 2F21 Monoscope

The operation of the monoscope depends on the much greater secondary emission ratio of the slightly oxidized aluminum (~3) as compared with that of carbon (<1). Whenever the beam strikes the aluminum, a signal current approximately twice as great as the beam current flows through the signal lead in such a direction as to make the grid of the input tube positive; when it strikes the carbon, a small current in the opposite direction tends to make it negative. If a monoscope replaces an Iconoscope without changes in the amplifier, the portions of the pattern printed in carbon ink will appear bright in the final image. Dark and light may, of course, be interchanged by adding or subtracting one stage in the video amplifier. A peak-to-peak signal amplitude of several microamperes may be obtained with this tube.

12. THE ORTHICON

The primary defects of the Iconoscope, namely, shading and low efficiency of operation, both arise from the redistribution of secondary electrons and photoelectrons on the mosaic. This, in turn, is a consequence of the fact that the equilibrium potential of the mosaic under the beam is close to anode potential, in fact, slightly positive with respect to it. If, however, the beam arriving at the mosaic has, initially, a kinetic energy of 10 electron volts or less, the secondary emission ratio is less than unity and the potential of the mosaic will drop to a value slightly below that of the emitting cathode; at this equilibrium potential no additional electrons can reach the mosaic. Instead, the beam electrons reverse their direction at a point close to the mosaic and are collected by some electrode at positive potential. Portions of the mosaic which are in complete darkness remain continuously at the equilibrium potential and, hence, give rise to no signal current. Illuminated areas, on the other hand, lose electrons, between successive scannings, in exact proportion to the quantity of light incident on them. The low-velocity beam, as it sweeps over such areas, supplies just enough electrons to the mosaic to neutralize the stored charge and causes the passage of an equal signal current through the signal lead. In brief, the actual operation of such a low-velocity Iconoscope fits perfectly the original, oversimplified version given for the operation of the Iconoscope.

The practical realization of the low-velocity Iconoscope demands fulfilment of two conditions: (1) in order that the equilibrium potential (and scanning spot) may be uniform over the mosaic, the beam must be perpendicular to the mosaic at all points; (2) to keep the effective spot size small, the lateral velocity components of the electrons must be kept small. These requirements are met by the special methods of beam deflection and focusing incorporated in the *orthicon.*

The envelope of a typical orthicon (Fig. 11) is a 4-in.-diameter tube 14 in. long with a short neck for the gun at one end and a flat, clear window for the transmission of the

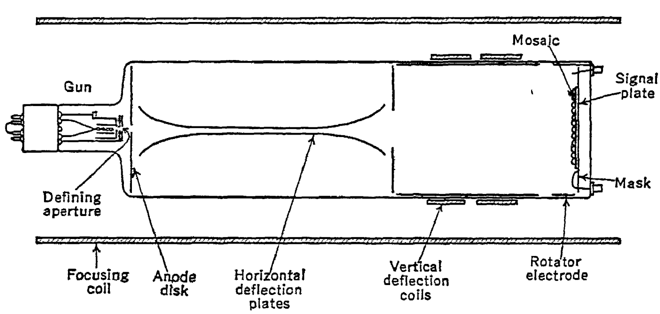

FIG. 11. Orthicon with Electrostatic Horizontal Deflection

optical image at the other. It is inserted in a long solenoid providing a uniform longitudinal magnetic field of 0.007 weber/m^2. The envelope contains, in addition to the gun, a pair of curved electrostatic deflection plates which occupy half of the tube nearest the gun, and a mosaic with a translucent signal plate having a target area 2 $^5/_{16}$ by 1 $^3/_4$ in. The horizontal deflection is accomplished with the aid of the electrostatic deflection plates; the vertical deflection, by a pair of coils mounted over a portion of the second half of the 4-in. cylinder.

The principal peculiarities of the deflection and focusing properties of the orthicon are a consequence of the presence of the longitudinal magnetic focusing field. In particular, near the mosaic, where the magnetic field lines are perpendicular throughout to the mosaic surface, the field assures the normal incidence of the electron beam: In a strong magnetic field the electrons spiral about the magnetic field lines.

Proceeding from one end of the tube to the other, the electrons leaving an indirectly heated cathode through an aperture in the grid cylinder (cut-off voltage, −40 volts) are accelerated through an aperture at 225 volts and restricted to a narrow pencil by a defining aperture 0.0025 in. in diameter which is electrically connected to the accelerating aperture. This pencil, the scanning beam, is focused by the longitudinal field, which is strong enough to form a succession of images of the defining aperture less than 2 in. apart. Its current is generally of the order of 0.3 microampere, i.e., just enough to discharge the most strongly illuminated portions of the mosaic. After passing through another larger aperture in the anode disk (at 250 volts), which separates the gun chamber from the deflection chamber, the electrons enter the electrostatic deflecting field between flared plates. The simultaneous action of the electrostatic field and the longitudinal magnetic field causes a lateral displacement of the beam parallel to the plates and proportional to the deflection voltage (160 volts, peak to peak). The flaring, making the increase and decline of the deflecting field gradual, prevents the development of cycloidal loops in the crossed fields and, hence, the acquisition of considerable lateral velocity components by the beam electrons.

Next, the beam passes through the magnetic deflecting field (0.0025 weber/m^2, peak to peak) which simply warps the field lines, so that the beam experiences a second displacement, in the direction of the deflecting field (*not* at right angles thereto). After leaving this deflecting field the electrons pass through a decelerating ring electrode at 100 volts (designated as "rotator electrode," since the simultaneous action of the lateral components of the decelerating field and the longitudinal magnetic field causes a slight rotation of the scanning pattern) painted on the envelope to the mosaic, which is inserted in a mask maintained 3 volts negative with respect to the cathode. Both the signal plate and the photosensitive mosaic are translucent. Although the requirement of translucence reduces the photoemission of the mosaic, as compared with that of the Iconoscope, this is more than compensated by the greater efficiency of operation.

SENSITIVITY. It is found in practice that a studio scene with a brightness of 700 lumens/m^2, transmitted with an $f/2$ lens, will yield a picture with a signal-to-noise ratio of 100. The target area being 0.0026 m^2 (4 in.^{2}), the figure of merit of the orthicon becomes

$$\frac{2^2}{700 \cdot 0.0026} = 2.2 \tag{13}$$

This is the same as the figure for film and better by a factor of 5 than that for the Iconoscope. However, since the orthicon does not compress the brightness scale in the same manner as the Iconoscope, but has a strictly linear response throughout, a signal-to-noise ratio higher by a factor of 2 or 3 may be required in the transmission of naturally contrasty outdoor scenes to attain an equal freedom from noise in the low lights. Hence, under such circumstances a more appropriate value for the figure of merit is 1.

SIGNAL-TO-NOISE RATIO AND RESOLUTION. A signal-to-noise ratio of 100 is readily obtained. Attempts to exceed this value by increasing the brightness of the light image frequently result in a loss of resolution and a local distortion of the scanning pattern at the boundaries between bright and dark areas.

UNIFORMITY. If the image brightness is kept within the normal operating range the signal output yields a faithful representation of the geometry and tonal values of the scene. Scene details of excessive brightness (e.g., the explosion of flash bulbs) may, however, cause a portion of the scene to be blacked out. At such points the photoemission charges the mosaic up to a positive potential at which the secondary-emission ratio of the beam electrons exceeds unity, so that the beam renders the illuminated area more positive instead of discharging it. After the cause has been removed, normal operating conditions are gradually re-established by surface leakage.

13. THE IMAGE ORTHICON

In the image orthicon a very great gain in sensitivity has been combined with the freedom from spurious signals at low light levels which is characteristic of the orthicon and the stability of operation at high light levels characteristic of the Iconoscope at the expense of greater complexity of construction and alignment. The principal features which distinguish the image orthicon from the ordinary orthicon are (1) an electron-optical imaging section, making possible the employment of a more sensitive, continuous, photocathode and secondary-emission multiplication at the target; (2) a two-sided target, permitting limitation of the target voltage to a value sufficiently low to insure stability at all light levels by providing a separate collector on the side opposite to the scanned side; and (3) a secondary-emission signal multiplier, for the return beam current, which renders the signal output sufficiently large that the shot noise in the beam, rather than amplifier noise, determines the noise content in the reproduced picture.

Figure 12 shows, schematically, the construction of the type 2P23 image orthicon. The tube has approximately the same length, but, with the exception of the short end section, a much smaller diameter than the 1840 orthicon. As with the latter tube, a long focusing solenoid must be provided which envelops all the tube except the gun and multiplier portion at the right extremity. The light image is projected on the flat transparent photocathode (maintained at −300 volts) at the left end of the tube, and the photoelectrons released by the light are focused by the magnetic field through a very fine-mesh (500–1000 meshes per inch), high-transmission screen on the target. Since the secondary-emission ratio of the glass target screen for 300-volt electrons is much greater than unity, a positive charge pattern corresponding to the light distribution in the scene is formed on the target. The secondary electrons are drawn to the closely spaced target screen, which is usually maintained at a potential slightly positive (e.g., at +1 volt) with respect to the scanning-beam cathode.

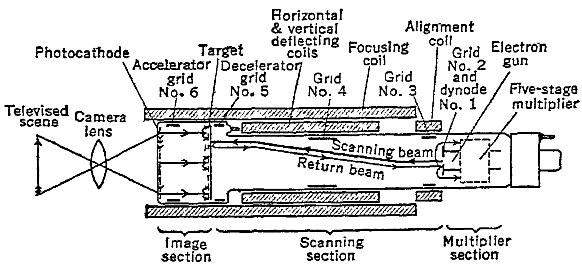

FIG. 12. The Image Orthicon

The target itself is a very thin disk of low-resistivity glass. Its properties are such that in the course of a frame time potential differences between the two sides of the target built up at the instant of scanning are neutralized by conduction while the transverse leakage of stored charge between neighboring picture elements still remains negligible.

The gun of the image orthicon has the same general construction as that of the orthicon. However, the defining aperture is formed in the final disk electrode, which is exposed to the return beam. The beam deflection is magnetic throughout, since this causes the return beam to travel practically the same path as the scanning beam in reverse direction, striking finally the electrode containing the defining aperture. The return beam itself carries the signal; when the scanning beam strikes a portion of the target which has been rendered positive by secondary emission, electrons equal in number to those lost in the course of a frame time by the element under consideration are abstracted from the beam, reducing, correspondingly, the current in the return beam.

The return beam strikes the defining-aperture disk with an energy of the order of 200 electron volts and ejects from it secondary electrons which, persuaded by the lower potential of the electrodes facing it and the higher potential of a second stage of a pinwheel multiplier structure surrounding the gun, spill over into the same emitting a larger number of electrons, which are drawn to the next stage. The total gain of the 1500-volt five-stage multiplier is from 200 to 500, which is adequate to raise the shot noise level in the beam ($i_b^{1/2} \cdot 10^{-6}$ amp) above the amplifier input tube noise current ($2 \cdot 10^{-9}$ amp, both for a 5-megacycle band width). At very low lights the proper value of the beam current may, under ideal circumstances, be as low as 10^{-10} amp, leading to a useful multiplier gain of 200; for a high-light picture a gain of 20 would suffice.

SIGNAL VERSUS LIGHT CHARACTERISTICS. Figure 13 shows a typical variation of the signal output of the image orthicon with the high-light illumination of the photocathode. The photosensitivity of the photocathode is of the order of 10 microamperes per lumen.

In the low-light range the image orthicon functions just as the orthicon, the signal current being proportional to the light signal. At the knee of the curve the secondary-emission charges the target just to the potential of the target screen; beyond this point the response curve flattens out, since an increasing number of secondary electrons are forced to return to the emitting element. As the target becomes sufficiently positive to lose only as many electrons by secondary emission as it receives from the photocathode, the response curve becomes completely flat. This does not mean, however, than no intensity differences are transmitted.

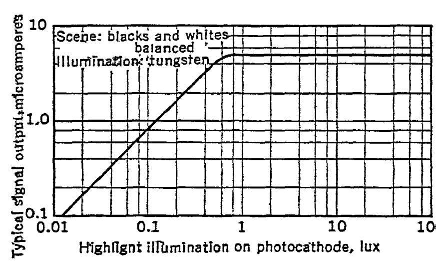

FIG. 13. Signal-versus-Light Characteristic of Type 2P23 Image Orthicon

Redistribution of secondary electrons near boundaries between areas of different intensity of bombardment (different brightness) results in potential differences at such boundaries. Thus a bright spot on a less bright background is transmitted as a bright spot with a dark halo on a bright background.

SENSITIVITY. It is found that an image orthicon provided with an $f/2$ lens and capable of transmitting a picture with a signal-to-noise ratio of 100 can do so if the scene brightness is 20 lumens/m^2. Since the target area is approximately 0.0008 m^2 (1.2 in.^{2}), the figure of merit of the image orthicon becomes

$$\frac{2^2}{20 \cdot 0.0008} = 250 \tag{14}$$

This is approximately 100 times as great as the figure for film and for the ordinary orthicon and over 500 times as great as that for the Iconoscope. A factor of 5 in this gain must be attributed to the increased photosensitivity of the photocathode and the secondary-emission amplification at the target; the remainder, to the signal multiplication in the multiplier. To maintain freedom from objectionable noise in the low lights of high-contrast scenes, it may be necessary, just as with the orthicon, to increase the signal by a factor of 2 or 3, reducing the figure of merit to unity. It may be noted that the sensitivity of the tube is sufficient to transmit pictures with some entertainment value even at a scene brightness of 0.2 lumen/m^2, corresponding to the brightness of light objects in full moonlight.

RESOLUTION. The resolution of the image orthicon may be limited by the electron-optical imaging process, the target screen, transverse leakage on the glass target, and scanning spot size, the last being influenced by the defining aperture, the angle of approach of the beam to the target, the initial velocity distribution of the beam electrons, and the potential of the scanned area. In practice it is possible to attain a resolution of 500 lines as with the other tubes.

UNIFORMITY. In the low-light range (the sloping part of the curve in Fig. 13), the signal output is a linear function of brightness. For higher light values the tonal scale is compressed, and, ultimately, contrasts, rather than absolute light values, are transmitted primarily. This condition does not detract materially, however, from the apparent naturalness of most reproduced pictures. Geometric distortions are inappreciable, although slight non-uniformities in the target and the presence of the target screen tend to make the picture somewhat inferior to that transmitted by the other pick-up tubes described.

14. FIELDS OF APPLICATION OF PICK-UP TUBES

The characteristics of the several pick-up tubes here discussed mark out spheres of application for which each is particularly suitable. Thus, the relatively insensitive image dissector, with its freedom from signal distortion, may be employed for the transmission of motion pictures, for which very high light levels can readily be provided. The standard Iconoscope is well suited for both movie and studio work, where the light distribution can be controlled so as to simplify the compensation of shading. Its smaller, 2-in. version is a convenient television pick-up device for industrial and experimental purposes. Spot pick-up, with the attendant unpredictable conditions of lighting, demands the employment of the image orthicon which, in view of its greater complexity and somewhat inferior picture quality, may under other circumstances be replaced advantageously by the less sensitive tubes. It is to be hoped and expected that further development of the image orthicon, as the most recent of the pick-up devices, will raise the level of its picture quality to that of the older pick-up tubes.

LUMINESCENT AND TENEBRESCENT MATERIALS

By H. W. Leverenz

Luminescence is a production of light in excess of thermal radiation (see ref. 5 on p. 15-41). Thermal radiation is emitted by electrons, atoms, ions, and molecules oscillating or rotating singly or in groups as occasioned by thermal agitation.

An ideal thermal radiator is the perfect *black body*, which has complete absorptivity at all wavelengths; i.e., it has oscillators available at all frequencies. The monochromatic emissive power, E_ν, of a perfect black body (in vacuum) at frequency ν (in sec^{-1}), is a function of temperature, T (in degrees Kelvin), according to Planck's radiation law:

$$E_\nu = 4.63 \times 10^{-50}\nu^3(\varepsilon^{h\nu/kT} - 1)^{-1} \quad \text{watts/m}^2 \tag{1}$$

where $h = 6.624 \times 10^{-34}$ joule-sec (Planck's constant).
$\varepsilon = 2.71828\cdots$ (base of Napierian logarithms).
$k = 1.38 \times 10^{-23}$ joule/deg (Boltzmann's constant).

The peak wavelength, λ_{max}, of the broad emission band of black-body radiation varies with absolute temperature according to Wien's displacement law:

$$\lambda_{max} = 2.897 \times 10^{-3}T^{-1} \text{ m } (1 \text{ m} = 10^6 \text{ microns } (\mu) = 10^{10} \text{ angstrom units } (\text{Å})) \tag{2}$$

The total emissive power, E_T, of a black body is proportional to the fourth power of the absolute temperature according to the Stefan-Boltzmann law:

$$E_T = 5.67 \times 10^{-8}T^4 \quad \text{watts/m}^2 \tag{3}$$

At room temperature, $\approx$300 deg Kelvin, λ_{max} is in the far infrared at 9.7 microns, and E_T is only 459 watts/m². It should be noted that the nature of the material plays no role in eqs. (1), (2), and (3). Although thermal radiation is emitted by all materials at temperatures greater than 0 deg Kelvin such radiation does not become visible until the temperature is raised above about 1000 deg Kelvin, when incandescence is observed. A temperature of the order of 6500 deg Kelvin is required to shift the peak wavelength, λ_{max} of thermal radiation into the visible region of the spectrum (4000 to 7000 Å). Thus far, no solid material has been developed to endure prolonged operation above 4000 deg Kelvin, and so most of the energy emitted from solid incandescent materials lies in the infrared and their efficiencies of light production are generally less than about 5 per cent.

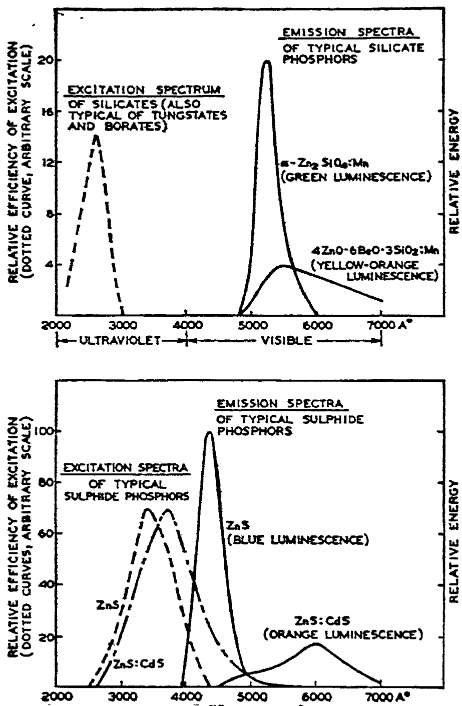

FIG. 1. Excitation and Emission Spectra of Some Typical Phosphors

Luminescence is occasioned by absorbed photons, so-called undulatory energy (e.g., ultraviolet, x-rays, γ-rays), or corpuscular energy (e.g., cathode rays or α-particles) which excite electronic transitions directly rather than through the intermediate stage of thermal agitation of atoms and ions. Luminescence emission is usually in the form of spectral lines or narrow bands superimposed on the broad band of thermal radiation from a material. The spectral distributions and efficiencies of luminescent materials are determined largely by their chemical compositions and, if the materials are solids, by their crystalline structures. The characteristic monochromatic spectra of attenuated gases are relatively simple luminescences whose efficiencies may approach 100 per cent for the case of resonance radiation ($\lambda_{excitation} = \lambda_{emission}$). In liquids and solids, however, the perturbations imposed by near neighbors of a luminescing atom or ion complicate the mechanism and generally lower the efficiency of luminescence.

The generic term luminescence is commonly modified by a prefix indicative of the excitant used to cause luminescence. For example, *photoluminescence* is luminescence excited by photons, and *cathodoluminescence* is luminescence excited by cathode rays. A further distinction is made with respect to duration of luminescence after cessation of excitation; i.e., *fluorescence* lasts less than about 10^{-8} second whereas *phosphorescence* lasts longer than about 10^{-8} second. The value of 10^{-8} second is the approximate lifetime of excited non-metastable isolated atoms or ions and serves as an arbitrary demarkation between fluorescence and phosphorescence. Materials, such as gases, liquids, organic materials, and many glasses which exhibit fluorescence are called *fluors*; while phosphores-

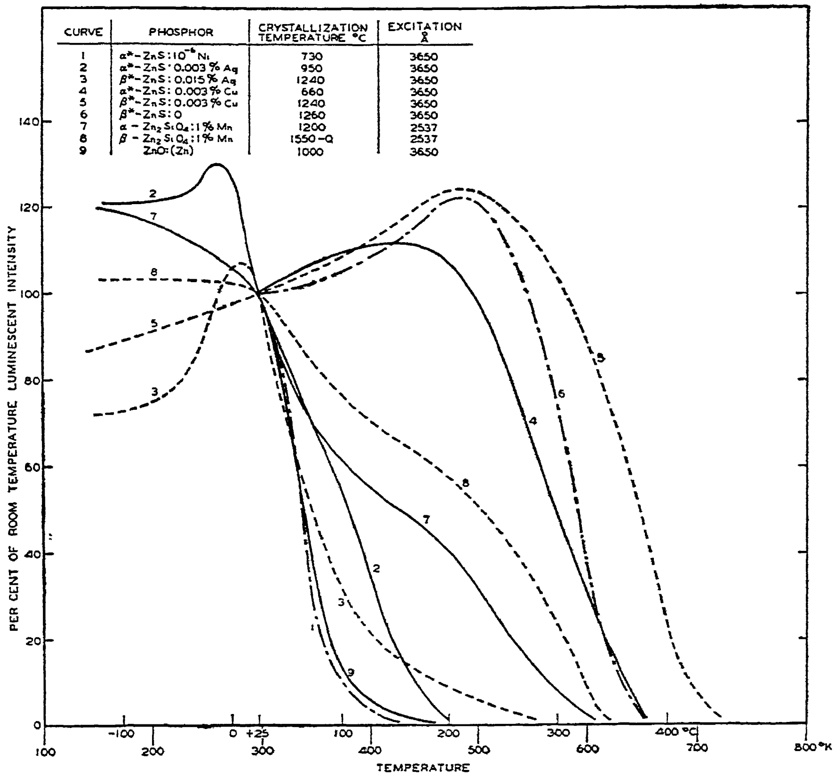

Fig. 2. Photoluminescences of Some Phosphors as a Function of Temperature

cent materials, which are chiefly crystalline inorganic materials, are called *phosphors.* Some typical excitation and emission spectra of phosphors are shown in Fig. 1; several temperature-dependence curves of phosphor photoluminescences are shown in Fig. 2, and some typical excitation and decay characteristics of phosphors are indicated in Fig. 3.

Phosphor light outputs may be modulated by three methods:

1. Positive modulation of luminescence is the normal increase of light output with increasing excitation density at temperatures below the fairly critical temperature, T_c, above which the efficiency of luminescence sharply decreases.

2. Negative modulation of luminescence is accomplished by increasing the temperature of an excited phosphor above T_c and thereby decreasing the luminescence.

3. Positive modulation of incandescence is accomplished by further raising the temperature of the phosphor until incandescence supplants luminescence.

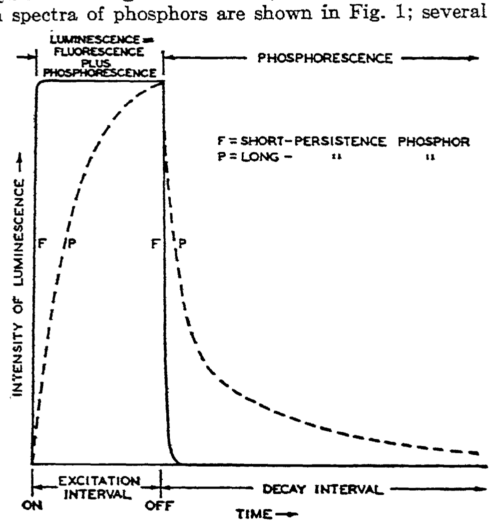

Fig. 3. The Relationships of Luminescence, Fluorescence, and Phosphorescence

The last two methods of modulation involve thermal inertia of matter as contrasted with the purely electronic transitions in positive modulation of luminescence. Positive modulation of luminescence is unique in allowing useful modulation up to frequencies of the order of 10^7 cycles per second, the limit for any particular phosphor being inversely proportional to its characteristic decay time (the time taken to decay to an arbitrary percentage, e.g., 1 per cent, of the luminescence at the last instant of excitation).

Tenebrescence is any non-intrinsic absorption of light induced in a material. For example, normally colorless potassium chloride, KCl, whose intrinsic absorption is in the far ultraviolet (left side of Fig. 4), may have an absorption band induced in the visible part of the spectrum by irradiation with cathode rays or x-rays (see right side of Fig. 4). The induced darkening (tenebrescence) may be bleached by irradiating the darkened material with light having wavelengths lying within the induced absorption band. The bleaching is accelerated by heat. Tenebrescent materials become increasingly difficult to bleach as the duration and intensity of the primary irradiations used to induce tenebrescence are increased. The relatively unbleachable absorptions are similar to those of pigments or dyes which convert absorbed photons into heat. Bleachable tenebrescences are ascribed to temporary trapping of electrons; unbleachable tenebrescences apparently involve concomitant ionic displacements.

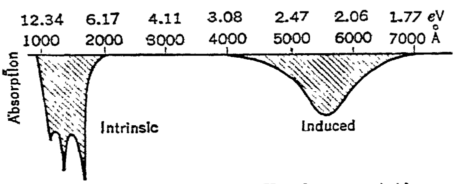

FIG. 4. Intrinsic and Induced (Tenebrescence) Absorption Bands of Potassium Chloride

Tenebrescent materials, such as the crystalline halides of alkali or alkaline-earth metals, are called *scotophors*.

15. PREPARATION AND NOTATION OF PHOSPHORS

Successful preparations of synthetic phosphors require highly specialized chemical and physical operations wherein even the most skilled and careful workers sometimes have difficulty in reproducing results. Phosphor ingredients must be purified to contain less

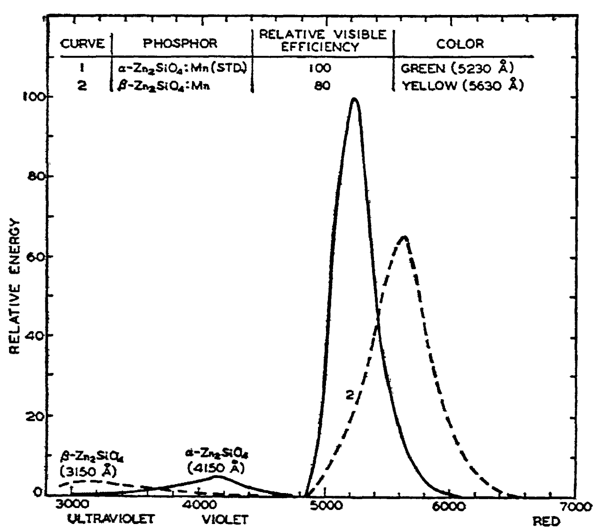

FIG. 5. Cathodoluminescence Spectra of α- and β-Zn_2SiO_4:Mn with and without Manganese Activator

than about 10^{-4} per cent of undesirable metallic-ion impurities (e.g., iron, nickel, and chromium), since as little as 10^{-4} per cent of combined nickel in a zinc-cadmium-sulfide phosphor lowers efficiency about 25 per cent. On the other hand, 10^{-4} per cent of combined silver in the foregoing *pure* phosphor increases efficiency 100 per cent. The final crucial step in preparing phosphors is crystallization, where the purified ingredients are

CURVE	PHOSPHOR	TEMP. FOR 2hr.	RELATIVE VISUAL RESPONSE	NATURAL COLOR	COLOR OF LUMINESCENCE

mixed in fused-silica or platinum crucibles and heated in electric resistance furnaces, generally to temperatures between 600 and 1600 deg cent. The resultant phosphors are masses of tiny crystals ranging from less than 0.01 to about 100 microns in diameter. Most phosphor crystals average about 1 to 15 microns in diameter. Some typical initial compositions and corresponding notations of the resultant phosphors are given in Table 1.

The luminescence emission spectra of phosphors are strongly influenced by changes in crystallization and composition, as shown in Figs. 5, 6, and 7. Phosphors such as P3, P4(Y), and P7/2 belong to "families" wherein gradual base-material variations enable one to produce emission spectra which may be varied continuously from one end of the visible spectrum to the other. Other properties, such as

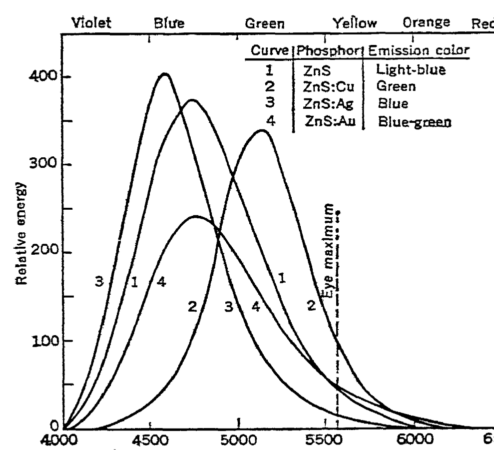

FIG. 7. Cathodoluminescence Emission Spectra of Zinc-sulfide Phosphors Prepared with (1) no added activator, (2) copper activator, (3) silver activator, and (4) gold activator

absorption spectrum, efficiency, and phosphorescence, are also considerably affected by changes in the structures and compositions of phosphors.

Table 1. *Approximate* **Compositions and Notations of Some Useful Phosphors**

RMA Code	Base Material Ingredients, grams	Activator Salt, grams	Flux, grams	Crystallization Temperature, deg cent	Phosphor Notation
P1	81 ZnO + 31 SiO_2	0.5 MnO	....	1250	α-Zn_2SiO_4:Mn

α * = cubic; β * = hexagonal.
† = optional. (B) = blue, (G) = green, (Y) = yellow, (R) = red. The Ag and Cu activator ions may also be added as nitrates.

16. MECHANISMS OF PHOSPHORS

Energy transductions during excitation and emission of phosphor luminescences have the following chronological sequence:

$$E_{\text{primary}} = aE_{\text{reflected}} + bE_{\text{absorbed}} + cE_{\text{escaped}} \tag{4}$$

$$bE_{\text{absorbed}} = b_1E_{\text{transmitted to activator centers}} + (b - b_1)E_{\text{heat}} \tag{5}$$

$$b_1E_{\text{in activator centers}} = b_2E_{\text{stored}} + (b_1 - b_2)E_{\text{internal fluorescence}} \tag{6}$$

$$b_2E_{\text{stored}} = b_3E_{\text{internal phosphorescence}} + (b_2 - b_3)E_{\text{heat}} \tag{7}$$

$$(b_1 - b_2)E_{\text{internal fluorescence}} + b_3E_{\text{internal phosphorescence}} = b_4E_{\text{external luminescence}} + (b_1 + b_3 - b_2 - b_4)E_{\text{heat}} \tag{8}$$

where $a + b + c = 1$; $1 \geq b \geq b_1 \geq b_2 \geq b_3 \geq b_4$: and E_{escaped} is the residual primary energy which completely penetrates the phosphor crystals or which emerges from the side of incidence owing to internal scattering.

Luminescence emission is occasioned when a bound electron in energy state E_0 is excited to a higher allowed energy state, E_{ex}, and returns to the same or an intermediate energy level, E_{act}, emitting the energy difference, $\Delta E = E_{\text{ex}} - E_{\text{act}}$, as a photon of light. The relations between energy ΔE (in joules), frequency ν (in cycles per second), and wavelength λ (in meters), of photons are given by:

$$\Delta E = h\nu = \frac{hc}{\lambda} \tag{9}$$

where $c = 3 \times 10^8$ m/sec (speed of light in vacuum).

Some of the features of *corpuscular excitation* of phosphors, such as by cathode rays, may be exemplified with the aid of Fig. 8, which shows generalized sketches of the interiors of phosphor crystals, including three major classes of crystal irregularities (faults). The total penetration, x_t, of 10^3 to 10^6 volt cathode rays in a phosphor of density σ (in grams per cubic centimeter) is calculable from Terrill's equation:

$$x_t = \frac{V_0^2}{4 \times 10^{11}\sigma} \quad \text{cm} \quad (V_0 \text{ in volts}) \tag{10}$$

The fraction W/W_0, representing the power dissipated up to distance x in the crystal, is given by Stinchfield's equation:

$$\frac{W}{W_0} = 1 - \gamma\left(1 - \frac{x}{x_t}\right)^{1/2} \varepsilon - \frac{C'x/x_t}{[1+(1-x/x_t)^{1/4}]^4} \tag{11}$$

where $\gamma \approx 1$ for $x/x_t < 0.5$ (γ increasingly exceeds unity for $x/x_t > 0.5$), and $C' \approx 32$. Over 50 per cent of the cathode-ray power is dissipated in the first quarter of the total penetration distance, and over 80 per cent is dissipated in the first half of the total penetration distance.

A few phosphors, such as ZnO:[Zn], may be excited by cathode rays with energies as low as 5 volts, but such low-voltage excitation is quite inefficient because the excitation energy is expended in the distorted surface layers of the phosphor crystals and the ratio of secondary to primary electrons is usually less than unity at such low primary voltages. Conventional, unmetallized cathode-ray-tube screens must have secondary-emission ratios equal to or greater than unity to maintain a positive potential with respect to the cathode. The efficient range of primary voltages is above about 1000 volts, and preferably above 10,000 volts for phosphors whose limiting potentials (voltage above which the secondary-emission ratio falls below unity) are above 10,000 volts or phosphor screens which may be coated with an electron-pervious reflecting and conducting coating, such as a 1000-Å-thick layer of aluminum.

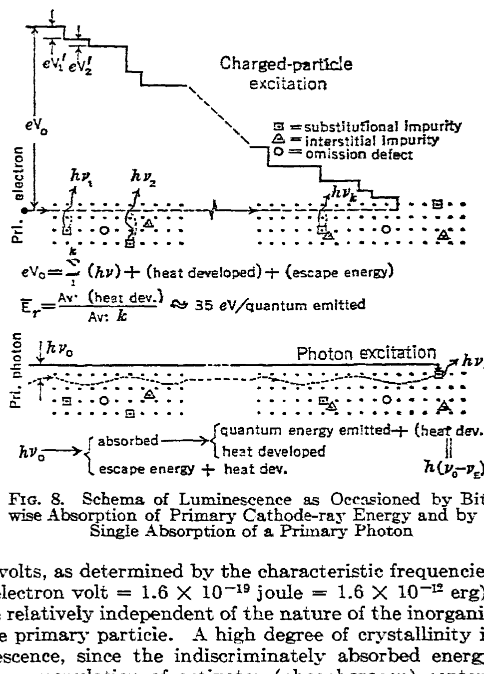

FIG. 8. Schema of Luminescence as Occasioned by Bitwise Absorption of Primary Cathode-ray Energy and by a Single Absorption of a Primary Photon

As indicated in Fig. 8, the initial energy, eV_0, of the primary particle is expended bitwise and indiscriminately to the crystal atoms and ions. The sizes of the absorbed energy bits average about 20 to 30 electron volts, as determined by the characteristic frequencies of bound electrons in the crystal (1 electron volt = 1.6×10^{-19} joule = 1.6×10^{-12} erg). The average absorbed energy bits are relatively independent of the nature of the inorganic material and the initial energy of the primary particle. A high degree of crystallinity is essential for efficient cathodoluminescence, since the indiscriminately absorbed energy bits must be transmitted to the sparse population of activator (phosphorogen) centers with the minimum of attenuation. Glassy structure, crystal faults, and undesirable impurities lower luminescence efficiency by converting absorbed primary energy into heat as indicated in eqs. (5) and (7). The efficiency loss (as heat) in eq. (8) is occasioned by the absorptivity of the phosphor crystal for its own luminescence. The more efficient cathodoluminescent materials require an average of over 30 electron volts of primary cathode-ray energy per 1.5 to 3 electron volt quantum of emitted luminescence. Hence, the efficiency of cathodoluminescent materials has thus far been less than about 10 per cent.

In *photon excitation* of phosphors, the primary photon, $h\nu_0$, seeks out a spot in the crystal to expend itself completely, not bitwise. The absorption of a primary beam, containing n_0 photons per unit cross-sectional area, is a function of penetration distance, x, into the phosphor, according to:

$$n = n_0 \varepsilon^{-Ax} \tag{12}$$

where the absorption coefficient A is strongly dependent on the frequency of the primary photon and the characteristic allowed frequencies in the phosphor crystal. The characteristic frequencies of bound electrons in the base materials comprising the bulk of phosphor crystals lie in the far ultraviolet ($\nu > 15 \times 10^{14}$ cycles per second, $\lambda < 2000$ Å)

Excitation of phosphors by near-ultraviolet photons results in direct excitation of the foreign activator centers, and there is no need for a high degree of crystallinity. Good photoluminescence, but inefficient cathodoluminescence, is obtained from amorphous materials such as organic dyes, inorganic glasses, and certain inorganic crystals such as the alkaline-earth-sulfide phosphors which contain some glassy structure caused by the residual non-volatile fluxes used in their preparation.

Photoluminescence efficiency is limited both by impurities and crystal faults, which convert primary photons and internal luminescence photons into heat according to eqs. (5), (7), and (8), and by the energy deficit, ΔE:

$$\Delta E = h(\nu_{\text{primary}} - \nu_{\text{emitted}}) \rightarrow \text{Heat} \tag{13}$$

Efficient phosphors, excited by near-ultraviolet photons, have photoluminescence efficiencies of the order of 60 to 80 per cent, with quantum efficiencies near unity. At very high energies of primary photons (or particles) the production of secondary radiations introduces added complications in the mechanisms of excitation of phosphors.

There are two major types of *luminescence-active centers* in phosphor cyrstals:

Substitutionally located activators are exemplified by manganese which replaces zinc, especially in phosphor crystals where oxygen or fluorine dominate the anion structure (e.g., zinc silicate, and zinc fluoride). These phosphors afford predominantly simple initial *exponential* (ε^{-at}) *decays* of light output, L, after excitation to a peak luminance, L_0, according to:

$$L = L_0 \varepsilon^{-at} \qquad (t \text{ in seconds}) \tag{14}$$

where the constant a has known values ranging from 10^6 for ZnO:[Zn] to 10 for $(Zn{:}Mg)F_2{:}Mn$. Exponential decays are determined largely by the chemical composition of the phosphor, being relatively unaffected by changes in crystal structure, in temperature, or in the type, duration, or intensity of excitation. The luminescence action is apparently localized in the substitutionally located activator sites as a metastable-state monomolecular process, without necessitating electron transport outside the immediate sphere of influence of the substitutional activator center. The observed weak photoconductivities of some ε^{-at}-decay phosphors are probably associated with their later-stage low-intensity power-law-decay "tails" which are strongly affected by changes in crystal structure, temperature, and excitation.

Interstitially located activators are exemplified by copper or silver interspersed among the regular lattice units in phosphors where sulfur and/or selenium dominate the anion structure. These phosphors afford so-called *power-law* (t^{-n}) *decays* represented by

$$L = L_0 \left(\frac{b}{b + t}\right)^n \tag{15}$$

where both b and n are not true constants but vary with changes in L_0, t, crystal structure, or temperature, and with the type and duration of excitation. For practical purposes, $0 < b < 10^{-3}$ and $0.2 < n < 3$ for known phosphors. There is a definite correspondence between the strong photoconductivities and phosphorescences of most t^{-n}-decay phosphors, indicating electron transport between the remote centers of trapping and emission. In these cases, monomolecular activated release followed by bi- or polymolecular mechanisms afford the complex t^{-n} decays.

The optimum activator concentrations and maximum allowable impurity concentrations in ε^{-at}-decay phosphors are about a hundredfold greater than those in t^{-n}-decay phosphors. Since the cube root of 100 is about 5, this means that interstitially located impurities are affected by other impurities five times as remote, as in the case of substitutionally located impurities. Substitutionally located impurities are in regions of lower potential energy and are better buffered by close coupling with the lattice forces.

The optimum number of active luminescence centers and/or electron traps is about 10^{17} per cubic centimeter in t^{-n}-decay phosphors and about 10^{19} per cubic centimeter in ε^{-at}-decay phosphors. From these data, and data on the penetrations and power densities of common excitants, it is possible to calculate the maximum phosphorescences of phosphors with given decays.

17. MECHANISMS OF SCOTOPHORS

Figure 9 shows a schematic section of a crystal of potassium chloride, KCl, indicating several omission defects and an interstitial defect. The fraction f of omission defects is a function of equilibrium temperature T (degrees Kelvin) according to

$$f = A\varepsilon^{-W_0/kT} \tag{16}$$

where, for KCl, $A \approx 10^4$ and $W_0 \approx 1.6 \times 10^{-19}$ joule. At temperatures near the melting point of KCl (1074 deg Kelvin), f becomes about 0.2, and many of the omission defects are frozen-in when KCl is evaporated and condensed, as in making P10 screens. Therefore, a large number of the 3.2×10^{22} lattice sites per cubic centimeter in P10-screen crystals are empty, and half of these omission defects are absent chlorine ions (Cl^-) whose vacant positions may be occupied by electrons to form scotophor color centers (so-called F-centers) as indicated in Fig. 9. The visible absorption band of tenebrescent KCl (Fig. 4) corresponds to absorption of light by F-centers, i.e., ejection of the trapped electrons. The maximum concentration of F-centers in KCl screens is about 10^{18} F-centers per cubic centimeter.

Tenebrescence is quantitatively expressed as contrast, C, defined by

$$C = \frac{100(L_0 - L_d)}{L_0} \quad \text{(in per cent)} \tag{17}$$

where L_0 and L_d are the luminances of the undarkened and darkened areas, respectively, when observed under light having wavelengths within the induced absorption band of the scotophor.

The decay of tenebrescence, i.e., the bleaching of induced darkening, is a power-law relation of the general type

$$C = C_0 t^{-n} \tag{18}$$

where C_0 is the tenebrescence (contrast) at time $t = 0$ and n decreases from about 1.5 to less than 0.1 with decreasing temperature or intensity of illumination and with increasing degree of tenebrescence. The useful decay intervals (time between successive excitations) of the best known scotophor, KCl, range between 1 and 60 seconds at temperatures near 40 deg cent and illuminations of the order of 10,000 foot-candles of light from incandescent lamps.

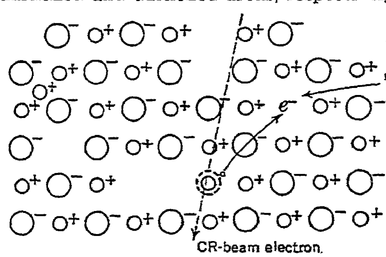

FIG. 9. Schematic Section of a Crystal of Potassium Chloride (KCl), showing the formation of an F-center. Large circles are Cl^-, small circles are K^+.

The sensitivity of cathodotenebrescent KCl is about $^1/_{100}$ that of efficient cathodoluminescent phosphors; i.e., perceptible tenebrescence requires about 100 times as much cathode-ray excitation energy as is required to produce perceptible luminescence.

18. SPECIFIC CHARACTERISTICS OF USEFUL PHOSPHORS AND SCOTOPHORS

Phosphors and scotophors may be considered as high-frequency transformers which can transform a megavolt-wide range of invisible photon or particle energies into emission or absorption of light in or near the 1.5-volt-wide visible region of the electromagnetic spectrum. The output frequencies of these materials are in the range from about 4×10^{14} to 8×10^{14} cycles per second (red to violet).

The chief commercial uses of phosphors are in electron discharge devices, such as fluorescent lamps and cathode-ray tubes for radar or television. *Fluorescent lamps* contain mercury vapor at a pressure of about 4 μ, which, under electron excitation, emits invisible 2537 Å radiation which, in turn, excites visible luminescence in an internal phosphor coating. White-emitting coatings for fluorescent lamps are made by mechanically mixing blue-emitting magnesium tungstate and yellow-emitting manganese-activated zinc-beryllium-silicate phosphors which afford quantum efficiencies of the order of 90 per cent and overall efficiencies four times as great as most incandescent lamps.

Cathode-ray-tube screens comprise a much greater range and variety of materials than those used in fluorescent lamps. Table 2 shows some *approximate* general properties of the more useful cathode-ray-tube screens, including all those presently coded by the Radio Manufacturers Association (RMA). The screens are arranged in the order of their approximate persistences after excitation by 6-kv cathode rays at about 1 microampere per square centimeter. The dark-trace screen at the right of Table 2 exhibits decelerated decay as the excitation density is increased; the sulfide-type bright-trace phosphor screens exhibit accelerated decays with increasing degree of excitation. By observing a tenebrescent image at some time after excitation, it is possible to obtain greater relative contrast between image traces than during the excitation interval. Conversely, the normal bright-trace screens may be used as contrast or ratio compressors.

Remarks	Low efficiency, but stable relative to P12	Difficult to apply and unstable during operation	Largely superseded by P7 and P14	Two-layer cascade screen	Two-layer cascade screen	Bright image, but low contrast and unduly long decay

α * = cubic; β * = hexagonal. (B) = blue, (Y) = yellow.

Representative *spectral distribution curves* of the major cathode-ray-tube screens are shown in Fig. 10. The numbers near the peaks of the emission bands of individual phosphors are the heights of the bands relative to the peak of the cathodoluminescence band of α-Zn_2SiO_4:Mn (P1) which is arbitrarily set equal to 100. The visible cathodoluminescence efficiency of conventional P1 screens is about 3 candles per watt at 6 kv and 1 microampere per square centimeter. The spectral distribution curves of the white-emitting P4 (monochrome-television) and P6 (color-television) screens may vary considerably among different manufacturers, since there are many possible ways of producing equivalent-appearing white colors. The optimum white is yet to be decided by popular approval, although P4 screens are presently standardized at a color temperature of about 6500–7000 deg Kelvin. The P4 screen is usually a two-component mixture of blue-emitting and yellow-emitting phosphors [all-sulfide(selenide) or sulfide(selenide)-silicate]; the P6 screen is usually a three-component mixture of blue-, green-, and red-emitting sulfide- (selenide) phosphors.

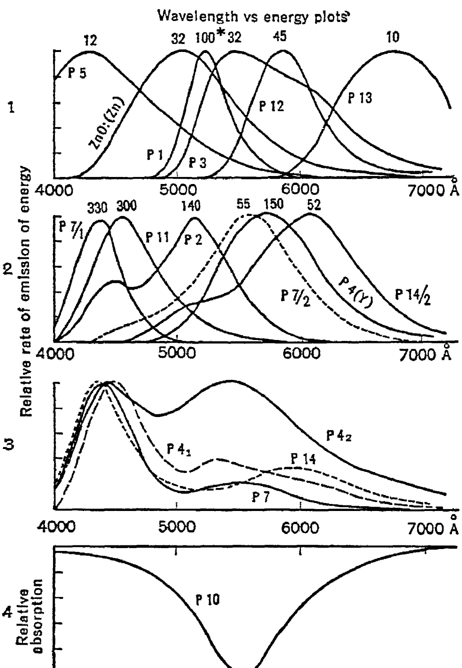

FIG. 10. Representative Spectra of Some Cathode-ray-tube Screens. P4 and P6 screens vary considerably among different manufacturers.

The optimum *screen thicknesses* for cathode-ray tubes vary from about 1 mg/cm² for phosphors having average particle sizes less than 1 micron, to 22 mg/cm² for cascade-screen (P7 and P14) phosphors having average particle sizes near 15 microns. The evaporated P10 (KCl) screen thickness is about 12 microns. These thicknesses are for operation below about 10 kv and must be increased for higher voltages according to eqs. (10) and (11).

The strontium-containing phosphors listed at the bottom of Table 1 are *infrared-stimulable materials* which have quite deep electron traps (of the order of 1 electron volt). These materials can store most of their latent phosphorescence energy for several days, even at room temperature. Efficient release of the stored phosphorescence energy is obtained by irradiating the previously excited material with near-infrared which may be varied in intensity to alter the normal concave-upward decay of the phosphor. These phosphors are good photoluminescent materials but are relatively inefficient under cathode rays. By cocrystallizing sulfate ions in copper-activated zinc sulfide phosphor, an unusual *infrared-quenchable phosphor* is produced which affords long phosphorescence plus the ability to decrease or terminate the phosphorescence by quenching with infrared at an arbitrary instant during the decay time. Infrared-sensitive phosphors may be used to store information for controllable time intervals or to convert positive images into negative images (or vice versa).

The intensity and duration of phosphorescence after cathode-ray excitation is generally less than that obtained after excitation by photons. Cathode-ray-excited phosphorescence may be increased by using the cascade principle. The cascade principle involves constructing a stratified-layer screen wherein an efficient photophosphorescent material is covered with a layer of an efficient cathodoluminescent material whose emission band overlaps the excitation band of the photophosphorescent material. By this method, cathode-ray energy is intermediately converted into photon energy which is more efficient in exciting phosphors to produce phosphorescence. Cascading may be used also to excite cathode-ray-modulated photoluminescence in materials, such as the infrared-stimulable phosphors, which are inefficient under direct cathode-ray excitation. The P7 and P14 screens are examples of practical cascade screens which were devised for radar cathode-ray tubes.

CATHODE-RAY TUBES

By L. E. Swedlund

The cathode-ray tubes considered herein are those electron tubes in which a relatively low-current electron beam of small circular cross-section is focused on, and deflected across, a luminescent screen. Their principal applications are in television receivers, oscillographs, and radar-type indicators. Their great value is the ability to display variations in voltage and current without the limitations of mechanical inertia, and their relatively low cost. Except for a few specialized designs, they are sealed-off, high-vacuum tubes, having an electron gun with a heater-type, oxide-coated cathode located in the neck of a cone-shaped glass bulb. A luminescent screen is deposited in the large, nearly flat end of this cone. Figure 1 shows an electrostatic-focus, electrostatic-deflection oscillograph-type cathode-ray tube, and Fig. 2 a magnetic-focus, magnetic-deflection tube, for television image reproduction. Magnetic focus is very seldom used with electrostatic deflection, but electrostatic focus is often used with magnetic deflection. The principal parts of the cathode-ray tube are the electron gun, the bulb, and the luminescent screen.

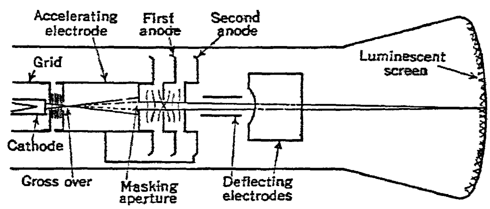

FIG. 1. Electrostatic-focus Electrostatic-deflection Cathode-ray Tube

19. ELECTRON GUN

The design of the electron gun is based on the principles of electron optics outlined in Section 14. However, owing to the complex nature of the electron paths, particularly in the region of the grid and cathode, and to the large number of interrelated factors, much of the design is based on experimental information. The active cathode surface is a small, flat, oxide-coated nickel surface normal to the gun axis. Directly heated, high-temperature cathodes are occasionally used in high-voltage tubes to withstand better the effects of positive-ion bombardment. A control grid having a round aperture of approximately 0.04-in. diameter is spaced as closely as practical to the cathode. As the spacing may amount to only 0.002 in. when the cathode is hot, it is difficult to hold this spacing constant from tube to tube. This small variation in spacing results in a fairly large variation in control-grid voltage for beam-current cutoff. The control grid is nearly always designed to operate at a negative potential with respect to the cathode. The beam is accelerated by means of a screen grid, first anode, and second anode; by a screen grid and anode; or directly by an anode to full-beam potential. In each case, the

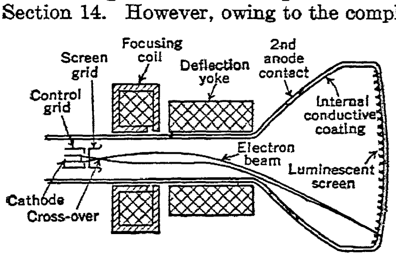

FIG. 2. Magnetic-focus Magnetic-deflection Cathode-ray Tube

spacing between the first accelerating electrode and the control grid is adjusted to provide about the same accelerating field at the cathode. Maximum beam currents of the order of 1 milliampere are drawn at zero bias, and the specified control-grid bias for beam cutoff varies from approximately 20 to 100 volts.

OPERATION OF THE ELECTRON GUN. The field above the cathode draws the electrons into a focus in a few millimeters' travel. In this field they cross over, and beyond it they travel in straight paths until they enter the final focusing field near the end of the gun. Here the electrons are made to converge to a second focus or cross-over at the screen. The final focusing field or electron lens may be either electrostatic or magnetic. The electrostatic lens consists of coaxial cylinders, apertured disks, or a combination of both. These components are always mounted inside the tube. The magnetic lens is always mounted outside the neck of the tube and usually is a coaxial coil encased in an iron shell except for a short axial magnetic gap on the inside surface. In both cases a very good degree of rotational symmetry is required. The usual error due to any lack of symmetry is astigmatism, which results in an elliptical shape when the spot is focused. Electrostatic focus is adjusted by varying the first-anode voltage. The first-anode voltage is usually about one-fifth the second-anode voltage. Magnetic focus is adjusted by changing the magnetic field in the region of the electron beam. This is done by varying the current in an electromagnetic focus coil or by varying a magnetic shunt in a permanent-magnet focus unit.

ELECTROSTATIC DEFLECTION. Figure 1 shows two pairs of deflecting plates at right angles to each other at the exit of the electron gun. The average potential of each pair should be near that of the second anode of the gun since a difference will produce a focusing effect. Since such focusing produces a strong astigmatic effect it is sometimes possible to adjust their average potential to counteract astigmatism in the electron gun. Most tubes, however, are so well made that such correction is not needed. The best uniformity of focus is attained with symmetrical or push-pull deflection. It is possible to connect one plate of a pair to the second anode and apply voltage only to the other at the expense of focus and sometimes linearity of deflection. When the deflection plates are parallel the deflection can be calculated from the following equation.

$$h = \frac{LlV_d}{2V_bd} \qquad (1)$$

where h is the deflection from the center, L is the plate to screen distance, l the deflecting-plate length, V_d the difference in potential between the plates, V_b the second-anode or beam voltage, and d the spacing between plates. In order to provide maximum sensitivity, the plates are usually shaped to follow the contour of the deflected beam. The expression for deflection becomes more complex but has about the same proportionality factors.

MAGNETIC DEFLECTION. Magnetic deflection is accomplished by placing a magnetic field at right angles to the beam path. This field is usually provided by a pair of coaxial coils placed on opposite sides of the neck in order to produce a nearly uniform deflecting field. The beam moves at right angles to the magnetic field in a direction indicated by the familiar left-hand motor rule, remembering, however, that conventional current flow is opposite that of electrons. Unlike electrostatic deflection, it is possible and advantageous to place a second pair of coils for orthogonal deflection in the same region as the first. A combination of deflection coils is known as a deflection yoke and is ordinarily designed to meet the rather specialized requirements of television. Magnetic pole pieces and return paths are sometimes provided to decrease the current required by reducing the reluctance of the magnetic path. The deflection h at the screen for a magnetic field of length l having uniform flux density of B at a distance L from the screen, and for a final voltage E_b, is

$$h = \frac{0.298 \times 10^{-6}BlL}{\sqrt{V_b}} \qquad (2)$$

Since there is a large air gap in these coils, the flux density is proportional to the current and thus deflection is proportional to the current. Although some approximations have been made, this equation holds well up to 60° total deflecting angle. It is seldom desired that the field be uniform across the neck because the screen is usually not properly curved to produce a pattern which looks rectangular. In the reflective optics projection system, for example, the pattern is made to "barrel" slightly to correct for "pin-cushion" distortion in the optics (see Section 14).

COMPARISON OF MAGNETIC AND ELECTROSTATIC DEFLECTION. In comparing eqs. (1) and (2) for electrostatic and magnetic deflection, it is to be noted that, with an increase of beam voltage, deflection decreases with the anode voltage in the former and as the square root of the anode voltage in the latter. Thus, magnetic deflection becomes relatively more favorable as the voltage is raised. In television, this, plus relatively better focus and economic factors, sets the dividing point at about 5 kv. Electrostatic and magnetic deflection are occasionally combined in one tube, though tubes designed specifically for this type of operation have not found many applications.

DEFLECTION DEFOCUSING. Deflection is accompanied by a deterioration of focus known as deflection defocusing. It appears as an elongation of the spot in the direction of deflection in electrostatic deflection and as an elongated and rotated spot in magnetic deflection. It increases approximately as the square of the deflecting angle. Thus deflection distortion limits the deflecting angle and indirectly the beam current because the amount of current which can be focused into a given size spot is determined by the size of the beam as it leaves the gun. For high currents and wide deflecting angles the deflection distortion is five to ten times as great with electrostatic deflection as with magnetic deflection. As a result, electrostatic-deflection tubes are designed for smaller focused currents and narrower deflecting angles than magnetic-deflection tubes. The change of focus due to the increase of gun to screen distance with deflection is small compared to deflection defocusing even with flat screens. But, since deflection defocusing also produces a shortening of the image focal distance, it is possible to make a small amount of compensation by slightly underfocusing the beam at the center of the screen. This effect is usually so small that it is not worth while to modulate the focus voltage in synchronism with scanning to improve the uniformity of focus.

20. BULBS FOR CATHODE-RAY TUBES

The bulb of the cathode-ray tube must meet specialized requirements for mechanical strength, dimensions, optical quality, and electrical insulation. Special grades of glass are needed to meet these demands. Although the bulb has to withstand only atmospheric pressure (15 lb per sq in.) it is good practice to design for a breaking strength of 60 lb or more per sq in. This is done to avoid failure due to slight scratches, temperature shock, and aging. Great care should be exercised, particularly in handling the larger tubes, to protect personnel from flying glass in the event of accidental implosion. Generally the zone of highest stress in a bulb is near the rim of the face. Here the outside surface of the glass is in tension, in which it is weak, and so particular care should be taken to avoid scratches and shocks in this zone. In the past large bulbs were usually made of heat-resisting, low-thermal-expansion glasses, but because of both cost and optical quality most bulbs are now made of a soft glass. For all but the low-voltage oscillograph-type tubes, this is a lead-type glass in contrast to the usual lime-type soft glass. It is chosen to obtain high electrical resistivity. Large bulbs are mass-produced by pressing parts which are fused together. If the surface must be very good and accurately shaped, as in projection type tubes, the face plate may be ground and polished before sealing to the bulb.

LIMITATIONS IMPOSED BY THE LUMINESCENT SCREEN. The luminescent screen is a very important part of the cathode-ray tube. (See articles 15–18.) The limitations and requirements of the luminescent screen have an important bearing on gun-design problems. Both the amount of current that can be sharply focused and the amount that can be utilized efficiently by the screen are limited at low voltage. High brightness, consequently, has to be obtained by raising the beam voltage applied to the screen. Although raising the anode voltage improves the focus and screen efficiency, it also increases electrical insulation problems, introduces screen charging, and requires higher deflection energy. Specially developed, low-current, high-voltage power supplies which have low cost, compactness, and safety have made this problem less difficult.

SCREEN SIZE AND BRIGHTNESS. When the screen size is increased without changing the gun or deflecting angle, the anode voltage must be raised to maintain the same number of lines resolution and brightness. This is due to the fact that the size of the focused spot increases with bulb length and that the beam energy per unit of screen area determines the brightness. Projection tubes require the highest screen brightness and are therefore operated at the highest voltages. Luminescent screens are very thin and thus have a very small thermal storage capacity. Great care must be taken not to move the beam slowly or over too small an area. With a small overload the screen may be damaged only temporarily, as by overheating, or to a light "burn" which gradually fades out. The total time of screen bombardment during the life of a tube is surprisingly small. Consider a television tube scanned with a 525-line raster. This provides roughly 360,000 picture elements; and so, neglecting blanked-out return line time and modulation, each element of the picture area is being bombarded only 1/360,000th of the time. One thousand hours amounts to 3,600,000 seconds. Thus in a representative tube lifetime, the screen has been bombarded less than 10 seconds. However, during this short time it is bombarded at a very high momentary energy density; for example, in a 5-in. projection tube it amounts to 25 kw/cm^2.

DISCHARGE OF SCREEN. Luminescent screen materials are good electrical insulators and are prevented from charging up negatively under electron bombardment only by virtue of a secondary-to-primary electron-emission ratio equal to or greater than unity. The range of voltage where this is true varies with the type of screen material, its manufacture, and application. Under favorable conditions screens can be discharged by secondary emission over the 500 to 25,000 volt range. At the upper end of the range not all phosphors can be used and a charge of several thousand volts may build up on the screen, thus reducing the effective screen voltage. In general, secondary emission becomes poorer at low current density and with use. Poor secondary emission at low voltage causes the screen to charge up enough to deflect the beam off the screen. For example, trouble is likely to occur if beam current flows to the screen while the anode voltage is building up. A charge is then built up before the screen is bombarded with full-voltage electrons. At the upper end of the range the light output fails to increase at the normal rate with voltage increase and the pattern may become unstable. The effects of poor secondary emission may be overcome by mounting the phosphor on a conducting surface and, above about 7000 volts, by placing a very thin, light metal back on the luminescent screen. The metal back is especially desirable because it can be made light-reflecting in order to utilize the light ordinarily lost through the back of the screen. It can also serve as an effective barrier to negative ions.

ION SPOT IN SCREEN. Ion spot in the screen is a problem, particularly in magnetically deflected tubes. It is the area in the luminescent screen which has been damaged by negative-ion bombardment. The screen is damaged almost altogether by the negative ions which form in or near the cathode surface when it is bombarded by positive ions. The rate of damage increases with voltage, but it is most noticeable at about 7 kv because above this voltage the electrons begin to penetrate below the damaged surface layer of the screen. It is greatly affected by the amount and kind of gas left in the tube, but it is almost impossible to eliminate ion damage completely by evacuation and gas getters. Because electrostatic focusing is independent of mass and magnetic focusing is not, electrostatic focus guns focus the ions, thus forming small ion spots rather quickly whereas magnetic focus tubes form large ion spots slowly. Initially the small spot is more objectionable, but with time the large spot becomes more objectionable. In addition to the metal-backed screen, which is rather expensive to apply to low-voltage tubes, there is another effective solution known as the "ion trap" electron gun. Figure 3 shows two constructions of this idea. Both are simplified modifications of the mass spectrograph. The combined beam of ions and electrons is directed off the center of the gun into a trap in *A* by bending the anode and accelerator and in *B* by means of a tilted electrostatic lens. In both, a magnetic field is applied to restore the electrons to the axis. The secondary magnetic field used in construction *B* is useful not only in aligning the beam with the gun axis but also in overcoming the slight mechanical misalignments that may be present.

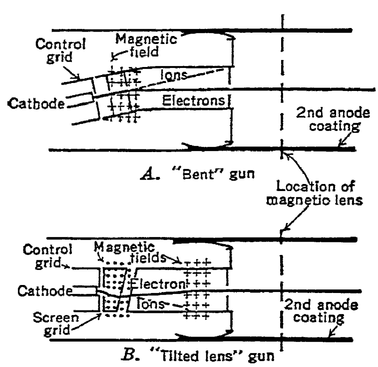

FIG. 3. Sectional Views of Ion Trap Guns

21. CHARACTERISTICS OF THE IMAGE

SPOT SIZE. The image detail or resolution is determined principally by the size of the focused electron image on the screen. Contrast and grain size of the screen may also be factors. The spot does not have a definite edge but decreases in brightness from the center approximately as a segment of a sine wave. When the beam scans a television-type raster it is found that, when the lines overlap to the point where the brightness is half that of the center, the line structure practically disappears. For this reason it is convenient to express spot size as the width at these half-brightness values. This is the basis of the "compressed raster" method of measuring spot size sometimes used for oscillograph-type tubes. However, the rate at which the brightness falls off toward the edge of the spot is important in determining the resolving power, and so for television reproduction tubes a resolution pattern signal which takes this into account is generally used. (See Fig. 10, p. 15-25.)

The resolution pattern has sets of spaced black and white lines usually converging in wedges along with circles and bars for other tests. The limiting resolution is defined as the point where the black and white lines merge. It is important that the black to white grid signal level be maintained beyond the value of resolution being read. If the reproduction tube is not to limit the resolution of the television signal noticeably, its limiting resolution should be about three times that of the television signal. The resolution is best at the center of the raster and poorest in the corners, and since it depends on the deflection yoke it may vary with the direction of scanning. Its value is usually expressed in terms of the number of black and white lines required to fill the vertical height of the raster. In photographic and optical literature it is generally the practice to count only the number of black lines per unit of length.

CONTRAST. The ability to see an image on a screen depends not only on the brightness of the trace but also on the ratio of this brightness to the background brightness. This is known as the brightness contrast ratio. This ratio, also sometimes referred to as contrast range, determines the number of distinct half tones which can be reproduced. Its value depends not only on the inherent characteristic of the screen but also upon the area and distribution of illumination in the screen. The minimum or limiting value of contrast ratio can be found by uniformly scanning all but a small black spot in the center of the raster. A contrast ratio representative of large areas can be found by scanning half the picture area and measuring the brightness in the center of each half.

GAMMA. The term gamma is borrowed from photographic practice to designate the half-tone characteristics of a television system. Over the brightness range useful for television reproduction the eye recognizes brightness differences as percentage increases in steps of 1 to 2 per cent. For this reason it is convenient to plot the grid drive versus light output of a picture tube on log-log scales. The slope of this curve is known as the gamma. In the same way each part of the system from the light in the scene on through the amplifiers has a gamma value. The overall gamma is the product of those of the series of elements. Unity overall gamma, which is usually desired, then represents brightness values in the image proportional to those in the scene. The gamma should be uniform over the whole brightness range for accurate reproduction, but it is usually less at the low and high brightness levels, as is also true in photographic reproduction. It is the practice in photography to refer to gamma as "contrast." This should not be confused with contrast ratio.

It has become the practice to mark the d-c bias and the signal controls of television receivers as "brightness" and "contrast" respectively. However, both controls affect the gamma and brightness. Overbiasing increases gamma by eliminating detail in the shadows; underbiasing decreases it by "washing out" shadow detail. Average brightness varies with d-c bias. Increase in brightness by signal increase is usually limited by the increase in spot size or amplifier overload. This loss of detail and contrast in the highlights is sometimes referred to as "blooming." In a picture tube the average gamma varies from 3 to 2, depending on the amount of masking in the gun. Correction to match the gamma of a standard transmitted signal must be done by introducing suitable curvature in the amplifier input versus output characteristic.

POST ACCELERATION. The beam is sometimes accelerated after deflection in order to increase the spot brightness without a proportionate increase in deflection energy. For this purpose the bulb conductive coating is separated and brought out to a third anode terminal. It has been applied only to electrostatic deflection tubes because little or no gain results when it is used with magnetic deflection. Post acceleration results in a focusing action which tends to bend the deflected beam back to the axis. There is also a small amount of focusing action on the spot which is readily corrected by raising the first anode voltage a small amount. In a typical post-accelerator-type oscillograph tube the deflection voltage must be raised 20 per cent when the third anode is increased from equal to double the second anode voltage. This increase in deflection voltage is accompanied by an increase in deflection defocusing so that the sharpness of focus is not as good as an equivalent non-accelerator tube whose screen voltage is the same. The deflection sensitivity also will not be as much less as indicated on the comparative tests on the accelerator tube because the deflection plates can be designed for closer spacing. However, the gain in brightness and deflection sensitivity along with the fact that the high-voltage power supply is grounded between its negative and positive terminals often justifies the higher cost of a tube of this type. The accelerator ratio is ordinarily limited to about 2, but where very high spot brightness is needed tubes may be designed to operate up to a ratio of 10 times.

PHOTOGRAPHY OF CATHODE-RAY-TUBE TRACES. A permanent record is sometimes needed, and when a tracing of the pattern on the tube cannot be readily made it can usually be photographed. Unless a time exposure can be made the brightness level suitable for viewing must usually be increased by raising the beam current and possibly by raising the screen voltage. Luminescent screens such as the P5 and P11 are particularly suited to photography. The blue light of these screens provides energy where the film is most sensitive. The lower-cost "color blind" films may sometimes serve nearly as well as the orthochromatic and panchromatic films. Since the P11 screen has approximately 10 times the photographic and visual efficiency of the P5 screen it is preferred, but occasionally its longer persistence may be a limitation. The proper exposure depends on lens speed, film sensitivity, screen size, spot brightness, and spot velocity. Tables suitable for estimating the best exposure are available from tube manufacturers, but usually a suitable value can be found from a few test exposures. Single television frames can be photographed with a hand camera having a fast lens and by using high-speed panchromatic film. For motion-picture records the camera must be exposed in synchronism with the frame frequency.

22. TELEVISION CATHODE-RAY REPRODUCTION TUBES

Cathode-ray tubes for television image reproduction are known as picture tubes or kinescopes. In directly viewed tubes the size of the screen largely determines the cost and operating voltage. Below a diameter of 7 in. the reduction in cost is not great and the image size is too small for comfortable viewing. Ten-, fifteen-, and twenty-inch bulbs provide images in steps of double-sized areas. Intermediate sizes such as 12 in. are also used. In the largest bulbs the economic limit for evacuated glass bulbs is reached. Larger images have to be produced by optical projection from a small screen tube. This small tube, known as a projection tube, must produce a much brighter image to illuminate the larger viewing screen and to make up for the losses in the optical system and so is operated at a higher anode voltage.

Table 1. Television Picture-reproduction Cathode-ray Tubes

Type	Size, in.		Typical Operation								Comments
	Nominal Diameter	Length	Heater Volts	Heater Amperes	Anode 2, kv	Anode 1, volts	Grid 2, volts	Control Grid Cutoff	Focus

20BP4...	20	28 3/4	6.3	0.6	15		250	−45	M	Large directly viewed

Note: The above table includes the tubes commercially available. Developmental tubes and those recommended for replacement only are not included. However, some of the tubes in these lists are in fact outmoded and will in time become obsolete. Owing to changes and additions which are constantly being made, up-to-date and more detailed information should be obtained from tube manufacturers or their agents.

The deflecting angle in all the above tubes is 50° or slightly above. All use P4-type screens.

DEFLECTION AND FOCUS OF PICTURE TUBES. Magnetic deflection is used for all but the smallest television picture tubes because it permits the use of wider deflection angles and higher beam currents. Owing to the desire for short overall length, particularly in the large tubes, the deflecting angle is made as large as practicable. Fifty-degree total angle has been found to provide a good compromise between focus uniformity, beam current, and deflecting power. Both magnetic and electrostatic focus guns are used, the former being favored for directly viewed tubes and the latter for projection-type tubes. At the high anode voltages used in the projection tube, energy for the focusing coil becomes a more important factor and the coil is also difficult to mount in the reflective optics system generally used for projection. The highest-voltage power supplies tend to have the poorest voltage regulation, so that a first anode which can be held in focus by means of a tap on the bleeder across the high-voltage supply is quite desirable. The bulb size of projection tubes is limited by the cost and bulk of the optical system used with them. For home use a 5-in. bulb and 27 kv appears to be an economic choice. For intermediate and theater-size images larger tubes and much higher operating voltages are justified.

23. OSCILLOGRAPH-TYPE CATHODE-RAY TUBES

These tubes are nearly always of the electrostatic-focus, electrostatic-deflection type. Their largest field of application is in low-voltage oscillographs for visual observations. These operate in the range of 500 to 2000 volts, but, for the observation and photography of high-frequency transients, anode voltages up to 30 kv may be used. The higher brightness and sharper focus afforded by higher-voltage operation are desirable but it results in lower deflection sensitivity and higher cost tubes and accessories. The signal must usually be amplified, and because a wide band width is desired the gain per stage is low. The size of the screen also influences the choice of anode voltage, since the energy to the screen should go up with its size. Conversely, with a given anode voltage, a small-diameter tube may indicate more detail than a large screen tube. Of the factors determining oscillograph-tube performance, deflection sensitivity is the most important. Deflection sensitivity is customarily expressed as the number of millimeters' deflection at the screen per volt (d-c) of deflection voltage. The reciprocal of this term, the deflection factor, is usually expressed in d-c volts per inch of deflection. The latter term is favored for design work. Spot size and contrast are next in importance. Grid modulation sensitivity is of relatively less importance than in television. It is desirable that the focus remain sharp while the beam current is varied, so most oscillograph-type tubes utilize an electron gun requiring essentially zero-first-anode current in order to avoid the effects of voltage regulation in the first anode circuit.

HIGH-FREQUENCY DEFLECTION. When the deflecting electrode leads must have minimum inductance, capacitance, and coupling to other leads, they are brought directly through the neck of the bulb. This is also of value when very wide frequency band amplifiers are used. For frequencies of about 100 megacycles and above it is necessary to take into account the electron transit time through the plates. Special tubes with short-length plates and high beam voltage have been used to record frequencies as high as 10,000 megacycles per second.

MULTIPLE GUN OSCILLOGRAPH TUBES. Oscillograph-type tubes with two or three independent guns and deflection systems are available for simultaneously producing two or more traces. Owing to their more complex construction their cost is higher than that of the equivalent number of single tubes. An electronic switch or the simultaneous use of two or more tubes is sometimes satisfactory.

RADIAL DEFLECTION TUBES. Radial deflection tubes have a rod-type deflecting electrode extending through the face into the middle of the cone. The deflection sensitivity of the rod decreases as the square of the deflection so that it cannot readily be calibrated. It is used principally to make a marker pip on a circular time base.

24. CATHODE-RAY-TUBE DISPLAYS

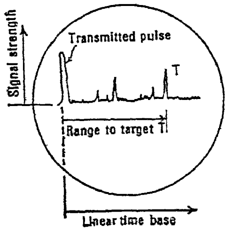
By T. Soller

A cathode-ray-tube display is a means of presenting information concerning a signal (which may be any quantity that can be put into the form of an electrical voltage) in terms of one or more independent variables on which the signal depends. Usually at least one of these variables is an explicit or implicit function of time. The variables are represented by displacements along cartesian or polar coordinate axes; the displacements are usually periodic, a single traversal along any axis being called a "sweep."

A display is said to be deflection-modulated if the signal produces a lateral displacement of the electron beam from some base line or sweep; it is said to be intensity-modulated if the signal voltage is used to increase or decrease the intensity of the electron beam. A deflection-modulated display is used when quantitative information regarding the nature of the signal is required, for an intensity-modulated display can at best yield only qualitative information regarding the signal strength or shape. An intensity-modulated display offers the advantage of being able to present the signal in terms of two variables, rather than the single variable (usually time) of the deflection-modulated display. Well-known examples of these two general types of display are the usual form of cathode-ray oscillograph (deflection-modulated) and the television display (intensity-modulated).

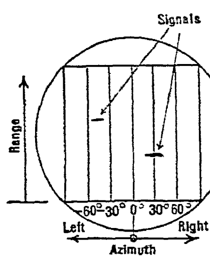
Many different types of display were developed in connection with the applications of radar during World War II. In many of these an attempt was made to present on the two-dimensional surface of the CRT screen information regarding the signal involving three variables, for example, range, azimuth, and elevation. The designation and geometry of these various display types are shown in the following pages.*

* For a more complete discussion of the subject, see: M.I.T. Radiation Laboratory Series, Vol. 22, *Cathode Ray Tube Displays*, McGraw-Hill Book Co., New York, 1947.



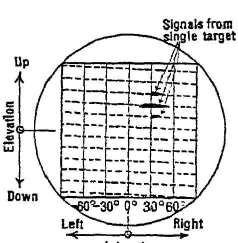
Type A

A deflection-modulated display, commonly used with electrostatic-deflection types of cathode-ray tubes. Consists of a linear horizontal time base, with the signal voltage applied to give a vertical deflection. Used primarily to measure the time of occurrence (in radar, the range) of the signal, as well as its shape and strength. There are many modifications of this basic display type (see types K, L, M, N, O, R).



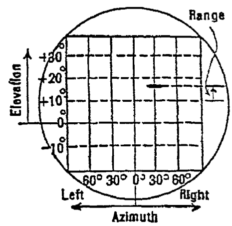
Type B

An intensity-modulated (radar) display in which the horizontal sweep is synchronized with the antenna direction, and the vertical sweep is a linear time base repeated with each transmitted pulse. The received signal is applied to the control grid or to the cathode of the CRT in such a polarity as to brighten the screen. The display has a large distortion from a true map when the range sweep starts with the transmitted pulse and a large azimuth sector is displayed. By delaying the range sweep, and by simultaneous proper control of the azimuth expansion, a good approximation to a true map may be obtained, over a limited region. Such variations are called "delayed B-scans" or "micro-B scans."



Type C

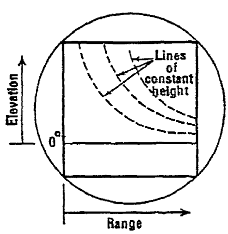
An intensity-modulated display, with azimuth as the horizontal coordinate and elevation as the vertical. This is the television type of scan. In radar, principally used in aircraft for location of other aircraft. Gives no indication of range. This type of indication is very bad from the signal-to-noise ratio standpoint, unless "range-gating" of the signal (from information obtained from a type B display, for example) is possible. Number of horizontal scanning lines used in radar is quite small, and signal appears on several scans because of wide angle of transmitted beam.



Type D

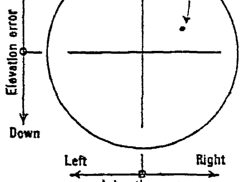
A modification of type C indication, for airborne radar, giving crude elevation information (widely separated elevation lines), but also yielding range information. As any line is scanned slowly from left to right, a short range sweep extending from one elevation line to the next is simultaneously applied. Thus, for the signal shown, the pertinent data are: azimuth, 30° to right; elevation, + 10°; range, 2 miles (assuming distance between elevation lines is equal to 3 miles).

Listed for record purposes only; never used in production.



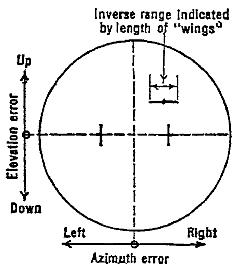
Type E

Similar to type B, but with range as the horizontal coordinate, and elevation angle as the vertical. Presents a distorted vertical cross-section, since lines of constant height are curved, as indicated. Chiefly used where elevation angle (and not height) is of importance.



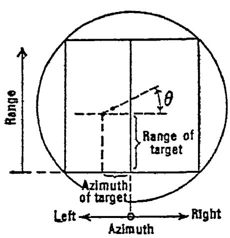
Type F

Sometimes called a "spot" error display. No sweep is employed, but the azimuth error of the signal is indicated by the horizontal coordinate and the elevation error as the vertical.



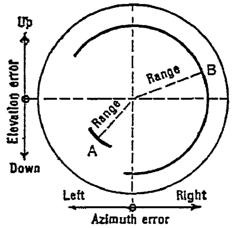
Type G

Sometimes called a "spot with wings" display. Similar to type F, with spot extended to a line whose length is inversely proportional to range to the target. Used mainly for gun-laying, the correct direction and range being indicated when the signal just fits between the two short vertical reference lines.



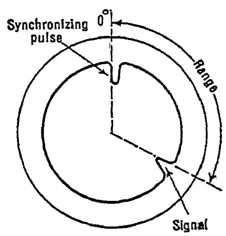
Type H

Known also as the "double dot" display, indicating range, bearing, and elevation. A modified type B display, in which alternate range sweeps are displaced slightly horizontally, thus producing two "dots" from a single echo. The position of the left dot is that which would be indicated by the type B display. The right dot is displaced vertically by an amount such that the angle θ is roughly proportional to the elevation of the target.



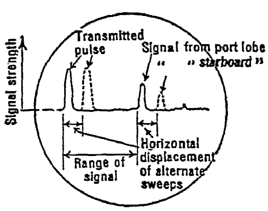
Type I

An intensity-modulated radar display, sometimes called a "broken circle" display, used with a conical scanning antenna. Each echo is represented by an arc of a circle whose radius represents range, and for which the shortness of the arc indicates the error in pointing at the target. Thus the arc A represents a target far to the left and below, while B is a target just a little above and to the right. A target dead ahead would be represented by a complete circle.



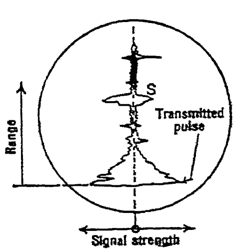
Type J

Essentially a type A display bent into a circle. Useful for accurate time or range measurement when a continuously running (crystal or other) oscillator can be used. The circular trace is obtained by applying two sinusoids from the same source to the two pairs of deflection plates, one sinusoid being 90° out of phase with the other. The synchronizing pulse which occurs at 0° also initiates the phenomenon to be observed, and the time to be measured, for example the range of a radar echo or the delay in a network is obtained from the angular position of the observed signal. The radial deflection is obtained by applying the signal voltage to a central electrode of the CRT (type 3DP1). The sweep may be delayed so that zero time occurs at 0° on some previous rotation of the sweep.



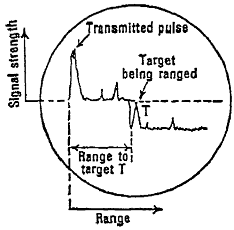
Type K

A radar display used with systems sending out two beams in slightly different directions. The type A sweeps from the two lobes are displaced slightly horizontally. By adjusting the angular position of the transmitting antennas until the signal height of the two corresponding displaced signals is the same, bearing or elevation information as well as range may be obtained.



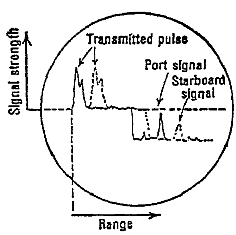
Type L

Sometimes called "back-to-back" A displays. Used with two-lobe radar systems, the signal *S* would indicate a target to the *left*. Changing the direction of the antennas until the opposite signals are of equal strength gives bearing or elevation of target as well as range.



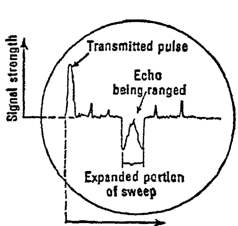
Type M

A modification of the basic type A display, in which a calibrated variable delayed "step" voltage is applied to one of the vertical deflection plates, in order to give more accurate range information. In practice, the step is shifted along the display until the signal to be ranged comes just at the edge of the step.



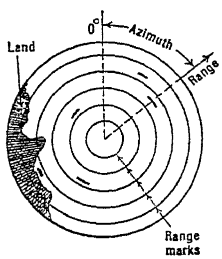
Type N

Combines features of types K and M in order to give more accurate range and bearing or elevation information.



Type O

Sometimes designated as a "type A with a notch" display. Useful for accurate ranging on an echo. The horizontal sweep speed is increased for a short time interval, the beginning of the interval being adjustable and accurately calibrated. The signal under observation is placed in the center of this expanded portion of the sweep, whereupon the reading of the delay dial gives the range directly.



Type P or PPI
